FIG. 10

APPARATUS FOR DETECTING A FOCUSING CONDITION OF AN OBJECTIVE LENS

BACKGROUND OF THE INVENTION

This invention relates to an apparatus for detecting a focusing condition of an objective lens provided in an optical machinery such as a still camera comprising a focusing screen arranged at a position optically conjugated with a predetermined focal plane such as a film plane, a view finder for inspecting an image of an object formed on the focusing screen, at least one photodetector array arranged on or near a plane optically conjugated with the predetermined focal plane, means for projecting a part of the object image upon the photodetector array, and a control unit for processing output image signals supplied from the photodetector array in accordance with a given evaluation function to derive a signal representing the focusing condition of the objective lens.

Such a focus detecting apparatus is known and is used in a still camera. The apparatus comprises the photodetector array comprising a number of photodetectors. A part of an optical image of an object to be photographed is projected upon the photodetector array in such a manner that when an infocused image is projected upon a film, an infocused image is also projected upon the photodetector array. Therefore, by detecting a contrast or sharpness of the image projected upon the photodetector array, it is possible to detect the focusing condition of the objective lens. Usually the image detected by the photodetector array is selected to a central portion in the field of view and thus, when the camera is directed toward the object in such a manner that a subject in a scene is situated at the center of the field of view, the focusing condition of the objective lens with respect to the interesting subject can be correctly detected. However, the subject image is not always situated at the center of the field of view or an image of object in foreground or background may be projected upon the photodetector array. In such a case, the focusing condition of the objective lens could not be detected accurately and the objective lens might be erroneously focused onto the object in the foreground or background.

SUMMARY OF THE INVENTION

The present invention has for its object to provide an apparatus for detecting a focusing condition of an objective lens, which can obviate the above mentioned drawback of the known focus detecting apparatus.

It is another object of the invention to provide an apparatus for detecting a focusing condition of an objective lens, in which an active region of a photodetector array used for detecting the focusing condition of the objective lens can be electrically adjusted at will in accordance with the size of a scene to be picked up.

It is still another object of the invention to provide an apparatus for detecting a focusing condition of an objective lens, in which a user or photographer can monitor or certify by means of a view finder which part of an image of an object is used for detecting the focusing condition.

According to the invention, in an apparatus for detecting a focusing condition of an objective lens of an optical machinery comprising a focusing screen arranged at a position optically conjugated with a predetermined focal plane, a view finder for inspecting an image of an object formed on said focusing screen, a photodetector array having a number of photodetectors arranged closely side by side on or near a plane which is optically conjugated with the predetermined focal plane, means for projecting a part of the image of the object upon said photodetector array, and means for receiving image signals supplied from said photodetectors and for processing the image signals in accordance with an evaluation function to detect the focusing condition of the objective lens, the improvement comprises means for selecting the size (magnitude) and/or position of an active region of said photodetector array used for detecting the focusing condition of the objective lens in accordance with the size of the image of the object projected upon the photodetector array.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic view showing a construction of a single-lens reflex camera comprising a known focus detecting apparatus;

FIGS. **2** and **3** are plan views illustrating finder images of the camera shown in FIG. **1**;

FIG. **4** is a graph representing a relationship between a position of an objective lens and a value of an evaluation function;

FIG. **5** is a block diagram showing an embodiment of the focus detecting apparatus according to the invention;

FIG. **6** is a plan view showing a finder image of the apparatus according to the invention;

FIG. **7** is a perspective view illustrating an embodiment of a device for selecting a region of a photodetector array used for detecting the focusing condition of the objective lens;

FIG. **8** is a perspective view depicting a single-lens reflex camera comprising the focus detecting apparatus according to the invention;

FIG. **9** is a circuit diagram showing an embodiment of a display control circuit according to the invention; and

FIG. **10** is a plan view illustrating an embodiment of a display device according to the invention.

DETAILED EXPLANATION OF THE PREFERRED EMBODIMENTS

FIG. **1** shows schematically a single-lens reflex camera comprising a known focus detecting apparatus. Prior to photographing by focusing an image of an object or subject **1** by means of an objective lens **2** onto a photographic film **3**, a light flux emanating from the lens **2** is divided by a half mirror **4** provided in a quick return mirror **5** and a divided light flux is made incident upon a photodetector array **7** by means of a small reflection mirror **6** secured to a rear surface of the quick return mirror **5**. In this manner, a part of the image of the object **1**, i.e. a central part of the object image is projected upon the photodetector array **7**. A light flux reflected by the quick return mirror **5** is focused on a focusing screen **8** to form an image and the image thus formed is inspected by means of a view finder comprising a penta prism **9** and an eye piece **10**. It should be noted that the photodetector array **7** and the focusing screen **8** are arranged in planes which are optically conjugated with the film **3**, i.e. a predetermined focal plane.

In such a camera it is preferable that a user or photographer knows which portion of the object image is made incident upon the photodetector array **7**. For this

purpose, as shown in FIG. **1**, a mark **11** corresponding to the photodetector array **7** is formed in the focusing screen **8**. Therefore, the user can see the mark **11** in an image **12** of a field of view by means of the finder. In the known focus detecting apparatus, since a magnitude and/or position of a region of the photodetector array **7** used for detecting the focusing condition of the objective lens is fixed, a size and/or position of the mark **11** is also fixed.

In case of taking a photograph of a person standing in front of a tree as illustrated in FIG. **3**, not only the image of the person, but also the image of the tree are projected upon the photodetector array **7**, because the mark **11** extends beyond the person into the tree in the background.

Now it is assumed that the photodetector array **7** comprises M photodetectors closely arranged side by side and each photodetectors produce image signals Xm. Then a sharpness of the image projected upon the photodetector array **7** may be represented by an evaluation function F(x) given by the following equation:

$$F(x) = \sum_{m=2}^{M} |Xm - Xm - 1|$$

In this case, an infocused condition may be detected when the evaluation function F(x) has the maximum value. However, in the situation shown in FIG. **3**, the evaluation function F(x) has two peak values as illustrated in FIG. **4**. When the objective lens **2** is moved along its optical axis from an infinite point and comes in a position a, the evaluation function F(x) has a first peak, because the focused image of the tree in the background is formed on the photodetector array **7**. When the lens is further moved toward the nearest point and comes into a point b, the evaluation function F(x) has a second peak, because the infocused image of the person is projected upon the photodetector array **7**. In this manner when the evaluation function has a plurality of peaks the objective lens **2** might be focused for the tree which is not a subject. This drawback occurs not only in an automatic focusing system, but also in a simple focusing system in which only the detected focusing condition is displayed in the view finder.

FIG. **5** shows an embodiment of the apparatus for detecting a focusing condition of an objective lens according to the invention. A photodetector array **20** comprises a number of photodetectors **21-1** to **21-M** closely arranged side by side and a part of an image of a scene is projected upon the photodetector array **20** by means of an objective lens. The photodetectors **21-1** to **21-M** are operated by a driving circuit **23** under the control of a center processing unit **22** so as to derive from the photodetectors analog image signals representing light intensities of light impinging upon respective photodetectors. The image signals thus derived are converted by an analog to digital converter **24** into digital signals which are then stored in a memory **25**. According to the invention in order to preset or select an active region of the photodetector array **21** used for detecting the focusing condition of the objective lens in an electrical manner in accordance with the size of the object image projected upon the photodetector array, there is provided a photodetector presetting dial **26** for presetting externally photodetectors which are used for detecting the focusing condition. The photodetector presetting information is supplied to the central processing unit **22** and the central processing unit **22** selects given image signals among the image signals supplied from the photodetector array **21** on the basis of the presetting information. In the present embodiment, the presetting dial **26** is so constructed to denote the number of photodetectors which are not used for the focus detection. It is assumed that when the preset number is n, the image signals supplied from n photodetectors **21-1** to **21-n** and **21-(M−n)** to **21-M** on both sides of the array **20** are neglected and only the image signals supplied from central (M−2n) photodetectors **21-(n+1)** to **21-(M−n+1)** are used for calculating an evaluation function. The evaluation function may be represented by any form. For instance, a sum of differences between image signals from adjacent photodetectors may be used as the evaluation function. Then the evaluation function is expressed as follows.

$$F(x) = \sum_{m=n+1}^{M-(n-1)} |Xm - Xm + 1|$$

In the central processing unit **22** only the image signals supplied from the photodetectors selected by the presetting dial **26** are used to calculate the evaluation function F(x) and the focusing condition of the objective lens can be detected in accordance with the calculated evaluation function.

At the same time, in order to indicate for the user a range or area of the photodetector array **20** which is used for detecting the focusing condition, the central processing unit **22** supplies a signal to a display driver **27** to actuate a display device **28**. The display device **28** has a construction similar to the photodetector array **20** and comprises a number of light emitting elements **29-1** to **29-M** closely arranged side by side. The indication of the region is effected by selectively driving the light emitting elements. The display device **28** is placed on the focusing screen **8** shown in FIG. **1** and thus, the user can see an image **30** of the display device **28** through the finder as shown in FIG. **6**. In the image **30** a selected range **31** of the photodetector array **20** used for calculating the evaluation function is indicated by a hatched area and emits light. Therefore, the user can easily know the region of the photodetector array **20**. At the same time, the central processing unit **22** actuates a focusing display circuit **32** in accordance with the result of calculation and a light emitting diode **33** is lighted on to indicate the infocussed condition. It should be noted that the objective lens may be driven by a lens driving circuit on the basis of the result of calculation.

FIG. **7** is a perspective view showing an embodiment of the photodetector presetting dial **26**. The dial **26** comprises a rotary disc **35** connected to a rotating shaft **36** and a brush electrode **37** connected to the earth. A plurality of electrodes **38-1, 38-2, . . .** are arranged along a locus of a tip of the brush electrode **37**. These electrodes **38-1, 38-2, . . .** are connected to the central processing unit **22** by means of separate conductors. Therefore, the central processing unit **22** receives information representing an electrode connected to the brush electrode **37**, i.e. the region of the photodetector array preset by the dial **26**.

FIG. **8** is a perspective view showing a single-lens reflex type camera in which the photodetector region presetting dial **26** is installed. The dial **26** is so provided that a part thereof is exposed outside from a rear wall **39** of a camera body at a position underneath a film winder lever **40**. The user can easily change a desired region of

the photodetector array **20** by rotating the dial **35** with a thumb of his right hand, while looking into a finder **41**.

FIG. **9** is a block diagram showing an embodiment of an electric circuit including a portion of the presetting dial **26** to the display device **28**. The presetting dial **26** is represented by eight switches **50-1** to **50-8** composed of the brush electrode **37** and fixed electrodes **38-1**, **38-2**, . . . shown in FIG. **7**. Now it is assumed that the switch **50-5** is closed. The central processing unit **22** detects this and latches data of (11110000) into a latch circuit **52** through a data bus **51**. A reference numeral **53** denotes a signal line. The display device **28** comprises sixteen light emitting diodes **54-1** to **54-16** which are connected to output terminals **52-1** to **52-8** of the latch circuit **52** as illustrated in FIG. **9**. Therefore, when the outputs of the latch circuit **52** are (11110000), eight diodes **54-1** to **54-4** and **54-13** to **54-16** on opposite sides of the display device **28** are not lighted on and only central eight diodes **54-5** to **54-12** are lighted on as shown by a hatched region in FIG. **10**. The user can see the display device **28** through the finder and can know the active region of the photodetector array **20** with the aid of the bright region of the display device **28**. In this manner the user can easily and accurately adjust the size of the field of view for the focus detection in accordance with the size of the subject image onto which the objective image is to be focused.

As explained above in detail, according to the invention a region of the photodetector array which is used for detecting the focusing condition of the objective lens can be electrically changed or adjusted at will in accordance with the subject image. Further, the user can monitor or certify the region of the photodetector array with the aid of the image of the display device through the view finder. In this manner by means of the focus detecting apparatus according to the invention, the objective lens can be focused accurately with respect to a subject in a scene.

The present invention is not limited to the embodiments explained above, but many modifications may be conceived within the scope of the invention. In the above embodiment the display device is composed of the light emitting diodes, but it may be formed by a liquid crystal. In such a case, a region of the display device which is not lighted on is transparent and thus, an inspection of the finder image is less hindered by the display device. Further, in the above embodiment the region of the photodetector array is divided precisely, but it may be divided much more roughly. In such a case the presetting means and display means may be much simpler. Moreover, in the above embodiment the photodetectors which are not used for the focus detection are preset by the dial, but photodetectors which are used for the focus detection may be preset. It should be noted that two photodetector arrays may be arranged on both sides of the predetermined focal plane and in this case the focusing condition may be detected by deriving a difference between two values of the evaluation function each calculated from the image signals supplied from respective photodetector arrays.

In the above embodiments the region of the photodetector array used for detecting the focusing condition of the objective lens is manually selected from the external and the selected region is displayed in the finder. According to the invention, it is also possible to select automatically the region of the photodetector array used for detecting the focusing condition of the objective lens by means of the central processing unit. In such a case, it is not always necessary to display the automatically selected region of the photodetector array and thus, the display device may be dispensed with. The automatic selection of the region of the photodetector array used for detecting the focusing condition of the objective lens may be effected in various manners. For instance, when the evaluation function has more than two peak values, the maximum peak point may be detected as the infocused position.

What is claimed is:

1. In an apparatus for detecting a focusing condition of an objective lens of an optical device comprising a focusing screen arranged at a position optically conjugated with a predetermined focal plane, a viewfinder for inspecting an image of an object formed on said focusing screen, a photodetector array having a number of photodetectors arranged closely side by side on or near a plane which is optically conjugated with the predetermined focal plane, means for projecting a part of the object image upon said photodetector array, and means for receiving image signals supplied from said photodetectors and for processing the image signals in accordance with a given evaluation function to detect the focusing condition of the objective lens, the improvement comprising:

means for selecting an active region portion of said photodetector array for use in detecting the focusing condition, to enable the active region portion to be selectively changed in size and position within the photodetector array to change the size and position of that part of the object image which is used to control focusing.

2. An apparatus according to claim **1**, further comprising means for displaying in said viewfinder, the selected active region portion of said photodetector array.

3. An apparatus according to claim **2**, wherein said selecting means comprises means for manually selecting the active region portion of said photodetector array.

4. An appaparatus according to claim **1**, wherein said selecting means comprises means for presetting desired photodetectors in the photodetector array whose image signals are used for detecting the focusing condition.

5. An apparatus according to claim **3**, wherein said selecting means comprises a dial rotatably arranged, a movable electrode arranged rotatably together with the dial, a plurality of electrodes arranged fixedly along a moving locus of said movable electrode and a plurality of conductors each for connecting respective one of said fixedly arranged electrodes to said processing means.

6. An apparatus according to claim **5**, wherein said dial is so arranged in a housing of the optical device that a part of the dial is exposed to the outside through an opening formed in said housing.

7. An apparatus according to claim **6**, for use in a camera, wherein said opening through which a part of the dial is exposed to the outside is provided in a rear wall of the camera housing beneath a film winding lever.

8. An apparatus according to claim **2**, wherein said displaying means comprises an array of a plurality of indicating elements arranged closely side by side and means for actuating given indicating elements in the array corresponding to the selected region of the photodetector array.

9. An apparatus according to claim 8, wherein said indicating elements are arranged on said focusing screen.

10. An apapratus according to claim 9, wherein said indicating element array is formed by an array of a plurality of light emitting diodes arranged closely side by side.

11. An apparatus according to claim 10, wherein said actuating means comprises a latch circuit having a plurality of output terminals each connected to respective light emitting diodes and said latch circuit is controlled to store an information signal representing the size of the active region portion of the photodetector array selected by said selecting means.

12. An apparatus according to claim 11, wherein said latch circuit is so constructed that said information signal denotes light emitting diodes which are not actuated.

13. An apparatus according to claim 1, wherein said latch circuit is so constructed that said light emitting diodes which are not actuated are selected symmetrically with respect to a center of the light emitting diode array.

14. An apparatus according to claim 1 wherein said means for selecting an active region includes means for selecting the size of said active region in response to the size of the object image projected upon the photodetector array.

15. An apparatus according to claim 1 wherein said means for selecting include means for selecting the position of the active region of said photodetector array in response to the size of the object image projected upon the photodetector array.

16. An apparatus for detecting the focusing condition of an objective lens comprising:

an objective lens for projecting an object image;

means having a detection region including an active region for detecting the focusing condition of the objective lens with respect to a part of an object image; and

means for selectively altering the size and position of said active region within the detection region of said means for detecting to change the size and position of that part of the object image used to control focusing.

17. The apparatus of claim 16 wherein said means for altering said active region includes means for altering the size of said active region in accordance with the size of said object image.

18. The apparatus of claim 16 wherein said means for altering includes a means for altering the position of the active region in response to the size of the object image.

19. The apparatus of claim 16 wherein said means for altering includes means for altering the size and position of the active region in response to the size of the object image.

[57] **ABSTRACT**

Disclosed is a two-component zoom objective having a first lens component of negative power and a second lens component of positive power with the variable air separation between the first and second components effecting zooming. The aforesaid first lens component is constructed with four lenses. The first lens counting from the front is given an aspheric surface, and the air lens defined by the second and third lenses counting from the front and the four lenses in the aforesaid first lens component are appropriately configured to increase the angular field up to an ultrawide angle, while still permitting good correction of aberrations.

ULTRAWIDE ANGLE ZOOM OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to wide angle zoom objectives, and more particularly to two-component zoom objectives having a first lens component of negative power and a second lens component of positive power with the air separation therebetween variable to effect a change in the focal length of the entire system.

2. Description of the Prior Art

Up to now, a two-component zoom objective lens whose first component counting from the front is of negative power and whose second is of positive power as illustrated in FIG. 1, or a so-called inverted telephoto type, has represented a form of lens system offering a great advantage at an increase in the angular field. But, since the wide angle setting for the maximum possible angular field takes place when the first and second components I and II are most widely separated from each other, the diameter in the front members tends to increase as the maximum possible angular field increases. This tendency becomes prominent when a much-desired increase in the angular field is intended. With a lens system having such a wide angular field, when its bulk and size is reduced unduly, the barrel type distortion in the wide angle position increases so rapidly that correction thereof becomes very difficult to perform.

Conventionally, most wide angle two-component zoom objectives include, as the first lens L1 in the first component I, either a meniscus lens of negative power convex toward the front, or a meniscus lens of positive power convex toward the front. They contribute somewhat different advantages to their respective systems. It is generally known that, as stated in Japanese Laid Open Patent No. Sho 52-134452, the choice of the latter type is preferable to achieve good correction of distortion, and a minimization of the diameter of the front lens members is facilitated by employing the former type.

Examples of two-component wide angle zoom objectives are disclosed in U.S. Pat. Nos. 4,159,865 and 4,153,339.

SUMMARY OF THE INVENTION

The present invention is concerned with a two-component zoom objective, and aims to provide an ultrawide angle zoom objective with the front lens members of reduced diameter, while still permitting good correction of aberrations particularly regarding distortion in the wide angle position without causing this correction of distortion to deteriorate the other aberrations. For example, the spherical aberration in the telephoto position and the various aberrations in the intermediate zooming region.

According to the present invention, despite the fact that the zoom objective has an ultrawide angular field corresponding to a zoom lens having a range of 20 to 35 mm for the 35 mm single lens reflex camera, the various aberrations beginning with the distortion can be very well corrected by using a reduced number of lens elements. At the same time, a minimization of the bulk and size of the lens system as a whole can be achieved. Further since the lens system takes the mechanically-compensated form to maintain a constant image plane, the present invention has the advantage of providing an ultrawide angle zoom objective suitable for use particularly in still cameras, or in cinematographic camera or television-transmitting cameras.

One of the features of the present invention is that the ultrawide angle zoom objective is constructed such that a first lens group I of negative power and a second lens group II of positive power constitute a complete objective and are moved in differential relation to each other to effect a change in the focal length of the entire system, the aforesaid first lens group I comprises four lens elements of which the first L1 counting from the front is a meniscus lens of negative power convex toward the front, the second L2 is a bi-convex lens, the third L3 is a bi-concave lens with its rear surface of strong power, and the fourth L4 is a lens of positive power with its front surface convex towards the front, wherein the absolute value of the radius of curvature of the rear surface R4 of the aforesaid second lens L2 is made to be larger than that of the radius of curvature of the front surface R5 of the aforesaid third lens L3, and good correction of aberrations is facilitated by giving an aspheric surface to the first lens L1.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a schematic view illustrating how the two-component zoom objective is zoomed.

FIGS. 2 to 6 are lens block diagrams of embodiments 1 to 5 of the invention respectively.

FIG. 7 is a diagram of geometry considered to define an aspheric surface.

FIG. 8 is a diagram of geometry considered to define factors in paraxial formulae.

FIGS. 9 to 13 are graphic representations of the various aberrations of the objectives of FIGS. 2 to 6 respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is described in connection with embodiments 1 to 5 thereof by reference to FIGS. 2 to 8.

An important feature of the invention is the design of the two-component zoom lens such that the first lens L1 of the first lens component is configured to a negative meniscus lens to achieve a minimization of the diameter of the front lens elements. Letting R4 denote the radius of curvature of the rear surface of the second lens L2 and R5 the radius of curvature of the front surface of the third lens L3. The absolute value of R4 is made larger than that of R5 so that the air separation D4 between the second and third lenses L2 and L3 is in the form of weak divergence to perform good correction of astigmatism, and the aforesaid first lens L1 is made aspheric to reduce the distortion, so that the necessary number of constituent lens elements is lessened. An ultrawide angle zoom objective in which the angular field reaches 93° in the wide angle setting is realized. In more detail, as regards the air separation D4 between the second and third lenses L2 and L3, according to the prior art, a converging action is taken. However, when the angular field is ultrawidened up to 90° or more, the aforesaid converging action of the air lens contributes to an under-correction of curvature in the field for the meridional rays with an increase of the astigmatic difference so that the lesser number of constituent lenses no longer suffices to correct the distortion and astigmatism in good balance. According to the present invention, the aforesaid air lens is imparted with a weak diverging action to achieve good correction of astigma-

tism. In addition thereto, the first lens L1 which makes the largest contribution to distortional correction not only fulfills the aforesaid requirement but also has an aspheric surface, thus providing an assurance in the correction of the various aberrations.

Further, in the present invention, to correct lens aberrations for higher grade imaging performance, the following conditions are set forth:

$$0.95 < |f_2/f_1| < 1.20 \quad \text{(i)}$$

$$1.25 < |f_1/f_w| < 1.95 \quad \text{(ii)}$$

$$1 < l_w/f_w < 1.5 \quad \text{(iii)}$$

$$0.2 < \Psi < 0.35 \quad \text{(iv)}$$

$$-0.4 < \Omega < -0.05 \quad \text{(v)}$$

where

f_1 is the focal length of the 1st lens component I;

f_2 is the focal length of the 2nd lens component II;

f_w is the shortest focal length of the entire lens system;

l_w is the distance (axial air separation) between the 1st and 2nd lens components I and II in the wide angle position;

Ψ is the sum of the 3rd order coefficients of the aspheric surface applied to the 1st lens L1; and

Conditions (i) to (iii) concern power distribution over the lens system. Condition (i) represents a compromise between the requirements of minimizing the bulk and size of the entire lens system and of increasing the angular field. When the lower limit of condition (i) is exceeded, the increase in the angular field exceeding 90° not only is unfeasible, but also the total length of the lens system in the wide angle position will be objectionably elongated. When the upper limit is exceeded, image aberrations cannot be stably maintained throughout the zooming range. To avoid this, it is necessary to increase the number of constituent lenses in the first lens component I that is incompatible with the minimization of the bulk and size of the lens system.

When the upper limit of condition (ii) is exceeded, it becomes difficult to achieve good correction of distortion and other various aberrations. When the lower limit is exceeded, though the aberrational problem decreases, a great increase in the bulk and size of the complete objective is involved, thus contradicting the object of obtaining a compact zoom objective. The upper limit of condition (iii) also is to minimize the bulk and size of the complete objective, and the lower limit of condition (iii) is determined to prevent a drawback in that the total zooming movement becomes too short to provide a desired zoom ratio.

Conditions (iv) and (v) represent factors for calculating an aspheric surface. The following is an explanation of these factors. In general, an equation for the aspheric surface is expressed as follows: In FIG. 7, putting the aspheric surface whose paraxial region has the radius of curvature R with its vertex at an original point of rectangular coordinates and taking the direction in which light advances on the optical axis as an x-axis, and the axis in a direction perpendicular to the optical axis and passing through the vertex as a y-axis, we have the deviation quantity x in the x-coordinate at H in the y-ordinate:

$$x = R\left\{1 - \sqrt{1 - \left(\frac{H}{R}\right)^2}\right\} + B^2H^4 + CH^6 + DH^8 + EH^{10} + \quad (1)$$

The first term of this equation (1) arises from only the aforesaid paraxial radius of curvature R, and the second term and those that follow give the complete information concerning the aspheric surface. Letting N denote the index of refraction of the medium ahead the aspheric surface, and N' the index of refraction of the medium behind the aspheric surface, the coefficient B in the second term is related to the third order aspheric coefficient Ψ as follows:

$$\Psi = 8\,(N' - N)B \cdot f_w^3 \quad (2)$$

Also the coefficient C in the third term is related to the fifth order aspheric coefficient Ω as follows:

$$\Omega = 48\,(N' - N)C \cdot f_w^5 \quad (3)$$

Here, the aspheric coefficient Ψ contributes to the third order aberrational coefficients of the theory of spherical aberration I, coma II, astigmatism III, sagittal curvature of the field IV and distortion V the following respective changes. That is, the use of the aspheric surface results in the changes of the third order aberrations expressed as follows:

$$\Delta I = h^4 \cdot \Psi \quad \text{(4a)}$$

$$\Delta II = h^3 \bar{h} \cdot \Psi \quad \text{(4b)}$$

$$\Delta III = h^2 \bar{h}^2 \cdot \Psi \quad \text{(4c)}$$

$$\Delta IV = h^2 \bar{h}^2 \cdot \Psi \quad \text{(4d)}$$

$$\Delta V = h \cdot \bar{h}^3 \cdot \Psi \quad \text{(4e)}$$

where h and $\bar{h}$ are the quantities for use in tracing two different paraxial rays, one of which advances along the optical axis to an image point on the optical axis while cutting all the lens surfaces at heights, h, and another ray which is incident on the frontmost lens surface at an angle of inclination with the optical axis and passes through the center of the area of the diaphragm opening (paraxial pupil ray), while cutting all the lens surfaces at heights, $\bar{h}$, measured from the optical axis. Upon consideration of a certain particular lens surface, the values of the h and $\bar{h}$ in the equations (4) vary with zooming. In other words, the introduction of a certain aspheric surface figuring constant Ψ leads to changing all the third order aberration coefficients by zooming.

The reason why the present invention makes use of an aspheric surface in the first lens L1 of the first lens component is, as has been stated before, to produce a great advantage in correcting the distortion in the wide angle positions which results from the increase in the angular field of, and the reduction in the bulk and size of, the lens system. And the satisfaction of conditions (iv) and (v) assures that, as the various aberrations for the telephoto positions are not adversely affected, good stability of aberration correction is maintained throughout the entire zooming range. When the lower limit of condition (iv) is exceeded, insufficient correction of

distortion in the wide angle region results. When the upper limit is exceeded, aberrations other than distortion deteriorate rapidly, and it becomes difficult to correct these aberrations by lens surfaces other than the aspheric one. Particularly astigmatism varies to a very large extent with the image angle and, even in magnitude also, becomes large. Therefore, good correction of the various aberrations can be achieved within condition (iv).

Also, condition (v) is to correct mainly higher order distortion and astigmatism in good balance. That is, the fifth order distortion coefficient $\widehat{V}$ is generally taken at a negative value from the start of design, or otherwise higher order of distortion would become large barrel type distortion. Since the fifth order aspheric surface figuring constant Ω affects the $\widehat{V}$ as

$$\Delta\widehat{V}=h\cdot\bar{h}^5\Delta\Omega$$

it follows that when the Ω has a large value of negative sign, $\Delta\widehat{V}>0$ results, causing a difficult problem of correcting higher order distortion. On the other hand, as for astigmatism, to correct higher order astigmatism to the positive direction, it is required that the following terms be of negative value

$$(\widehat{III}+\widehat{III}/4)-(3III+P)^2\cdot(f/2f_w)$$

where $\widehat{III}$ is the fifth order astigmatism coefficient, $\widehat{IV}$ is the fifth order sagittal field curvature coefficient, P is the Petzval sum and f is the overall focal length. Here, Ω affects the $\widehat{III}$ and $\widehat{IV}$ as:

$$\Delta\widehat{III}=h^2\cdot\bar{h}^4\cdot\Delta\Omega$$

$$\Delta\widehat{IV}=H^2\cdot\bar{h}^4\cdot\Delta\Omega$$

thereby offering the advantage of improving the state of correction of astigmatism which would otherwise be difficult to perform particularly in the wide angle region. Like this, the fifth order aspheric surface has reciprocal effects on the higher order distortion and astigmatism, and, therefore, correction of the various aberrations in good balance can be achieved only within condition (v).

Specific embodiments 1 to 5 of the present invention which have satisfied the foregoing conditions can be constructed in accordance with the following numerical data for the radii of curvature, R, the axial thicknesses and air separations, D and l1, and the refractive indices, N, of, and the Abbe numbers, ν, of, the glasses of the lens elements, which are all expressed with the subscripts numbered from front to rear.

What is claimed is:

1. An ultrawide angle zoom objective having the following conditions:

two lens components of which the first counting from the front is of negative power and the second is of positive power;

an air separation between said first and said second lens components being made variable to effect zooming,

said first lens component consisting of four lens elements from front to rear, the first being frontmost and the fourth being rearmost,

the first lens element being a meniscus lens of negative power convex toward the front,

the second lens element being a bi-convex lens,

the third lens element being a bi-concave lens with its rear surface having a stronger refractive power,

the fourth lens element being a lens of positive power with its front surface convex toward the front,

the absolute value of the radius of curvature of the rear surface of said second lens being larger than the absolute value of the radius of curvature of the front surface of said third lens, and

said first lens element having an aspheric surface.

2. An ultrawide angle zoom objective according to claim 1, satisfying the following condition:

$$|f_1| < f_T$$

where f_1 is the focal length of said lens component, and f_T is the longest focal length of the entire lens system.

3. An ultrawide angle zoom objective comprising two lens components of which the first counting from the front is of negative power and the second is of positive power;

an air separation between said first and said second lens components being made variable to effect zooming,

said first lens component consisting of four lenses from front to rear, the first being frontmost and the fourth being rearmost,

the first lens being a meniscus lens of negative power convex toward the front,

the second lens being a bi-convex lens,

the third lens being a bi-concave lens with its rear surface having a stronger refractive power,

the fourth lens being a lens of positive power with its front surface convex toward the front,

the absolute value of the radius of curvature of the rear surface of said second lens being larger than the absolute value of the radius of curvature of the front surface of said third lens, and

said first lens having an aspheric surface and further satisfying the following conditions:

$$0.95 < |f_2/f_1| < 1.20$$

$$1.25 < |f_1/f_w| < 1.95$$

$$1 < l_w/f_w < 1.5$$

where

f_1 is the focal length of said 1st lens component;

f_2 is the focal length of said 2nd lens component;

f_w is the shortest focal length of the entire system; and

l_w is the distance (air separation) between said 1st and said 2nd lens components in the wide angle position.

4. An ultrawide angle zoom objective comprising two lens components of which the first counting from the front is of negative power and the second is of positive power;

an air separation between said first and said second lens components being made variable to effect zooming,

said first lens component consisting of four lenses from front to rear, the first being frontmost and the fourth being rearmost,

the first lens being a meniscus lens of negative power convex toward the front,

the second lens being a bi-convex lens,

the third lens being a bi-concave lens with its rear surface having a stronger refractive power,

the fourth lens being a lens of positive power with its front surface convex toward the front,

the absolute value of the radius of curvature of the rear surface of said second lens being larger than the absolute value of the radius of curvature of the front surface of said third lens, and

said first lens having an aspheric surface and further satisfying the following conditions:

$$0.2 < \Psi < 0.35$$

$$-0.4 < \Omega < -0.05$$

wherein

Ψ is the sum of the third order aspheric surface coefficients applied to the first lens; and

Ω is the sum of the fifth order aspheric surface coefficients applied to the first lens.

5. An ultrawide angle zoom objective according to claim **3**, wherein

Ψ is the sum of the third order aspheric surface coefficients applied to the first lens; and

Ω is the sum of the fifth order aspheric surface coefficients applied to the first lens.

[57] **ABSTRACT**

A phase type diffraction grating and a microprism for splitting the light beam from an objective lens into three light beams. The three light beams are split in one direction by the diffraction grating and are directed onto three rows of line sensors disposed on the same plane. In the two optical paths between the diffraction grating and the line sensors, there is disposed an optical path length difference imparting element for forming on the line sensors images at a predetermined focal plane of the objective lens and planes forward and rearward of the predetermined focal plane. Thus, the line sensors detect the images at the predetermined focal plane and at planes forward and rearward of the predetermined focal plane.

4 Claims, 3 Drawing Figures

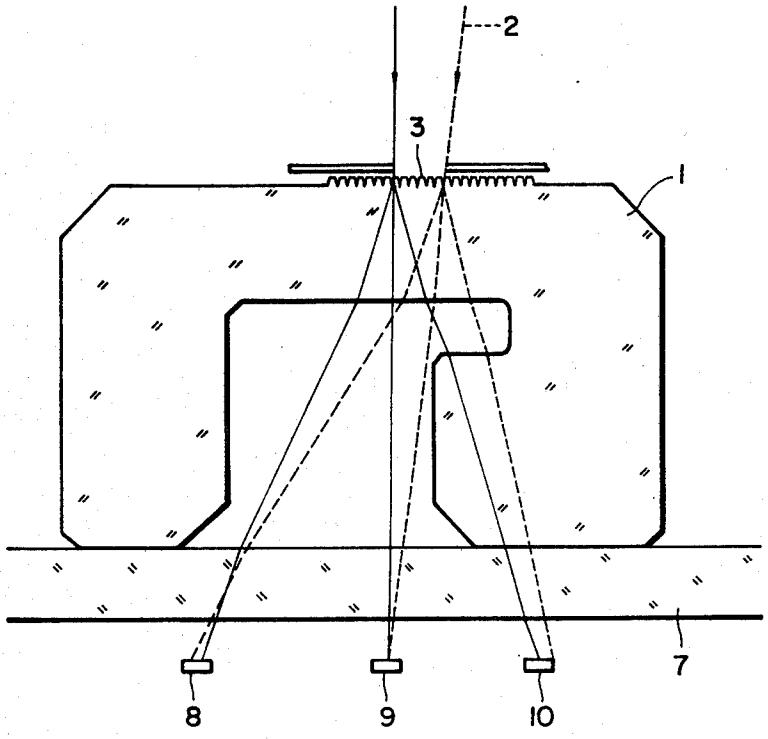

FIG. 1

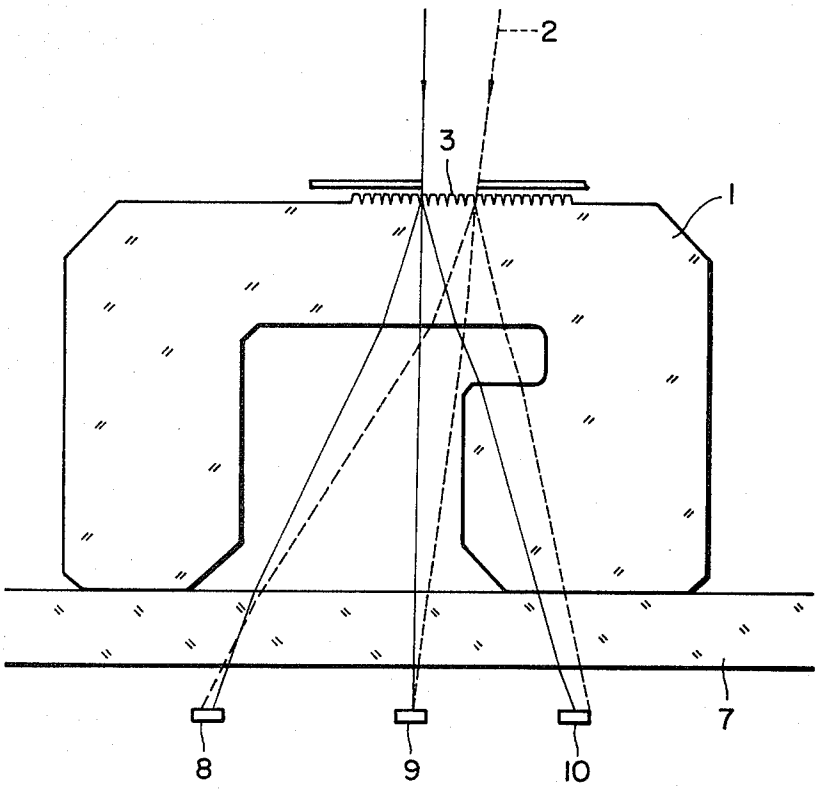

FIG. 2

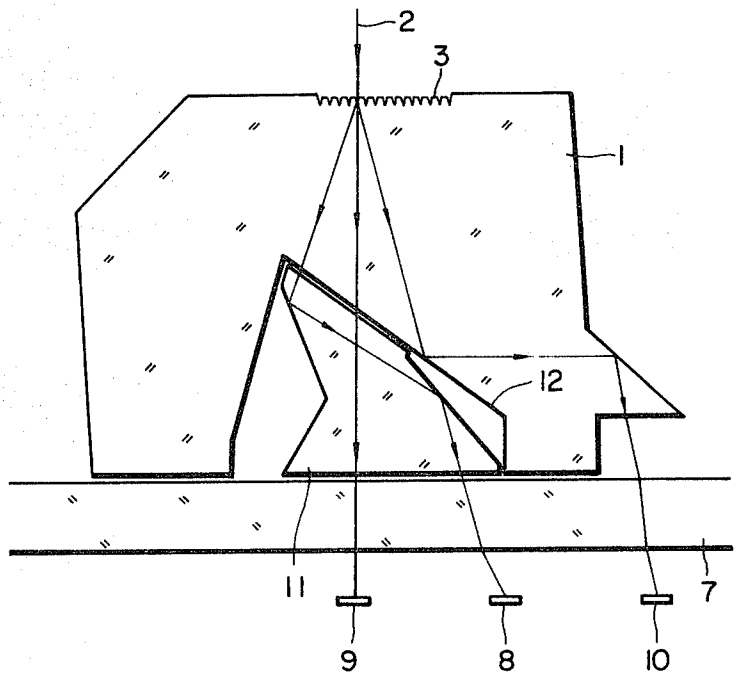

FIG. 3

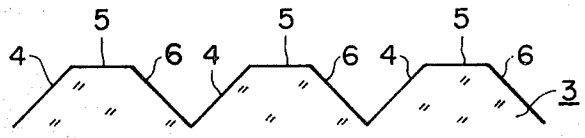

DEVICE FOR SPLITTING LIGHT FROM AN OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a beam splitting device and more particularly to a beam splitting device in which the light beam from an objective lens is split by a beam splitter and an optical path length difference is imparted to at least one of the optical paths of the split light beams, so that at least two images having an optical path length difference are formed on a plurality of rows or sensors disposed substantially on the same plane, whereby these images are detected.

2. Description of the Prior Art

A device of the described type is applicable to a focus detecting system for a camera. As the means for splitting the light beam from the objective lens of this reading apparatus, the assignee of the subject application has already proposed an area-type beam splitter in Japanese patent application No. 98524/1980 filed on July 17, 1980 corresponding to U.S. patent application Ser. No. 283,001 filed on July 13, 1981. In this prior application, there is disclosed, as an example of the area-type beam splitter, a beam splitter comprising dot-like or stripe-like minute reflecting mirrors deposited on a glass substrate by evaporation and effecting beam splitting by reflection and transmission.

However, these beam splitter, which comprises minute reflecting mirrors deposited on a glass substrate by evaporation, is costly and difficult to manufacture.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a beam splitting device which eliminates the above-noted disadvantages.

The invention will become fully apparent from the following detailed description thereof taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** shows a first embodiment of the present invention.

FIG. **2** shows a second embodiment of the present invention.

FIG. **3** shows a diffraction grating.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In FIG. **1**, reference numeral **1** designates a beam splitter unit. This beam splitter unit **1** is formed of a transparent material such as glass or acrylic resin, and comprises a portion performing the function of beam splitting and a portion imparting an optical path length difference, the two portions being constructed integrally with each other. The light beam **2** from an objective lens, not shown, which includes image information enters from the entrance surface of the beam splitter unit **1**. A beam splitter **3** is formed on this entrance surface. This beam splitter has a number of grating lines formed in the entrance surface thereof. In the present embodiment, the split light rays should only shift in one-dimensional direction and therefore, the grating lines are formed in one direction.

Turning back to FIG. **1**, reference numeral **7** designates a transparent substrate to the surface of which is fixed the beam splitter unit **1**. This substrate itself also has the function of imparting an optical path length difference. Denoted by **8**, **9** and **10** are photoarray sensors such as CCD's formed on the same substrate.

The light beam **2** from the objective lens which has entered the beam splitter **3** is diffracted by a diffraction grating.

That is, the positive first order diffracted light travels toward the array sensor **8**, the 0-order diffracted light rectilinearly travels toward the sensor **9** and the negative first order diffracted light travels toward the sensor **10**. These light beams travelling toward the sensors **8**, **9** and **10** differ in the length through the transparent body block **1** and the substrate **7**. Accordingly, there is created an optical path length difference. This optical path length difference is determined so that if an in-focus image is formed on the array sensor **9**, the array sensor **8** has its image formed in front thereof and the array sensor **10** has its image formed behind the sensor. These images having the optical path length difference are detected by the sensors **8**, **9** and **10**, respectively.

In the embodiment of FIG. **1**, the optical path length difference is imparted by a transparent body having a refractive index difference, but the split light rays may also be caused to by-pass i.e. by reflection.

FIG. **2** shows an embodiment in which the optical path length difference is imparted by such by-passing. In this embodiment, the block **1** has an air-plastic boundary surface **12** inclined with respect to the optical path, and has another plastic block **11**. The 0-order diffracted light passes through the boundary surface **12** and block **11** and travels toward the array sensor **9**. The positive first order diffracted light passed through the boundary surface **12** into the block **11** and is twice subjected to total reflection and travels toward the array sensor **8**. The negative first order diffracted light is subjected to total reflection by the boundary surface **12** and subjected to total reflection by the block **1** and travels toward the sensor **10**. The split light rays differ in optical path length by a reflection amount and therefore, images having an optical path length difference are formed on the respective sensors.

The above embodiments have been described with respect to a case where a phase type one-dimensional diffraction grating is used as the beam splitter, but the beam splitter provided on the plane orthogonal to the optical axis of the phototaking lens may be of another type.

FIG. **3** shows another form of the beam splitter. The beam splitter **3** is formed by three kinds of minute inclined surfaces **4**, **5** and **6** which differ in inclination with respect to the incident light. These inclined surfaces **4**, **5** and **6** are regularly formed at intervals of 30μ–90μ. The number of kinds corresponds to the number into which it is desired to split the light beam. The inclined surfaces **4**, **5** and **6** have no inclination in the direction perpendicular to the surface of the drawing sheet.

The light beam **2** from the objective lens which has entered the beam splitter **3** is split by the inclined surfaces **4**, **5** and **6**.

That is, the light ray which has entered the inclined surface **6** travels toward the array sensor **8** as in the FIG. **1** embodiment, the light ray which has entered the inclined surface **5** rectilinearly travels toward the sensor **9**, and the light ray which has entered the inclined surface **4** is deflected and travels toward the sensor **10**. These light beams travelling toward the sensors **8**, **9** and

10, respectively, differ in the length through the transparent body block 1 and the substrate 7.

Accordingly, there is created an optical path length difference. This optical path length difference is determined so that an in-focus image is formed on the array sensor 9, the array sensor 8 has its image formed in front of the sensor and the array sensor 10 has its image formed behind the sensor. These images having the optical path length difference are detected by the sensors 8, 9 and 10, respectively.

What we claim is:

1. A beam splitting device for causing a plurality of sensors disposed in the vicinity of a predetermined imaging plane of an objective lens to detect images of different imaging states, respectively, comprising:

light splitting means for splitting the light beam from the objective lens into a plurality of light beams, said splitting means having a light incidence surface disposed orthogonally with respect to the optical axis of the objective lens, said surface being formed with a grating of surface relief structure; and

optical means for establishing different optical path lengths for the split beams between said splitting means and the sensors, said optical means being disposed between said splitting means and the sensors so as to provide different effects on the plurality of split beams, respectively.

2. A beam splitting device according to claim 1, wherein said optical means establishes said different optical path lengths for the split beams by providing at least one of the paths of the split beams with a refractive index different from the refractive index of the other paths.

3. A beam splitting device according to claim 1, wherein said optical means establishes said different optical path lengths for the split beams by causing at least one of the split beams to be reflected a pluality of times.

4. A beam splitting device according to claim 1, wherein said light splitting means and optical beams constitute a unitary structure.

[57] **ABSTRACT**

A focus condition of an objective lens is detected on the basis of a lateral shift of two images formed by first and second light fluxes which are transmitted through right- and left-hand halves of the lens, respectively. In order to separate the first and second light fluxes, there is arranged an array of triangle prisms each having first and second surfaces which are inclined symmetrically with respect to the optical axis of lens by a critical angle so that one of the light fluxes is transmitted through the one of the surfaces, but is totally reflected by the other surface of each prism. The first and second light fluxes transmitted through the prisms are received by an array of light receiving elements in such a manner that the first and second light fluxes are selectively received by odd and even numbered light receiving elements, respectively.

METHOD AND APPARATUS FOR DETECTING FOCUS CONDITION OF OBJECTIVE LENS

BACKGROUND OF THE INVENTION

The present invention relates to a method and an apparatus for detecting a focus condition of an objective lens for use in a still camera, a cinecamera, an optical apparatus for taking microphotographs, etc.

Until now various types of the focus detection methods and apparatuses have been proposed. For example, in a Japanese Patent Laid-open Publication No. 60,645/73, the apparatus has been proposed wherein light fluxes transmitted through symmetric portions of an objective lens with respect to its optical axis are received by light receiving elements respectively through a vibrating lattice and a focus condition of the lens is detected on the basis of a difference between photoelectrically converted outputs derived from these light receiving elements. However, in such focus detection apparatus, the lattice must be supported movably and must be vibrated by a driving system, a whole apparatus becomes large in size and complex in construction.

In order to eliminate such drawbacks, another known detection apparatus has been further proposed in a Japanese Paten Laid-open Publication No. 142,512/77, wherein an image to be inspected is divided into two images by means of two wedge-shaped prisms arranged symmetrically and the two images are projected onto two series of photo receiving elements through a relay lens and a focusing condition is detected on the basis of a lateral shift of the divided images by suitably processing output difference between these series of light receiving elements. In the focus detection apparatus mentioned above, the system construction can be made relatively simple because it is not necessary to provide the lattice vibrating system and the movably supporting mechanism. However, since the images divided by the wedge-shaped prisms are projected onto the two series of light receiving elements by means of the relay lens, it is not possible to satisfy sufficiently a requirement for a compact system and is extremely difficult to adjust an optical positional relation between the relay lens, the series of the light receiving elements, etc. Moreover, since use is made of the two series of light receiving elements which are arranged side by side, it is not possible to perform the focus detection in a highly accurate manner due to differences of their characteristics.

SUMMARY OF THE INVENTION

The present invention has for its object to eliminate the drawbacks mentioned above and to provide a focus detection method which can perform a focus detection in a highly accurate manner.

According to the invention, in a method of detecting a focusing condition of an objective lens for forming an image of an object on a predetermined focal plane by selectively introducing first and second light fluxes each emanating from at least a part of respective one of first and second halves of objective lens divided along a plane including the optical axis of objective lens, onto first and second light receiving means, respectively, and by processing photoelectrically converted outputs supplied from the first and second light receiving means, the improvement comprises

introducing the first and second light fluxes into first and second light splitting means arranged between the objective lens and the first and second light receiving means, respectively, said first and second light splitting means including first and second optical surfaces, respectively, each of which is formed by an interface between higher refractive index material and lower refractive index material viewed in a light propagating direction and said first and second optical surfaces being inclined symmetrically with respect to the optical axis by such angles that the first light flux is transmitted through the first optical surface, but is totally reflected by the second optical surface and that the second light flux is transmitted through the second optical surface, but is totally reflected by the first optical surface.

Another object of the invention is to provide a focus detection apparatus for carrying out the above mentioned focus detection method by means of a compact optical system.

According to the invention, an apparatus for detecting a focus condition of an objective lens for forming an image of an object on a predetermined focal plane comprises

light splitting means comprising first and second optical surfaces each of which is formed by an interface between higher and lower refractive index materials, said first and second optical surfaces being inclined symmetrically with respect to an optical axis by an angle substantially equal to a critical angle;

means comprising first and second light receiving elements arranged to receive first and second light fluxes emanating from first and second halves of the objective lens and transmitted through said first and second optical surfaces, respectively; and

means for processing photoelectrically converted outputs from said first and second light receiving elements to detect the focus condition of the objective lens on the basis of a lateral shift of two images formed by said two light fluxes transmitted through the first and second optical surfaces.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic view showing a theory of separating a light flux on the basis of a critical angle according to the invention;

FIG. **2** is a schematic view illustrating one embodiment of the focus detection apparatus according to the invention;

FIGS. **3A** to **3C** are schematic views showing a relation between a focal position and a light flux deviation in in-focused, forwardly-defocused, and backwardly-defocused conditions respectively;

FIG. **4** is a graph showing output signal distributions of first and second series of light receiving elements; and

FIG. **5** is a block diagram illustrating an embodiment of a calculation unit of the focus detection apparatus according to the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** is a schematic view explaining a theory of separating a light flux emanating from one half of an objective lens from a light flux emanating from the other half of the objective lens, said halves being divided along a plane including the optical axis of objective lens. In FIG. **1**, in an image side space of an objective lens such as a photographic lens **1** there is arranged a triangle prism **2**. An inclined surface **3** of the prism **2** is so set that an angle θ between an optical axis O and a

normal Z with respect to the inclined surface 3 is near a critical angle. For example, if it is assumed that the prism 2 is made of material having a refractive index n of 1.5 and is surrounded by an air, the angle $\theta(=\sin^{-1} 1/n)$ is set at about 42°. In this manner, light rays transmitted through a right-hand half portion of the lens 1 with respect to a plane perpendicular to the drawing and including the optical axis O are made incident upon the inclined surface 3 at angles greater than the critical angle, and thus a light beam consisting of these light rays is totally reflected by the inclined surface 3. On the contrary, light rays transmitted through a left-hand half portion of the lens 1 is made incident upon the inclined surface 3 at angles less than the critical angle, and thus a light beam consisting of these light rays is refracted by the inclined surface 3. In case of rotating the prism 2 about the optical axis O by 180°, the light beams transmitted through the right portion and the left portion of the lens 1 are refracted and reflected, respectively by the inclined surface 3. In this manner, by making use of the critical angle, it is possible to separate stably the light fluxes transmitted through the right and left portions of the lens 1 with respect to the plane perpendicular to the drawing and including the optical axis O.

In a preferred embodiment of the invention using the critical angle mentioned above, the light fluxes transmitted through the right portion (first region) and the left portion (second region) of the lens 1 are separated respectively by means of an array of prisms each having inclined surfaces which are so constructed that these light fluxes are made incident upon the inclined surfaces at the angles larger or smaller than the critical angle, and then at least a part of the light flux separated by the prism is received by a pair of light receiving elements.

FIG. 2 is a schematic view showing one embodiment of a construction of prisms and an arrangement of a pair of light receiving elements of the focus detection apparatus according to the invention. In the present embodiment, prisms 4-1, . . . , 4-(N-1), and 4-N are formed in one body and each prism has two inclined surfaces 5-1 and 5-2 upon which the light fluxes transmitted through the first and second regions are made incident. That is to say, the light flux transmitted through the first region (light rays shown by solid lines) is made incident upon the surface 5-1 at a smaller angle than the critical angle, but is made incident upon the surface 5-2 at an angle larger than the critical angle. This relation is entirely reversed for the light flux transmitted through the second region (light rays shown by dotted lines). In such a construction, as clearly seen from the light flux impinging upon a focal point a or b, the light fluxes transmitted through the first and second regions of the lens 1 are reflected by the inclined surfaces 5-2 and 5-1 respectively, so that only the light flux from the first region is transmitted through the inclined surface 5-1 and also only the light flux from the second region is transmitted through the inclined surface 5-2. Therefore, if a plurality of light receiving elements 6-1, 7-1; . . . ; 6-(N-1), 7-(N-1); 6-N, 7-N are arranged in an array in such a manner that the elements 6-1, 7-1; . . . 6-N, 7-N are symmetrical with respect to ridgelines of respective prisms 4-1, . . . , 4-(N-1), 4-N, only the light flux transmitted through the first region of the lens is made incident upon the light receiving elements 6-1~6-N (first series of light receiving elements) and also only the light flux transmitted through the second region is made incident upon the light receiving elements 7-1~7-N (second series of light receiving elements).

FIGS. 3A to 3C are schematic views showing a relation between a focal position and a light flux deviation. In FIGS. 3A to 3C, for the sake of simplicity, five prisms 4-1~4-5 and five light receiving element pairs 6-1~6-5; 7-1~7-5 are shown and the light fluxes transmitted through the first region of the lens are denoted by A~E, the light rays transmitted through the second region of the lens by A'~E', and focal points are denoted by a~e. In the present embodiment, the prisms 4-1~4-5 are arranged near a predetermined focal surface F which is conjugated with a focal plane on which an image of an object is to be formed. As shown in FIG. 3A, in case that the focal points a~e are located just on the focal surface F i.e. in an in-focused condition, the light rays A and A', B and B', . . . , E and E' are made incident upon the light receiving elements 6-1 and 7-1, 6-2 and 7-2, . . . , 6-5 and 7-5, respectively. In this case, since distributions of an incident light intensity upon the first series of light receiving elements 6-1~6-5 and the second series of light receiving elements 7-1~7-5 become the same, output distributions thereof are identical with each other. That is to say, the elements 6-1 and 7-1 receive the same light rays. Contrary to this, as shown in FIG. 3B, in case that the focal points a~e are situated backward the series of the light receiving elements i.e. in a forwardly-defocused condition, for example, the light rays B and B' are made incident upon the light receiving elements 6-1 and 7-3 respectively, the other light fluxes are made incident upon the light receiving elements each shifted from the in-focused condition. Therefore, in this case, distributions of the incident light intensity upon the first and second series of light receiving elements are different from each other and output distributions become also different as illustrated by curves I and II in FIG. 4. Moreover, as shown in FIG. 3C, in case that the focal points a~e are situated forward the focal surface F i.e. in a backwardly-defocused condition, the light fluxes A~E and A'~E' are shifted inversely in opposite directions as compared with the case shown in FIG. 3B, and thus output distributions of the first and second series of light receiving elements are shifted inversely as compared with the curves shown in FIG. 4.

Therefore, direction and amount of the defocused condition can be detected by detecting direction and amount of the relative shift of the two divided images impinging upon the light receiving elements. One preferred embodiment of the focus condition detecting method will be explained hereinbelow. At first, output differences between all the adjacent light receiving elements are measured to detect positions M and M' for the first and second series of the light receiving elements showing the maximum output differences of the same polarity. Then, the M and M' having the same polarity are compared with each other. Then the focusing condition is detected as follows; $M>M'$ . . . backwardly-defocused condition, $M<M'$ . . . forwardly-defocused condition, and $M=M'$ . . . in-focused condition. In addition, by calculating $M-M'$, a deviation amount from the in-focused condition can be obtained. It should be noted that if more than two maximum output differences having the same value are detected, the smallest numbers of positions may be chosen as the values M and M'.

FIG. 5 is a block diagram showing one embodiment of a calculation unit of the focus detection apparatus according to the invention. In the embodiment shown in FIG. 5, the first series of light receiving elements 6

comprising the light receiving elements 6-1~6-N and the second series of light receiving elements 7 comprising the light receiving elements 7-1~7-N are driven under the control of a control circuit 8. Then, photoelectrically converted output signals thereof are held by a sample and hold circuit 9 and then are successively converted into digital signals by means of an A/D converter 10. The digital signal are then supplied to a calculation circuit 11. In the calculation circuit 11, differences between successive light receiving elements of respective series are calculated so as to detect the positions M and M' of the light receiving elements producing the outputs which show the maximum difference and the same polarity, and then obtained M and M' are supplied to the control circuit 8 after comparing each other. The control circuit 8 functions to detect the focusing condition such as forwardly-defocused, backwardly-defocused, and in-focused conditions corresponding to the signal supplied from the calculation circuit 11, and to indicate the detected amount of deviation from the in-focused position on an indicator 12. In addition, in the defocused condition, the deviation amount from the in-focused condition is also represented on the indicator 12. Therefore, the focusing control can be effected manually or automatically corresponding to the information indicated on the indicator 12.

The present invention is not limited to the embodiments mentioned above, but various modifications and alternations are possible. For example, in the above embodiment the light fluxes transmitted through the first and second regions of the objective lens are separated by the triangular prism, but other polygonal prisms or a cone-shaped optical member can be used for such separation. In this case, such light dividing members may be arranged at the same position as the embodiment mentioned above. That is to say, each pair of the light receiving elements may be arranged symmetrically with respect to an apex or a ridgeline. Moreover, a parallel plate made of glass or plastics may be arranged on the bottom surface of the prism. In such a case, it is possible to receive only the desired light flux effectively by means of light receiving elements having a narrower width.

Further, the inclined surface of the prism is not always necessary to be formed by an interface between the prism and air, but may be formed by an interface between higher and lower refractive index materials.

According to the invention, since it is not necessary to provide the moving mechanism, the relay lens, etc., the whole apparatus can be made simple in construction and small in size. Moreover, since the light receiving elements for the first and second series can be formed integrally in an array, characteristic variation between the first and second series of the light receiving elements can be eliminated and thus the focus detection can be performed in a highly accurate manner.

What is claimed is:

1. In a method of detecting a focusing condition of an objective lens for forming an image of an object on a predetermined focal plane by selectively introducing first and second light fluxes each emanating from at least a part of respective one of first and second halves of objective lens divided along a plane including the optical axis of objective lens, onto first and second light receiving means, respectively, and by processing photoelectrically converted outputs supplied from the first and second light receiving means, the improvement comprising

introducing the first and second light fluxes into first and second light splitting means arranged between the objective lens and the first and second light receiving means, respectively, said first and second light splitting means including first and second optical surfaces, respectively, each of which is formed by an interface between higher refractive index material and lower refractive index material viewed in a light propagating direction and said first and second optical surfaces being inclined symmetrically with respect to the optical axis by such angles that the first light flux is transmitted through the first optical surface, but is totally reflected by the second optical surface and that the second light flux is transmitted through the second optical surface, but is totally reflected by the first optical surface.

2. A method according to claim 1, wherein said first and second light fluxes are introduced into an array of light receiving elements which are alternately belonging to said first and second light receiving means, by means of a prism member which includes an array of optical surfaces which are alternately belonging to said first and second light splitting means.

3. A method according to claim 2, wherein differences of outputs of successive elements of the first and second light receiving means are respectively derived to detect positions M and M' of the elements which produces the maximum differences of the same polarity, respectively, and the focus condition of the objective lens is detected in accordance with a difference M−M' of the detected positions.

4. A method according to claim 3, wherein a direction of a defocused condition is detected by a sign of said difference M−M'.

5. A method according to claim 3, wherein an amount of a defocused condition is detected by an amount of said difference M−M'.

6. An apparatus for detecting a focus condition of an objective lens for forming an image of an object on a predetermined focal plane comprising

light splitting means comprising first and second optical surfaces each of which is formed by an interface between higher and lower refractive index materials, said first and second optical surfaces being inclined symmetrically with respect to an optical axis by an angle substantially equal to a critical angle;

means comprising first and second light receiving elements arranged to receive first and second light fluxes emanating from first and second halves of the objective lens and transmitted through said first and second optical surfaces, respectively; and

means for processing photoelectrically converted outputs from said first and second light receiving elements to detect the focus condition of the objective lens on the basis of difference between said two light fluxes transmitted through the first and second optical surfaces.

7. An apparatus according to claim 6, wherein said first and second optical surfaces are formed by a prism.

8. An apparatus according to claim 7, wherein a plurality of prisms each having the first and second optical surfaces are arranged in an array and a plurality of pairs of the first and second light receiving elements are aligned in a corresponding array in such a manner that

the first and second light receiving elements are arranged alternately.

9. An apparatus according to claim 8, wherein said plurality of prisms are integrally formed in one body.

10. An apparatus according to claim 8, wherein said first and second light receiving elements are integrally formed in one body.

11. An apparatus according to claim 8, wherein said prisms are formed by triangle prisms.

12. An apparatus according to claim 8, wherein said processing means comprises a circuit for detecting the focus condition of the objective lens in accordance with a lateral shift of two images formed by the first and second light fluxes transmitted through the prisms.

[57] **ABSTRACT**

The wide angle objective of the inverted telephoto type with a high relative aperture. It includes from front to rear, a first lens group of negative power, a second lens group of positive power and a third lens group of positive power, well corrected for the various aberrations with predetermined conditions for the focal length of each lens group, lens form and refractive indices of the glasses of the lens elements.

INVERTED TELEPHOTO TYPE WIDE ANGLE OBJECTIVE OF LARGE RELATIVE APERTURE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to inverted telephoto type wide angle objectives of high relative aperture including those having a semi-angular field of 47° with a relative aperture of F/2.0, whose bulk and size is reduced and which are well corrected for aberrations.

2. Description of the Prior Art

Recently, in the field of wide angle objectives for use in single lens reflex cameras, progress has been made in the reduction of the bulk and size of the lens system and increasing of its relative aperture. Most of these wide angle objectives employ the so-called inverted telephoto type lens configuration which offers the advantage that the back focal distance can be generally elongated. On the other hand, because the symmetry of lens configuration is broken, it becomes difficult to achieve good correction of aberrations. This difficulty tends to rapidly increase as the angular field of view and the relative aperture increase and the bulk and size of the lens system is reduced.

The use of the inverted telephoto type in the design of such lens system is disclosed in, for example, U.S. Pat. Nos. 3,748,021, 3,976,366, 3,981,563, 4,013,350, 4,061,421 and 4,188,092.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide an inverted telephoto type wide angle objective of high relative aperture for use in single lens reflex cameras in which despite the increases in the angular field of view and the relative aperture, all aberrations are well corrected, and further the lens system can be made compact.

The wide angle objective of the invention comprises three groups, of which the first counting from the front is of negative refractive power, the second is of positive refractive power and the third is of positive refractive power, the focal lengths of the lens groups, with the lens forms and the refractive indices of the glasses of the lens elements being determined to provide good correction of aberrations.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1**, **2** and **3** are lens block diagrams of Example 1, Example 2 and Example 3 of embodiment of inverted telephoto type wide angle objectives of large relative aperture according to the present invention respectively.

FIGS. **4**(*a*) to **4**(*d*), **5**(*a*) to **5**(*d*) and **6**(*a*) to **6**(*d*) are graphic representations of the various aberrations of the objectives of FIGS. **1**, **2** and **3** respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is next described in connection with embodiments thereof by reference to FIGS. **1** to **3**.

In the drawings, the first lens group I has a negative refractive power, the second lens group II has a positive refractive power and the third lens group III has a positive refractive power. The first lens group I consists of, from front to rear, a positive meniscus lens **L1** of forward convexity, a negative meniscus lens **L2** of forward convexity, a second negative meniscus lens **L3** likewise convex to the front, a positive lens **L4** and a third negative meniscus lens **L5** of forward convexity. The second lens group II consists of a bi-convex doublet **L6**, **L7**. The third lens group III consists of, from front to rear, a cemented lens of a positive element **L8** and a negative element **L9**, a second cemented lens of a negative element **L10** and a positive element **L11** and two positive lenses **L12** and **L13**. A stop S lies between the second and third lens groups II and III. Such lens configuration make it possible to achieve a wide angle objective of the invention. Then, in order to facilitate a further minimization of the bulk and size of the objective lens while still preserving the possibility of achieving good correction of the aberrations, the following conditions are preferably satisfied:

$$0.72<|f_I|/f<0.79 \text{ where } f_I<0 \quad (1)$$

$$2.9<D_T/f<3.6 \quad (2)$$

$$1.2<D_{I,II}/D_{III}<1.7 \quad (3)$$

$$f1>f4 \quad (4)$$

$$|f2|>|f3| \text{ where } f2, f3<0 \quad (5)$$

$$1.7<(n2+n3)/2 \quad (6)$$

$$\|1>\nu4 \quad (7)$$

$$0.75<|R13|/f<0.9 \text{ where } R13<0 \quad (8)$$

$$50<\nu7 \quad (9)$$

$$25<\nu6<30 \quad (10)$$

$$0.30<n10-n11 \quad (11)$$

$$1.4<R18/f<1.8 \quad (12)$$

$$35<\nu10 \quad (13)$$

$$\nu9<30 \quad (14)$$

$$1.7<(n12+n13)/2 \quad (15)$$

wherein

f is the focal length of the entire system;

f_I is the focal length of the 1st lens group;

D_T is the total length of the lens system;

$D_{I,II}$ is the distance from the 1st surface of the 1st lens group to the last surface of the 2nd lens group;

D_{III} is the distance from the 1st to the last surface of the 3rd lens group;

fi is the focal length of the i-th lens element counting from the front;

ni is the refractive index of the glass of the i-th lens element counting from the front;

νi is the Abbe number of the glass of the i-th lens element counting from the front; and

Ri is the radius of curvature of the i-th lens surface counting from the front.

The reason why these conditions are given is as follows. Condition (1), condition (2) and condition (3) represent fundamental features of lens design. Condition (1) serves to make the negative refractive power of the first lens group I relatively strong so that, as the lens system is adapted to be used in the single lens reflex camera, a sufficient back focal distance is assured, and at the same time, the diameter of the front member is main-

tained minimum. When the upper limit of this range (1) is violated, the assurance of the sufficient back focal distance and the maintenance of the minimum diameter of the front member become difficult. When the lower limit is violated, the first lens group I produces large positive spherical aberrations including those of higher order, and an increase in the relative aperture becomes difficult. Condition (2) serves relatively to shorten the total length of the lens system and to achieve compactness. When the upper limit of this condition is violated, attainment of compactness becomes difficult. When the lower limit is violated, overall aberration correction becomes difficult. Condition (3) serves to minimize the diameter of the front lens member under the condition (2) by arranging the stop S relatively forward as compared with a conventional objective. When the upper limit of this condition is violated, the maintenance of the minimum diameter of the front member becomes difficult. When the lower limit is violated, the diameter of the rear member increases, and the third lens group produces large off-axis aberrations which are difficult to correct.

To achieve good correction of aberrations, each of the lens groups is given the following features. The first lens group is constructed from the positive lens **L1**, negative lens **L2**, negative lens **L3**, positive lens **L4** and negative lens **L5** which have conditions (4) to (7) within the framework of condition (1). Conditions (4) and (5) concern the focal lengths of the first and fourth lenses **L1** and **L4** and the second and third lenses **L2** and **L3** in the first lens group I and state that on whichever lens the off-axis light ray is incident at a greater height has a longer focal length than the other of lower height of incidence. Under this condition, the off-axis light ray is allowed to refract with ease so that while distortion is being corrected, various off-axis aberrations can be well corrected. Condition (6) represents higher indices of refraction of the negative lenses **L2** and **L3** in the first lens group which are reflected to moderate the radii of curvature. Since this leads to the possibility of constructing the first lens group in a thinner form, the diameter of the front member can be further minimized, and at the same time the various off-axis aberrations ascribable to the negative lenses can be reduced. Condition (7) concerns what glasses are used in the positive lenses arranged in the first lens group to correct chromatic aberrations of the first lens group. By virtue of condition (7), while the chromatic aberrations of the first lens group I are corrected by making the Abbe number of the first lens larger than that of the fourth lens, the color distortion and color coma ascribable to the positive lenses are minimized.

Conditions (8), (9) and (10) concern the second lens group. Condition (8) serves to compensate for the over-correction of coma by the first lens group I. When the upper limit of this condition is violated, the compensation for the over-corrected coma becomes difficult. When the lower limit is violated, the surface **R13** produces large negative spherical aberration which makes it difficult to achieve the increase of an relative aperture. Condition (9) serves to prevent production of color coma from the surface **R13** which takes a strong convex form under condition (8). When this condition is violated, the color coma becomes objectionably large. Condition (10) is to compensate for the under-correction of lateral chromatic aberration of the first lens group I, and represents the use of a glass of small Abbe number in the front or positive lens element **L6** constituting part of the cemented lens of the second lens group II. When the upper limit of this condition is violated, under-correction of lateral chromatic aberration results. When the lower limit is violated, under-correction of longitudinal chromatic aberration results.

On the other hand, the residual unsymmetric aberrations of the first lens group I have to be compensated for by the divergent surfaces in the third lens group. As the diverging action in the third lens group is stronger, however, higher order aberrations are produced, so that an increase of the relative aperture becomes difficult to achieve. The lenses of the third lens group III are constructed so that a positive lens **L8** and a negative lens **L9** which are cemented together form a single component, a negative lens **L10** and a positive lens **L11** which are cemented together to form a second single component, a positive lens **L12** and a positive lens **L13** are arranged in this order from the front, that whilst the physical length of the third lens group III is made relatively long within the framework of condition (3), many diverging surfaces are provided along with conditions (11) and (12), and that additional conditions (13), (14) and (15) prevail. Condition (11) represents a large difference between the indices of refraction of the 10th and 11th lenses **L10** and **L11** of the doublet component, and cooperates with condition (12) to impart thereto a large diverging action. When this condition is violated, sufficient diverging action cannot be obtained even when condition (12) is satisfied, thus making it difficult to correct unsymmetrical aberrations. Condition (12) represents an optimum range of values which are to be taken by the radius of curvature of the cemented surface in view of condition (11). When the upper limit of this condition is violated, good correction of unsymmetric aberrations cannot be attained. When the lower limit is violated, aberrations of higher order are produced, thereby the increase of the relative aperture is difficult to achieve. Conditions (13) and (14) serve to correct chromatic aberrations of the third lens group III. Condition (13) represents the use of a relatively low dispersion glass in the 10th lens **L10** by there is an intent to suppress production of color coma and color distortion when this lens is cemented. When the lower limit of this condition is violated, correction of color coma and color distortion becomes difficult. When the upper limit is violated, chromatic aberrations tend to be under-corrected which is difficult to compensate for even by giving condition (14). Condition (14) represents the use of a high dispersion glass in the 9th lens **L9** to correct chromatic aberrations which tend to be under-corrected by condition (13). When this condition is violated, correction of the chromatic aberrations becomes difficult. Condition (15) represents an increase in the indices of refraction of the rearwardly arranged two convex lenses **L12** and **L13** by which spherical aberration and off-axis halo are to be corrected. When this condition is violated, correction of spherical aberration and off-axis halo becomes difficult.

In order to avoid a loss in the image quality when focusing down to shorter object distances, it is preferred for the objective of the invention to employ a focusing method that the entire lens system is axially moved forward while simultaneously the air space between the surfaces **R8** and **R9** or the axial air separation **D8** is shortened thus maintaining good stability of aberration correction throughout the focusing range.

Example 1, Example 2 and Example 3 of specific objectives which satisfy the above-mentioned various

conditions can be constructed in accordance with the following numerical data for the radii of curvature of the lens surfaces **R1** to **R23**, the axial thicknesses and air separations **D1** to **D22**, and the indices of refraction, **n1** to **n13** and the Abbe numbers $\nu 1$ to $\nu 13$ of the glasses of the lens elements.

What is claimed is:

1. An inverted telephoto type wide angle objective of large relative aperture comprising:

three lens groups, from front to rear, the first lens group having a negative refractive power and having, front front to rear, a positive meniscus lens of convex curvature toward the front, a negative meniscus lens of convex curvature toward the front, a negative meniscus lens of convex curvature toward the front, a positive lens and a negative meniscus lens of convex curvature toward the front, the second lens group having a positive refractive power and having a cemented bi-convex lens, and the third lens group having a positive refractive power and having, from front to rear, a cemented lens of a positive lens and a negative lens, a cemented lens of a negative lens and a positive lens, and two positive lenses.

2. A wide angle objective as in claim **1**, including a stop in a space between the second and third lens groups and satisfying the following conditions:

$$0.72 < |f_I|/f < 0.79 \text{ where } f_I < 0 \quad (1)$$

$$2.9 < D_T/f < 3.6 \quad (2)$$

$$1.2 < D_{I,II}/D_{III} < 1.7 \quad (3)$$

where

f is the focal length of the entire system;

f_I is the focal length of the first lens group;

D_T is the total length of the objective;

$D_{I,II}$ is the distance from the first surface of the first lens group to the last surface of the second lens group; and

D_{III} is the distance from the first to the last surface of the third lens group.

3. A wide angle objective as in claim **2**, and satisfying the following conditions:

$$f1 > f4 \quad (4)$$

$$|f2| > |f3| \text{ where } f2, f3 < 0 \quad (5)$$

$$1.7 < (n2+n3)/2 \quad (6)$$

$$\nu 1 > \nu 4 \quad (7)$$

where

fi is the focal length of the i-th lens element counting from the front;

ni is the index of refraction of the glass forms i-th lens element counting from the front; and

νi is the Abbe number of the glass forming the i-th lens element.

4. A wide angle objective as in claim 3, and satisfying the following conditions:

$$0.75<|R13|/f<0.95 \text{ where } R13<0 \quad (8)$$

$$50<\nu 7 \quad (9)$$

$$25<\nu 6<30 \quad (10)$$

where Ri is the radius of curvature of the i-th lens surface counting from the front.

5. A wide angle objective as in claim 4, and satisfying the following conditions:

$$0.30<n10-n11 \quad (11)$$

$$1.4<R18/f<1.8 \quad (12)$$

$$35<\nu 10 \quad (13)$$

$$\nu 9<30 \quad (14)$$

$$1.7<(n12+n13)/2. \quad (15)$$

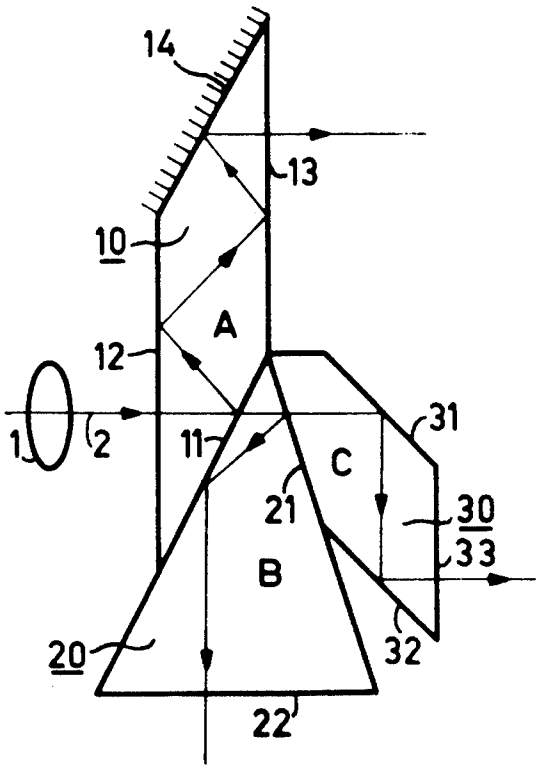

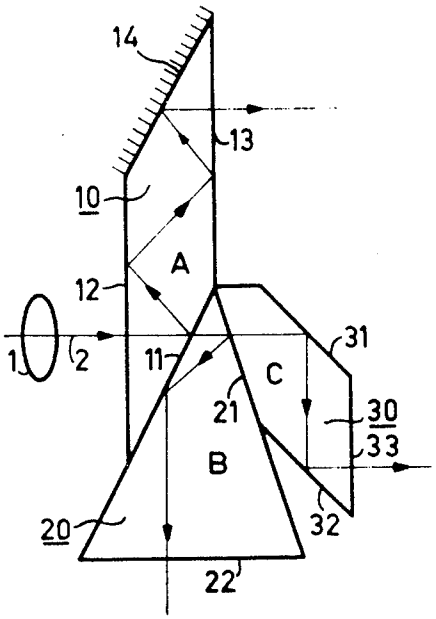

FIG.1

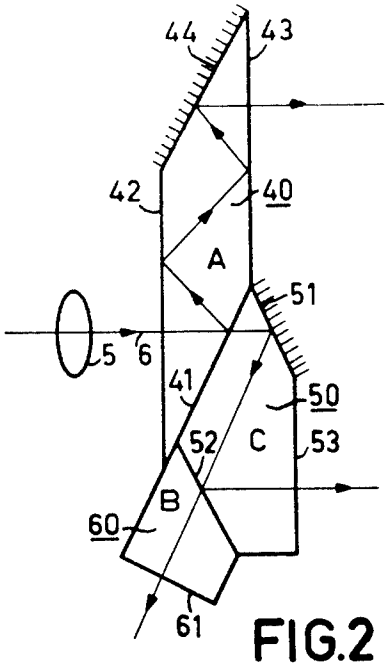

FIG.2

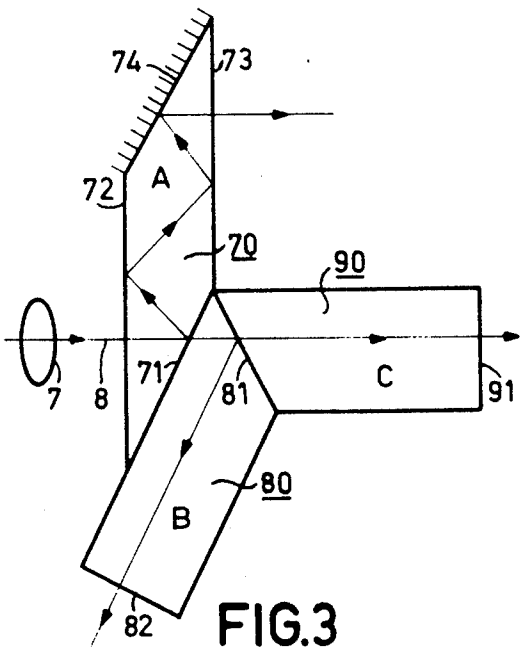

FIG.3

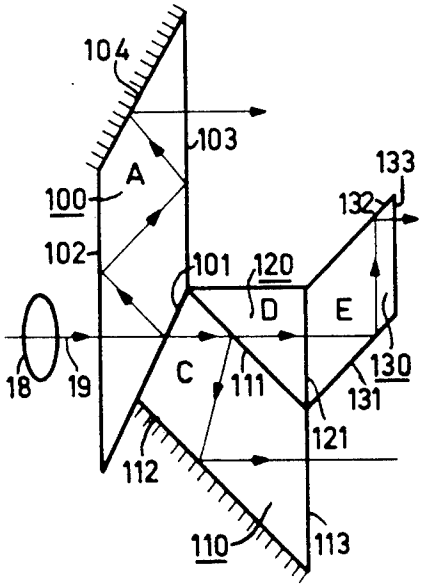

FIG.4

TELEVISION CAMERA EQUIPPED WITH A COLOR-SEPARATING ARRANGEMENT DISPOSED BEHIND THE OBJECTIVE

BACKGROUND OF THE INVENTION

The invention relates to a television camera equipped with a color-separating prism assembly disposed behind the objective. The assembly comprises a plurality of surfaces which adjoin dichroic layers of mutually different colors. In the camera, the separated light beams which emerge from the prism assembly, are transmitted to camera tubes. In the prism assembly, passing in the direction of the light which enters the prism assembly, there are provided, twice in succession, a plane air-glass transition and a dichroic layer. Each layer encloses an angle with the air-glass transition and adjoins a plane glass surface. At least one air-glass transition and the associated dichroic layer enclose an angle smaller than 30° with a plane which is normal to the nonreflected optical axis.

Such a television camera is known from U.S. Pat. No. 3,202,039 (Netherlands Patent Specification No. 113,911). The known television camera has the advantage that the glass-length of the prism assembly to be traversed by the light can be comparatively small. The prism assembly thus obtained can be comparatively compact because the totally reflecting air-glass transitions are plane. As a result of this, one zone of such an air-glass transition may serve both as an entrance surface for the light in the relevant prism section and as a totally reflecting surface for the light which is reflected by the dichroic layer associated with the air-glass transition. Since at least one air-glass transition and the associated dichroic layer enclose an angle smaller than 30° with a surface which is normal to the nonreflected optical axis, annoying polarization effects in the traversing light or color variations across the lens pupil and/or the image field are avoided.

In the known television camera the axes of the three camera tubes are arranged in different directions relative to each other. An arrangement of camera tubes in which the tube axes extend in different directions has the drawback that external magnetic fields, for example the earth's magnetic field, have a different influence on the electron beam in each tube. When the position of the television camera is changed this may give rise to registration errors. A further drawback is that with the known set-up of the prism assembly and camera tubes a compact design is not easy to realize.

SUMMARY OF THE INVENTION

It is an object of the invention to mitigate these problems. To this end a television camera of the type described above includes at least one prism having at least two interfaces of which are parallel to each other. At least one of the interfaces is provided with a dichroic layer.

Suitably, the parallel light beams emerging from the prism arrangement contain the green and the red spectral components of the light which is incident on the arrangement, because registration errors for red and green color pictures are most annoying. A compact set up of the prism arrangement and camera tubes is possible, so that a camera of small dimensions can be obtained. The third camera tube, which receives the blue spectral component of the light, may, for example, be accommodated in the grip of the camera.

BRIEF DESCRIPTION OF THE DRAWING

FIGS. **1**, **2**, **3** and **4** schematically show four embodiments of the television camera in according to the invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In FIG. **1**, the prism assembly comprises three prisms **10**, **20**, and **30**. The exit surface **11** of the prism **10** is provided with a dichroic layer which reflects the green component of the light. The exit surface **21** of the prism **20** is provided with a dichroic layer which reflects the blue component of the light. The light from the scene passes through the objective **1** and, via the entrance surface **12** of the prism **10**, it is incident on the exit surface **11**. The entrance surface **12** is normal to the optical axis **2**. The exit surface **11** makes an angle smaller than 30° with a plane perpendicular to the optical axis **2**.

The angle which the dichroic layer at surface **11** makes with the unreflected optical axis **2** is therefore greater than 30°. Since the dichroic layer on the exit surface **11** reflects the green component of the light, this layer determines the color separation both at the short wavelength end (blue edge) and at the long wavelength end (red edge). The dichroic layer on the exit surface **21** of the prism **20** may therefore comply with less stringent requirements as regards the accuracy of the wavelength edges. The green component of the light reflected by the surface **11** is reflected by the surface **12**, subsequently by the surface **13** of the prism **10** and finally by the reflecting surface **14** of the prism **10**. As the surface **14** is arranged parallel to the surface **11** and the surface **12** parallel to the surface **13**, the green light beam emerging from the prism **10** is parallel to the optical axis **2**.

The light beam transmitted by the dichroic layer on the surface **11** is incident on the exit surface **21** of the prism **20** which is also provided with a dichroic layer. The surface **21** subtends an angle greater than 30° with the plane perpendicular to the optical axis **2**. The red light component transmitted by the dichroic layer is reflected by the surface **31**, subsequently by the surface **32** of the prism **30** and emerges from the prism **30** via the surface **33**. As the surfaces **32** and **31** are parallel to each other and the surface **33** is parallel to the surface **12**, the red light beam emerging from the prism section **30** is parallel to the optical axis **2** and is thus parallel to the green light beam which emerges from the prism **10**.

The blue component of the light beam reflected by the dichroic layer on the surface **21** is reflected by the surface **11** and subsequently emerges from the prism **20** via the surface **22**.

In the embodiment shown in FIG. **2**, the prism **40** of the prism arrangement assembly is identical to the prism **10** of the prism assembly in FIG. **1**. The dichroic layer on the exit surface **41** of the prism **40** reflects the green component of the light beam which is incident on the entrance surface **42** via the lens **5**. This green component consequently emerges from the prism **40** after reflection by the is **6**surface **42**, the surface **43** and the reflecting surface **44**.

After reflection by the reflecting surface **51** of the prism **50** the light beam transmitted by the dichroic layer on the surface **41** is incident on the surface **52** of

the prism **50**, which surface **52** is provided with a dichroic layer. The surface **52** subtends an angle greater than 30° with a surface normal to the optical axis **6**. The red component of the light beam reflected by the dichroic layer emerges from the prism **50** via the surface **43**. As the surface **51** is parallel to the surface **52**, the red light beam emerging from the prism **50** is parallel to the optical axis **6** and thus parallel to the green light beam emerging from the prism **40**.

The blue component of the light beam transmitted by the dichroic layer on the surface **52** emerges from the prism **60** via the surface **61**.

In the embodiment shown in FIG. **3** the prism **70** of the prism assembly is identical to the prism **10** in the embodiment shown in FIG. **1**. The dichroic layer provided on the exit surface **71** reflects the green component of the light beam which is incident on the front surface **72** via the lens **7**. The green component emerges from the prism **70** via the exit surface **73** parallel to the optical axis **8** after reflection by the front surface **72**, the surface **73**, and the reflecting surface **74**.

The beam transmitted by the dichroic layer on the exit surface **71** is incident on the dichroic layer on the exit surface **81** of the prism **80**. The surface **81** makes an angle greater than 30° with a plane perpendicular to the optical axis **8**. The dichroic layer on the exit surface **81** reflects the blue component of the light beam and transmits the red component without refraction. The red beam which emerges from the prism via the exit surface **91** coincides with the optical axis **8** and is thus parallel to the green beam emerging from the prism **70**. The blue beam which is reflected by the dichroic layer on the surface **81** emerges from the prism **80** via the exit surface **82**.

In the embodiment shown in FIG. **4** the prism **100** of the prism assembly is identical to the prism **10** of the embodiment shown in FIG. **1**. It will therefore be evident that the green light beam emerging from the prism **100** is parallel to the optical axis **19**. The light beam which is transmitted by the dichroic layer on the exit surface **101** of the prism **100** is incident on the dichroic layer provided on the exit surface **111** of the prism **110**. This dichroic layer transmits, for example, the blue component of the light beam and reflects the red component. After reflection by the reflecting surface **112** of the prism **110** the red component emerges from the prism via the exit surface **113**. As the surfaces **112** and **111** are parallel to each other, the red beam emerging from the prism **110** is parallel to the optical axis **19** and thus parallel to the green beam. Via the prism **120** and the prism **130** the blue light beam transmitted by the dichroic layer on the surface **111** emerges from the prism **130** via the exit surface **133** after being reflected by the surface **131** and subsequently by the surface **132**. As the surfaces **131** and **132** are parallel, the blue beam which emerges from the prism **130** is parallel both to the red beam and to the green beam.

What is claimed is:

1. A television camera comprising:

an objective;

a color-separating prism assembly disposed behind the objective, said assembly having an entrance surface and three exit surfaces, light entering the assembly through the entrance surface being separated into different colors emerging from the exit surfaces;

three camera tubes, one tube arranged in the path of light emerging from each exit surface;

characterized in that the prism assembly comprises:

a first prism having an optical axis and a plurality of planar surfaces, one such surface being an entrance surface perpendicular to the optical axis, one other surface having a dichroic layer thereon; and

a second prism having a plurality of planar surfaces, one surface having a dichroic layer thereon;

wherein the surface of the first prism bearing the dichroic layer is arranged adjacent a surface of the second prism without a dichroic layer thereon, said adjacent surfaces being separated by an air gap, said first and second prisms arranged so that the optical axis passes through both dichroic layers;

wherein the surface of the first prism bearing the dichroic layer subtends an angle less than 30° with a plane perpendicular to the optical axis; and

wherein the first prism has at least one other surface parallel to the surface of the first prism bearing the dichroic layer.

2. A television camera as claimed in claim **1**, characterized in that the dichroic layer on the first prism reflects green light.

3. A television camera as claimed in claim **2**, characterized in that the dichroic layer on the second prism subtends an angle greater than 30° with a plane perpendicular to the optical axis.

4. A color-separating prism assembly having an entrance surface and three exist surfaces, said assembly comprising:

a first prism having an optical axis and a plurality of planar surfaces, one such surface being an entrance surface perpendicular to the optical axis, one other surface having a dichroic layer thereon; and

a second prism having a plurality of planar surfaces, one surface having a dichroic layer thereon;

wherein the surface of the first prism bearing the dichroic layer is arranged adjacent a surface of the second prism without a dichroic layer thereon, said adjacent surfaces being separated by an air gap, said first and second prisms arranged so that the optical axis passes through both dichroic layers;

wherein the surface of the first prism bearing the dichroic layer subtends an angle less than 30° with a plane perpendicular to the optical axis; and

wherein the first prism has at least one other surface parallel to the surface of the first prism bearing the dichroic layer.

5. A color-separating prism assembly as claimed in claim **4**, characterized in that the dichroic layer on the first prism reflects green light.

6. A color-separating prism assembly as claimed in claim **5**, characterized in that the dichroic layer on the second prism subtends an angle greater than 30° with a plane perpendicular to the optical axis.

[57] **ABSTRACT**

The objective comprises a plurality of movable lens components and at least one stationary lens component group, at least two of said components including an aspherical surface. The movable components are constituted by single lenses of which at least one lens comprises an aspherical surface, while the stationary lens component group(s) may comprise at least one aspherical surface. Steadiness of the image plane is obtained by mechanical compensation for focal-length variations with a ratio greater than five, which may readily reach the value eight. The aspherical lenses are arranged so that for the same focal length variation the total number of lenses of the objective, which may be spherical or non-spherical, is smaller than in any other variable-focus objective with a stationary image plane comprising solely spherical lenses:

This results in a reduction of the mass of the objective, namely of the movable parts, and a reduction of the power necessary for moving said parts.

Application to color television camera.

OBJECTIVE COMPRISING ASPHERICAL SURFACES, WHOSE FOCAL LENGTH IS VARIABLE OVER A WIDE RANGE

The invention relates to a variable focus objective with stationary image plane, comprising components including lenses; at least two of said components including a lens with an aspherical surface.

German Offenlegungsschrift No. 2,625,058 describes an objective of this type. A special feature of this objective is that it comprises only two components of lenses, which are both movable.

The objective in accordance with said Offenlegungsschrift has two sorts of drawbacks. Its optical performance is limited and provides a focal-length variation with a ratio between its maximum and minimum values which is hardly greater than 2 if allowance is made for the tolerances to be satisfied for chromatic and achromatic aberrations. On the other hand, although the number of constituent elements of each component is reduced by the inclusion of an aspherical surface in each of these components, this number remains high, which complicates the mechanical construction of the objective, specifically of the part by means of which the components are to be moved relative to each other.

It is the object of the invention to mitigate these drawbacks, and specifically to increase the range of focal-length variation. The invention also employs a certain number of aspherical surfaces in order to minimize the number of elements by means of which the objective is formed, the objective being of simple mechanical construction because the movable components comprise only one element. Since the movable components comprise only one optical element they have a low mass, so that they can be moved by means also having a low mass, for example employing microprocessors.

The invention utilizes methods of "compensating" for the focal-length variation, which are used in optical systems if the image plane is to remain satisfactory.

The so-called "optical compensation" method is not used, because it only provides a simple solution for the movable components if the focal-length variation is effected with a ratio smaller than 2.

The invention employs the "mechanical" method of compensating for the focal-length variation with stationary image plane. According to this method the spacing between the components and their displacement is subject to an analytical law obtained by computation. This method is extremely suitable for compensation in the case of focal-length variations with high ratios.

In the prior art this method has already been applied using the "Delano diagram" (see the article by Besenmatter "Analyse der primären Wirkung asphärischer Flächen mit Hilfe des Delano Diagrams" in Optik 51, 1978, pages 385 to 396). A prior-art objective obtained in accordance with this compensation method is the subject of the article by D. S. Volosov, entitled: "Design of complex photographic systems" in Gostekhizdat 1948. This objective has moderate specifications: a focal-length variation of 3 to 4 and an aperture from F/3 to F/5. The invention applies said method in such a way that it is more suitable for finding solutions yielding a higher performance. First of all the powers of the various components of stationary and movable lenses were examined and the ratios which should exist between said powers in order to obtain the desired focal-length variations and apertures, using the displacement rules for each component and the ratios between the diameters of the components and their focal lengths as feasibility criteria. Thus, a so-called "focal-length evaluation" diagram is obtained. If it is desired to have an objective comprising for example two stationary components and two movable components with the respective focal lengths F_1, F_4, F_2, F_3, the focal lengths of the movable components referred to F_1, i.e. the ratios F_2/F_1 are plotted as abscissae and ordinates on the axes of a two-dimensional diagram, those portions of the diagram which yield practical solutions then being selected on basis of considerations with respect to the focal-length variation and maximum power of the objective. According to the invention, a very limited portion of the diagram has thus been selected which corresponds to focal-length variations with a ratio of at least 5. For objectives comprising three movable components similar approaches consist in setting up a three-dimensional diagram of the powers and in selecting a three-dimensional zone yielding the desired great focal-length variations.

The objective in accordance with the invention, based on said investigations, is characterized in that it comprises a plurality of movable lens components and at least one stationary lens component group, in that the aspherical lenses are arranged so that for the same focal-length variation the total number of spherical or non-spherical lenses is smaller than in any other variable-focus objective with stationary image plane solely comprising spherical lenses, the steadiness of the image plane during a focal length variation greater than five being obtained through mechanical compensation, and that at least all the movable components are constituted by single lenses, of which at least one lens comprises an aspherical surface, whilst the stationary component(s) may comprise at least one aspherical surface.

In a first embodiment the objective comprises, from the object space to the image space, a first stationary component of positive power, a first movable component constituted by a single lens of negative power, a second movable component constituted by a single movable lens of positive power, and a second stationary component of positive power.

More specifically, when F_1, F_2, F_3 designate the respective optical focal lengths of the first stationary component, of the first movable component and of the second movable component, the focal lengths of these different components are such that:

$$-0.25 \leqq F_2/F_1 \leqq -0.1$$

$$0.9 \leqq F_3/F_1 \leqq 2$$

In a second embodiment the objective comprises 3 movable components.

In variants of these embodiments the focal-length variation ratio reaches values greater than 8, whilst half the field angle is greater than 24°, the aperture number ranging between F/2 and F/1.5, where F designates the focal length of the objective.

Furthermore, the image distance of the objective may be substantial and may be greater than 22 mm, which in accordance with the invention enables the use of said objective in a colour camera device with a colour-separating prism included between the objective and a camera with three camera tubes.

The invention will be more fully understood by means of the following description of some embodiments which are given by way of example, said description being accompanied by explanations and drawings of which:

FIG. **1** represents a diagram relating to the evaluation of the focal lengths of two movable components of an objective in accordance with a first embodiment of the invention;

FIG. *2a, 2b, 2c, 2d* represent the optical diagram of a first example of an objective with two movable components in accordance with the first embodiment of the invention, each of said Figures, in this order, corresponding to a value of the focal-length of the objective from its minimum to its maximum;

FIG. *3a, 3b, 3c, 3d* show the optical diagram of a second example of an objective with two movable components in accordance with the first embodiment of the invention, each of said Figures, in this order, corresponding to a value of the focal length of the objective from its minimum to its maximum;

FIGS. *4a, 4b, 4c, 4d* represent the optical diagram of a first example of an objective with three movable components in accordance with the second embodiment of the invention, each of said Figures, in this order, corresponding to a value of the focal length of the objective from its minimum to its maximum;

FIG. **5** represents a diagram relating to the movement of the movable components of the objectives of FIGS. *4a, 4b, 4c, 4d;*

FIGS. *6a, 6b, 6c, 6d:* show the optical diagram of a second example of an objective with three movable components in accordance with the second embodiment of the invention, each of said Figures, in this order, corresponding to a value of the focal length of the objective from its minimum to its maximum;

FIG. **7** represents diagrams relating to the movements of the movable components of the objective represented in FIGS. *6a, 6b, 6c, 6d.*

FIG. **1** relates to a first embodiment of the objective, which comprises two movable components between two stationary components. The focal lengths of the stationary components are F_1 and F_4 and those of the movable components F_2 and F_3. In a rectangular system of axes the ratios F_3/F_1 and F_2/F_1 are respectively plotted as abscissae and ordinates and the evaluation diagram for the focal lengths for said objective is drawn up. In accordance with the invention that zone in said diagram is selected which has a rectangular outline **12** defined by the relations:

$$-0.25 \leqq F_2/F_1 \leqq -0.1$$

$$0.9 \leqq F_3/F_1 \leqq 2$$

The points within 12 correspond to variable-focus objectives with a fixed image plane, which exhibit large fields of view of the order of 45° and focal-length variations of the order of 8. One of the best compromises for said objective is situated near point A in FIG. **1** with the coordinates:

$$(1)\begin{cases} \dfrac{F_2}{F_1} = -0.2 \\ \dfrac{F_3}{F_1} = 1 \\ \text{with } F_1 > 0 \end{cases}$$

This corresponds to an image size with a diagonal of 7 mm and an aperture of F/1.8, F being the focal length of the objective, which has a minimum value of the order of 6 to 8 mm and with a size, including the image distance, of the order of 140 mm. FIGS. *2a, 2b, 2c, 2d* represent a first example corresponding to this particular case, said Figures corresponding to focal length values of F=7.95 mm, F=15.00 mm, F=35 mm, and F=63.5 mm respectively. In these Figures the optical axis of the objective is designated **21** and the image field is designated **20**. The dioptric surfaces of the objective elements are designates **1** to **17** reckoned from the object field to the image field. The stationary component with a positive focal length F_1 is constituted by the lenses L_1, L_2, L_3, whilst the stationary component with a focal length F_4 is constituted by four lenses L_6 to L_9. The lenses L_1, L_2 constitute a convergent glued doublet, whilst the lens L_3 is a convergent meniscus lens. In the stationary component with the focal length F_4 the lens L_6 is convergent, its entrance surface **10** being aspherical, and the lenses L_7, L_8, L_9 constitute a non-glued triplet, the lens L_7 being convergent and substantially plano-convex, the lens L_8 being divergent and substantially plano-concave, and the lens L_9 being convergent and substantially equiconvex. The movable components are respectively constituted by a divergent lens L_4 with a focal length F_2 and a convergent lens L_5 with a focal length F_3. Each of said lenses comprises an aspherical surface, respectively corresponding to the dioptric surfaces **7** and **8**. The equation of the cross-sections of the aspherical dioptric surfaces **7**, **8**, **10** (rotationally symmetrical about the optical axis **21**) in the plane of the diagram of FIGS. *2a, 2b, 2c, 2d* plotted in a rectangular system of axes (x, y), is:

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1 + \lambda)C^2y^2}} + \sum_{i=2}^{i=n} \epsilon_i y^{2i} \qquad (2)$$

the abscissae x being measured from the apex of the dioptric surface on the positively oriented optical axis of the lens L_1 towards the image field **20** and the ordinates y being measured perpendicularly to the optical axis. The right-hand side of said equation comprises a first term corresponding to a conic section with an apex C and a coefficient λ and a second term describing distortions, higher than the second order, of the dioptric surface relative to said conic section. The Tables I and II give the construction parameters of said objective. The Table I indicates the distances E between two consecutive dioptric surfaces for the focal distance F=7.95 mm, the radius of curvature R of the dioptric surfaces, the index of refraction n of the materials, and the Abbe number ν relating to their dispersion. When the dioptric surface is aspherical, the column R indicates the radius of the circle of osculation to said surface on the optical axis. The Table II specifies the values C, λ and ϵ_i of the equation (2) relating to each aspherical surface developed up to the order 2n=10. The total length of the objective is 108.25 mm, whilst its image

distance (distance available between the last dioptric surface and the image plane) is 22.14 mm.

FIGS. 3*a*, 3*b*, 3*c*, 3*d* represent a second example of said first embodiment of the invention, which satisfies the relations (1) concerning the focal length, for a value of the focal length of F=8 mm, F=15 mm, F=35 mm and F=64 mm respectively. The structure of the objective is similar to that shown in FIGS. 2*a*, 2*b*, 2*c*, 2*d*, except that in this case a colour-splitting prism, known per se, is incorporated in the objective on the image-field side in such a way that the red, blue and green spectral components of the image are obtained spaced from each other. In FIGS. 3*a*, 3*b*, 3*c*, 3*d* the dioptric surfaces of the elements are designated 1 to 20, including the image field. In these Figures the shapes of the lenses L_1 to L_9 are found to be similar, the surfaces **7**, **8**, **10** being aspherical but having different construction parameters to allow for presence of the trichromatic separating prism. In each of the FIGS. 3*a*, 3*b*, 3*c*, 3*d* the movable lenses L_4 and L_5 are represented in a different position corresponding to one of the values of the focal length of the objective indicated in the foregoing. The reference numeral **23** designates the colour-splitting prism, which is schematically represented as a segment with parallel surfaces. The Tables III and IV, which correspond to Tables I and II, indicate the construction parameters relating to said second example, the equations for the sections of the aspherical dioptric surfaces being of the same form as (2). Table III relates to the value of the focal length F=7.90 mm. The total length of the objective, including the prism, is found to be 131.66 mm, the available image distance after the prism being 4.25 mm.

It is evident that in these examples use can be made of any other combination of stationary components in accordance with the prior art which is compatible with the nature of the movable components constituted by the lenses L_4 and L_5 respectively.

In a second embodiment of the invention the objective comprises 3 movable components between two stationary components. The focal lengths of the stationary components, from the object field towards the image field, are in this order F_1 and F_5, those of the

movable components F_2, F_3, F_4. A preliminary evaluation of the powers demonstrates that in accordance with the invention the elements of the objective should be selected so that the ratios F_2/F_1, F_3/F_1, F_4/F_1 should be situated between certain limits.

In accordance with a variant of this embodiment, for which the first stationary component has a negative focal length F_1, these limits are such that:

$$-0.7 \leqq F_2/F_1 \leqq 0.3$$

$$-1 \leqq F_3/F_1 \leqq 0.4$$

$$0.12 \leqq F_4/F_1 \leqq 0.3$$

An example of an objective in accordance with this variant is that corresponding to

$$F_2/F_1 = -0.385;\ F_3/F_1 = -0.500;\ F_4/F_1 = -0.150$$

This objective is shown in FIGS. **4***a*, **4***b*, **4***c*, and **4***d*, which correspond to values of the focal length of F=7 mm, F=14 mm, F=28 mm and F=56 mm respectively.

The stationary component of a focal length F_1 is constituted by the diversing meniscus lens L_1, whilst the component with a focal length F_5 is constituted by the combined converging and diverging lenses L_5 and L_6 respectively. The 3 movable components are each constituted by a lens L_2, L_3 and L_4 respectively, L_2 being a quasi plano-convex converging lens, L_3 a biconvex converging lens and L_4 a biconcave diverging lens. The dioptric surfaces of all the elements are designated 1 to 11 from the object field to the image field. The surfaces of the elements L_1, L_2, L_3, L_4, L_5 corresponding to the respective dioptric surfaces **2, 3, 5, 8, 9** are aspherical. In FIGS. **4***a*, **4***b*, **4***c*, **4***d* the movable lenses L_2, L_3 and L_4 are represented in a position corresponding to one of the previously stated focal lengths. The construction parameters of the ovjective are given in Tables V and VI in analog to the preceding Tables III and IV. In Table V the focal length considered has the minimum value F=7 mm. The maximum value is F=56 mm. The image distance is 22.19 mm.

In order to complete the description of the construction of said example of an objective, FIG. **5** is a diagram illustrating the movements of the lenses L_2, L_3, L_4 as a function of the value of the focal lengths F. The rules governing said movements are based on variations of the axial distances between certain stationary and movable dioptric surfaces and between certain movable dioptric surfaces, namely

E_1 between the dioptric surfaces **2** and **3**
E_2 between the dioptric surfaces **4** and **5**
E_3 between the dioptric surfaces **6** and **7**
E_4 between the dioptric surfaces **8** and **9**.

In the second variant of the embodiment of the objective with three movable components between two stationary components, when proceeding from the object space to the image space, the first stationary component has a positive focal length F_1 and the second stationary component a positive focal length F_5, whilst for the movable components, each constituted by a single element, the first one has a negative focal length F_2, the second one a negative focal length F_3 and the third component a positive focal length F_4. In accordance with the invention, a preliminary evaluation of the focal lengths of the movable components relative to those of the first stationary components, results in the selection of the focal lengths in such a way that the following inequalities are satisfied.

$$-0.5 \leqq F_2/F_1 \leqq -0.2$$

$$-0.5 \leqq F_3/F_1 \leqq -0.2$$

$$0.3 \leqq F_4/F_1 \leqq 0.8$$

FIGS. **6***a*, **6***b*, **6***c*, **6***d* given an example of said variant for different focal-length values, namely corresponding to

$$F_2/F_1 = 0.301;\ F_3/F_1 = 0.326;\ F_4/F_1 = 0.455$$

In these Figures the dioptric surfaces are designated 1 to 16 from the object field towards the image field. The first stationary component with a positive focal length F_1 is constituted by two combined lenses L_1, L_2, which are divergent and convergent respectively, the lens L_3 being convergent. The second stationary component with a positive focal length F_5 comprises the conver-

gent assembly constituted by the very thick lens L_7 and the lens L_8, which are cemented to each other, and the convergent lens L_9. In each of the FIGS. *6a, 6b, 6c, 6d* the movable components L_2, L_3, L_4 are shown in a different position, corresponding to focal-length values of the objective of F=7.5 mm, F=15 mm, F=13 mm and F=60 mm respectively. The first movable component with a negative focal length F_2 is the lens L_4, which is substantially planoconcave, the second movable component with a negative focal length F_3 is constituted by th lens L_5 which is also substantially planoconcave. The biconvex lens L_6 constitutes the third movable component with a positive focal length F_4. The lens surfaces corresponding to the dioptric surfaces **4, 7, 12** and **16** are aspherical. The Tables VII and VIII, which are analogous to the preceding sets of tables, give the construction parameters for this example, Table VII relating to a focal length value of F=15.00 mm.

Said focal length varies from 7.5 mm to 60 mm when the movable lenses perform the movements represented by the curves of FIG. 7. In this Figure, which is analogous to FIG. **5**, the movement of the movable lenses is represented by variations as a function of the focal length F of the distances E_1 to E_4 on the optical axis, namely

E_1 between the dioptric surfaces **5** and **6**
E_2 between the dioptric surfaces **7** and **8**
E_3 between the dioptric surfaces **9** and **10**
E_4 between the dioptric surfaces **11** and **12**.

The image distance of the objective is of the order of 22.2 mm.

Said objectives in accordance with the invention may be used in camera equipment. A variant of this application is a colour camera comprising three camera tubes for blue, green and red respectively. An objective with a long image distance (greater than or equal to 22 mm) is selected, which enables a colour-splitting prism to be included between the objective and the camera. The objective described with reference to FIG. **3**, which is designed so that it already incorporates said trichromatic separating prism, is particularly suitable for this application. In another variant of this application the camera equipment is formed by a simple camera with photosensitive film or a colour camera which comprising only one camera tube. It is then not necessary to include a trichromatic separating prism between the objective and the camera. The objective in accordance with the invention may then have a small image distance (smaller than 22 mm).

What is claimed is:

1. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having an aperture number between 1.5 and 2 and comprising components, each having at least one lens element, arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said components having positive focal lengths; and

(b) first and second movable components each comprising a single element, arranged in order between the first and second stationary components, said first movable component having a negative focal length and said second movable component having a positive focal length, at least one of said single elements having an aspherical surface, said movable components being axially displacable relative to each other to effect a focal length variation of at least 5 to 1.

2. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having an aperture number between 1.5 and 2 and comprising components, each having at least one lens element arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said first stationary component having a focal length F_1; and

(b) first, second and third movable components, each comprising a single element, arranged in order between the first and second stationary components and having focal lengths F_2, F_3 and F_4, respectively, where F_2/F_1 and F_3/F_1 are negative and F_4/F_1 is positive, at least one of said single elements having an

aspherical surface, said movable components being axially displaceable relative to each other to effect a focal length variation of at least 5 to 1.

3. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having a free image distance greater than 22 mm and comprising components, each having at least one lens element arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said components having positive focal lengths; and

(b) first and second movable components, each comprising a single element, arranged in order between the first and second stationary components, said first movable component having a negative focal length and said second movable component having a positive focal length, at least one of said single elements having an aspherical surface, said movable components being axially displacable relative to each other to effect a focal length variation of at least 5 to 1.

4. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having a free image distance greater than 22 mm and comprising components, each having at least one lens element, arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said first stationary component having a focal length F_1; and

(b) first, second and third movable components, each comprising a single element, arranged in order between the first and second stationary components and having focal lengths F_2, F_3 and F_4, respectively, where F_2/F_1 and F_3/F_1 are negative and F_4/F_1 is positive, at least one of said single elements having an aspherical surface, said movable components being axially displaceable relative to each other to effect a focal length variation of at least 5 to 1.

5. A variable focal length objective lens as in claim 3 or 4, characterized in that the aperture is F/1.8, and having the physical characteristics specified in the following Tables I and II, where the dioptric surfaces of the objective are designated 1 to 17 from the object field to the image field, where E designates axial distances between designated surfaces for a focal length F=7.97 mm, where n designates the refractive index, where ν designates the Abbe dispersion number, and where the symbols C, λ, ϵ_i represent coefficients in the following equation describing the cross sections of the aspherical dioptric surfaces 7, 8, 10 in a plane which passes through the optical axis

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1 + \lambda)C^2 \cdot y^2}} + \sum_{i=2}^{i=n} \epsilon_i y^{2i}$$

the abscissa x being measured from the apex of the dioptric surface along the optical axis, and the ordinate perpendicularly to said axis:

8. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having a free image distance smaller than 22 mm and comprising components, each having at least one lens element, arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said components having positive focal lengths; and

(b) first and second movable components, each comprising a single element, arranged in order between the first and second stationary components, said first movable component having a negative focal length and said second movable component having a posi-

tive focal length, at least one of said single elements having an aspherical surface, said movable components being axially displaceable relative to each other to effect a focal length variation of at least 5 to 1.

9. A variable focal length objective lens for focusing an image of an object at a stationary image plane, said lens having a free image distance smaller than 22 mm and comprising components, each having at least one lens element, arranged along an optical axis, including:

(a) first and second stationary components arranged in order between an object field and the stationary image plane, said first stationary component having a focal length F_1; and

(b) first, second and third movable components, each comprising a single element, arranged in order between the first and second stationary components and having focal lengths F_2, F_3 and F_4, respectively, where $F_2/F1$ and F_3/F_1 are negative and F_4/F_1 is positive, at least one of said single elements having an aspherical surface, said movable components being axially displaceable relative to each other to effect a focal length variation of at least 5 to 1.

10. A variable focal length objective lens as in claim **8** or **9**, characterized in that the aperture is F/1.8, and having the physical characteristics specified in the following Tables III and IV, where the dioptric surfaces of the objective are designated 1 to 20 from the object field to the image field, where E designates the axial distance between designated surfaces for the focal length F=7.90 mm, where n designates the refractive index, where ν designates the Abbe dispersion number, and where the symbols C, λ, ϵ_i represent coefficients in the following equation describing the cross sections of the aspherical dioptric surfaces **7**, **8**, **10** in a plane which passes through the optical axis

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1/\lambda)C^2 \cdot y^2}} + \sum_{i=2}^{i=n} \epsilon_i y^{2i}$$

the abscissa x being measured from the apex of the dioptric surface along the optical axis and the ordinate perpendicularly to said axis:

[57] **ABSTRACT**

A lens is provided with a first and second lens groups which can focus not only with their concurrent movement along the optical axis but also with the movement of either one of the two lens groups. The first and second lens groups are respectively carried by first and second movable barrels. First means is provided for shifting both of first and second movable barrels concurrently in accordance with manual focus control. Second means is provided for shifting the second movable barrel without causing any movement of the first movable barrel. Thus, members to be moved for focusing upon automatic focus control are less in number in comparison with the members upon manual focus control.

AUTOMATIC AND MANUAL FOCUS CONTROL FOR OBJECTIVE LENS ASSEMBLY

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an objective lens barrel for use in cameras such as 35 mm single lens reflex (SLR) camera, motion picture cameras and TV cameras, and more particularly to a lens barrel capable of being automatically and manually controlled to adjust the focus of the objective lens.

2. Description of Prior Art

In prior art Japanese Patent Application laid open under No. 50-151144, an attachment for automatic focus control was proposed, which is driven by an automatic focus control device, and which may be coupled with the focus control ring of a lens barrel. In the case of automatic focus control, the attachment is coupled with the focus control ring for rotating it by the automatic focus control device. The attachment may be disengaged from the focus control ring for allowing the free rotation thereof for manual focus control. Thus, the focus control can be achieved alternatively by manual control means or automatic control means.

In the above mentioned prior art, however, the automatic focus control device is required to have considerable power in order to drive the attachment overcoming the resistance provided in the focus control ring of the lens barrel for preventing undesirable or unexpected movement thereof. Further, the use of such a prior art focus control device results in an inconvenience for manual focus control operation as well as bulkiness, and unshapeliness of the camera since the attachment is to be engaged with the lens barrel on the outside thereof at the focus control ring.

SUMMARY OF THE INVENTION

The object of the present invention is to provide a novel lens barrel capable of being controlled by both manual and automatic focus control means.

Another object of the present invention is to provide a lens barrel capable of being controlled by a focus control ring as in a conventional lens barrel, and also by an automatic focus control device having relatively small driving power.

Still another object of the present invention is to provide a lens barrel capable of being automatically controlled without interfering with manual focus control.

According to the present invention, the lens system is provided with first and second lens groups which can change focus of the lens system not only with their integral movement along the optical axis but also with the axial movement of either one of the two lens groups. The first and second lens groups are respectively carried by first and second movable barrels. First means is provided for shifting both of the first and second movable barrels concurrently in accordance with manual focus control. Second means is provided for shifting the second movable barrel without causing any movement of the first movable barrel. Thus, with the structure of the present invention, members to be moved for focusing by automatic focus control is less in number in comparison with the members upon manual focus control.

According to one feature of the present invention, the mechanisms for manual focus control and automatic focus control may be actuated independently of each other, and the automatic focus control can be carried out at any manually controlled focus condition. In other words, the operations of both mechanisms may be associated to provide a focus as a sum of the adjustments by the manual control and automatic control. With this feature, the second lens group may be moved for a small distance upon automatic focus control, which enables quick response of the automatic focus control system. In addition, due to the independence of each other, the two mechanisms can have respectively adequate operational torques for driving the lenses.

Further, selection of the manual and automatic focus control modes can be made only by decoupling and coupling the automatic focus control mechanism with the second movable barrel carrying the second lens group thereby facilitating the switching of the focus control mode. When the coupling is made, the second movable barrel is driven relative to the first movable barrel carrying the first lens group by the automatic focus control mechanism as well as with the first movable barrel by the manual focus control mechanism. In this case, if either one of the automatic and manual focus control mechanism is set to its initial position, the focusing depends on only the other.

According to an embodiment of the present invention, means are provided for returning the second movable barrel to its initial position relative to the first movable barrel when the second movable barrel is decoupled from the automatic focus control mechanism.

According to a feature of the embodiments, an indication means is provided for indicating one or more ranges of object distance for which the lens system can be focused by the automatic focus control system, thereby enabling the user to determine whether he should select the automatic or manual focus control mode. Furthermore, another indication means may be provided for warning the user when the second movable barrel is driven by the automatic focus mechanism to one extremity of the available range.

Other and further objects of this invention will become obvious upon an understanding of the illustrative embodiments about to be described or will be indicated in the appended claims, and various advantages not referred to herein will occur to one skilled in the art upon employment of the present invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a semi cross-sectional view of a first embodiment of the present invention;

FIG. **2** is a side elevational view illustrating engagement between movable barrels and the connection between the movable barrels and a driving mechanism in the first embodiment;

FIG. **3** is a schematic view of an indication scale of the first embodiment;

FIG. **4** is a fragmentary cross-sectional view of the principal part of a second embodiment;

FIG. **5** is a side elevational view illustrating the engagement between the movable barrels and the connection between the movable barrels and the driving mechanism of the second embodiment;

FIG. **6** is a schematic view of an indication scale of the second embodiment;

FIG. **7** is a schematic view of the principal part of an electric warning means; and

FIG. **8** is a semi cross-sectional view of a third embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

With reference to FIG. **1**, lenses **1** through **3** are supported by first movable barrel **9** and lenses **4** through **6** by second movable barrel **10**, respectively. Diaphragm blades **7** and diaphragm actuating plate **8** are disposed between lenses **3** and **4** and are supported by first movable barrel **9**. Diaphragm actuating plate **8** is rotatable in response to the manual operation of diaphragm setting ring **17** so as to vary the size of the diaphragm aperture formed by diaphragm blades **7**. It should be noted that lenses **1** through **6** are designed such that their image forming properties are relatively stable even when the space between lenses **3** and **4** varies slightly. Lenses **1** through **6** are so designed as to effect focusing by the movement of all of the lenses **1** through **6** along the optical axis or the movement of lenses **4** through **6** relative to the lenses **1** through **3**.

Manual focusing ring **12** is connected through a helicoid coupling to fixed barrel **15**, with diaphragm setting ring **17** for diaphragm aperture setting being rotatably supported by fixed barrel **15**. In addition, first movable barrel **9** supporting lenses **1** through **3** and the diaphragm mechanism is connected through a helicoid coupling to manual focusing ring **12**. Guide pin **19** formed integrally with fixed barrel **15** extends into guide hole **9***a* formed in first movable barrel **9** in parallel to the optical axis, whereby the rotation of first movable barrel **9** relative to fixed barrel **15** is restricted. Second movable barrel **10** supporting lenses **4** through **6** is connected through a helicoid coupling to first movable barrel **9**. Formed on the circumferential surface of barrel **10** is a guide recess **10***a* into which guide portion **26** is engageable.

With the above construction, when manual focusing ring **12** is rotated relative to fixed barrel **15**, first movable barrel **9** is moved along the optical axis without being rotated relative to fixed barrel **15** as stated above. Consequently, second movable barrel **10** is also moved along the optical axis integrally with first movable barrel **9** without being rotated relative to fixed barrel **15**.

Description will now be given of the relationship between first movable barrel **9** and second movable barrel **10**, and a drive system for second movable barrel **10** with reference to FIGS. **1** and **2**. Referring to FIG. **2**, arm member **21** is secured on second movable barrel **10**. Springs **22** and **23** are tensioned between arm member **21** and peripherally spaced fixed points on first movable barrel **10** to maintain second movable barrel **10** at a predetermined angular position relative to first movable barrel **9** when second movable barrel **10** is free from an external force. Fixed to first movable barrel **9** are stoppers **24** and **25** on which arm **21** fixed to second movable barrel **10** is abuttable when second movable barrel **10** is rotated relative to first movable barrel **9**.

With the above construction, when no external force is applied to second movable barrel **10**, the angular position of second movable barrel **10** relative to first movable barrel **9** is maintained constant by springs **22** and **23**. In addition, the rotational movement of second movable barrel **10** relative to first movable barrel **9** is blocked when arm member **21** fixed to second movable barrel **10** abuts upon stopper **24** or **25** fixed to first movable barrel **9**. Since first movable barrel **9** and second movable barrel **10** are connected each other through a helicoid coupling, the amount of angular movement of second movable barrel **10** relative to the first movable barrel **9** is limited to a predetermined angle by stoppers **24** and **25**. This means that the amount of the axial movement of second movable barrel **10** is also limited. In the present embodiment, second movable barrel **10** is constructed such that it is movable as much as ± 1 mm along the optical axis relative to first movable barrel **9**.

Actuating ring **31** is rotatably mounted to a camera body (not shown), and gear portion **31***a* is formed partially on the circumference of actuating ring **31**. Engaged with gear portion **31***a* is pinion gear **32** fixed to the drive shaft of a motor **33** that is controlled by an automatic focus control device (not shown). Also fixed to actuating ring **31** are electromagnet **28** and spring holding plate **30**. Electromagnet **28** is activated when an automatic focus operating or actuating switch (not shown) provided on the lens barrel or the camera body is closed, while it is deactivated when the automatic focus operating switch is opened. Core **27** of electromagnet **28** is movable parallel to the optical axis (i.e., in the horizontal or lateral direction in FIGS. **1** and **2**), and one end of spring **29** is fixed to the rear end of core **27**. The other end of spring **29** is fixed to spring holding plate **30**, thereby causing core **27** to be retracted (i.e., to the right in the Figures) when electromagnet **28** remains deactivated. Core **27** is moved forward (i.e., to the left in FIGS. **1** and **2**) against the action of spring **29** when electromagnet **28** is activated. Furthermore, fixed integrally to the tip of core **27** is guide portion **26** engageable into recess **10***a* formed on the circumferential portion of second movable barrel **10**.

With the above construction, when an automatic focus actuation switch (not shown) is closed, electromagnet **28** fixed to actuating ring **31** is activated to move forward guide portion **26** which is integrally formed with core **27**, whereby guide portion **26** is engaged into recess **10***a* of second movable barrel **10**, thereby coupling actuating ring **31** to second movable barrel **10**. So long as the automatic focus actuation switch is kept closed, guide portion **26** is always biased forward. Accordingly, if guide portion **26** is not at the position to align with and engage into recess **10***a* of second movable barrel **10**, actuating ring **31** is at first separately rotated by motor **33** to bring guide portion **26** into registration with recess **10***a* so that guide portion **26** engages recess **10***a* of second movable barrel **10** to couple the latter with actuating ring **31**. Second movable barrel **10** is then rotated by motor **33**, and at this moment, the amount of angular movement of second movable barrel **10** relative to first movable barrel **9**, and accordingly the amount of axial movement thereof is limited or restricted by stoppers **24** and **25**. With the present embodiment, the interval between stoppers **24** and **25** is set so that second movable barrel **10** is movable as much as ± 1 mm along the optical axis relative to first movable barrel **9** from the initial state where springs **22** and **23** are balanced in tension for arm member **21**.

When an automatic focus actuating switch (not shown) is opened, electromagnet **28** is deactivated, causing core **27** and guide portion **26** to be retracted under the action of spring **29**, whereby guide portion **26** is retracted from recess portion **10***a* of second movable barrel **10** and as a result, the rotation of actuating ring **31** is not transmitted to second movable barrel **10**. This means that external force is no longer applied to second movable barrel **10**, and arm member **21** fixed thereto is rotated by spring **22** or **23** until the tension of springs **22** and **23** for arm member **21** becomes balanced. With the

above construction, the relative position of first movable barrel **9** and second movable barrel **10** is always maintained constant when automatic focusing is not performed.

It should be understood that the lengths of guide portion **26**, core **27** and other related elements are determined such that guide portion **26** may engage recess **10***a* of second movable barrel **10** at any axial position of the latter when the automatic focus actuating switch is closed, while guide portion **26** may completely be retracted from recess portion **10***a* of second movable barrel **10** at any axial position of the latter when the automatic focus actuating switch is opened.

FIG. **3** is a schematic view of an indication scale or graduation for indicating the focusable distance of an objective with manual focus control and the focusable distance range with automatic focus control. With reference to FIG. **3**, distance scale **35** is provided on the circumferential surface of manual focusing ring **12**. Index **36** is disposed on the circumferential surface of fixed barrel **15**. In manual focus control, the number on distance scale **35** that is in registry with index **36** represents the object distance on which the objective lens is focused. Automatic focus mark **37** is provided on the circumferential surface of manual focusing ring **12**, and mark **38** indicates the focusable distance range when automatic focus mark **37** is coincident with index **36** to select automatic focus control mode. Similarly, mark **40** indicates the focusable distance range when automatic focus mark **39** is coincident with index **36** to select another automatic focus control mode. Since the amount of the axial movement of second movable barrel **10** relative to first movable barrel **9** is limited as mentioned earlier, the range indicated by the mark **38** or **40** corresponds to the amount of the movement of second movable barrel **10**. When automatic focusing is performed with automatic focus mark **37** being moved into registry with index **36**, for instance, an automatic driving or focusing mechanism automatically shifts the objective to be focussed on a predetermined object distance within the range of approximately 1.4 m to infinity (∞). It is to be noted that automatic focusing is possible even if automatic focus mark **37** or **39** is not in registration with index **36**. In this case, however, the focusable range is not the one indicated by mark **38** or **40**. When, for example, "1.5" on distance scale **35** is in registry with index **36**, the automatic focusing mechanism can adjust the focusing within the object distance of approximately 1 m to 3 m.

An explanation follows of the operation of the present embodiment with the above construction. First, for manual focus control, an automatic focus operating switch (not shown) is open to maintain electromagnet **28** deactivated. Therefore, no external driving force is applied to second movable barrel **10**, as described above, whereby the relative position between first movable barrel **9** and second movable barrel **10** is maintained constant under the action of springs **22** and **23**. Under such condition, when manual focusing ring **12** is rotated manually relative to fixed barrel **15**, focusing ring **12** is moved along the optical axis under the guidance of the helicoid thread of fixed barrel **15**. First movable barrel **9** connected to manual focusing ring **12** is also moved along the optical axis. However, since first movable barrel **9** is restrained by guide pin **19** from rotation relative to fixed barrel **15**, first movable barrel **9** is translated along the optical axis. When first movable barrel **9** is moved along the optical axis, second movable barrel **10**, whose relative position to first movable barrel **9** along the optical axis is maintained constant, is also translated integrally with first movable barrel **9**. Therefore, lenses **1** through **6** supported by first movable barrel **9** and second movable barrel **10** are integrally moved without rotation along the optical axis, whereby manual focusing is performed. The object distance focused in the manual focusing mode is indicated by the number on distance scale **35** which is confronted by index **36** on fixed barrel **15**.

For automatic focus control, the automatic focus operating switch (not shown) is closed to energize electromagnet **28**. Then, guide portion **26** rotatable integrally with actuating ring **31** engages recess **10***a* of second movable barrel **10** as described above, whereby a drive system including motor **33** is connected to second movable barrel **10**. Even if, the second movable barrel **10** is left at any position along the optical axis after the manual focusing operation, the second movable barrel **10** is, without fail, connected to the drive system when guide portion **26** is moved forward parallel to the optical axis (i.e., to the left in FIGS. **1** and **2**). This is because the recess **10***a* is always kept in alignment with guide portion **26** since the movement of the second movable barrel is restricted to a straight direction parallel to the optical axis. When motor **33** is driven under the control of an automatic focus control device (not shown), actuating ring **31** is rotated as described above, whereby second movable barrel **10** connected to actuating ring **31** is rotated. Since second movable barrel **10** is connected by helicoid coupling to first movable barrel **9** whose rotational movement relative to fixed barrel **15** is prevented, second movable barrel **10** is moved along the optical axis. At this time, the amount of axial movement of second movable barrel **10** relative to first movable barrel **9** is limited by stoppers **24** and **25**, as described earlier. Thus, lenses **4** through **6** supported by second movable barrel **10** are moved along the optical axis with rotation while lenses **1** through **3** held by first movable barrel **9** are not moved, whereby focussing is effected. At this condition, the entire lenses **1** through **6** may be moved along the optical axis by manually operating manual focussing ring **12**. In this case, the focusing of the entire lens system is a function of the combined effects of the movement of the lenses **1** through **6** relative to the fixed barrel by manual focusing ring **12** and the movement of lenses **4** through **6** relative to lenses **1** through **3** by actuating ring **31**. For automatic focus control, when automatic focus mark **37** on manual focusing ring **12** is manually brought into registry with index **36** on fixed barrel **15**, lenses **4** through **6** are moved relative to lenses **1** through **3** within the range limited by stoppers **24** and **25**, whereby automatic focusing is made in the range of approximately 1.4 m to infinity (∞) as indicated by mark **38**. As stated above, changeover from manual focusing control to automatic focus control is possible without bringing automatic focus mark **37** or **39** into registry with index **36**, and in this case, the only difference lies in that the focusable range does not correspond to the range shown by mark **38** or **40**.

A changeover from automatic focus control to manual focus control is possible at any time merely by opening an automatic focus actuating switch (not shown). When the automatic focus actuating switch (not shown) is opened, electromagnet **28** is deactivated, causing guide portion **26** to retract from recess portion **10***a* of second movable barrel **10** under the action of spring **29**.

As a result, the drive system and second movable barrel **10** are disconnected from each other, causing the external driving force to be no longer transmitted to second movable barrel **10**. This means that second movable barrel **10** is rotated by the spring **22** or **23** until it reaches a predetermined angular position where the respective tensions of spring **22** and **23** are balanced. When the second movable barrel reaches the predetermined angular position, the object distance being focused is indicated by the number on the scale **35** of manual focusing ring **12** that is confronted by index **36** on fixed barrel **15**.

FIGS. **4** through **6** show a second embodiment of the present invention, wherein the same reference numerals are used for members corresponding to those of the first embodiment in FIGS. **1** through **3**, and the description thereof is omitted. In FIG. **4**, the manual focusing mechanism is exactly the same as shown in FIG. **1** and is accordingly not shown in FIG. **4** for the simplicity of illustration.

With reference to FIGS. **4** and **5**, second movable barrel **10** is connected by a helicoid coupling to first movable barrel **9** as in the first embodiment. When rotated, second movable barrel **10** is movable along the optical axis relative to first movable barrel **9**. In addition, radially projecting guide portion **41** is fixed to the circumference at the rear end of second movable barrel **10** in place of recess **10***a* in the first embodiment. The head of guide portion **41** engages guide groove **44***b* of relay ring **44**. Relay ring **44** is rotatably supported by fixed barrel **15** with projection **44***a* being engaged by circumferential groove **15***a* formed circumferentially on the inner surface of fixed barrel **15**. Formed on the inner circumferential surface of relay ring **44** is guide groove **44***b* extending parallel to the optical axis, with which the head of guide portion **41** is slidably engaged. Also formed at the rear end of relay ring **44** is engaging claw **44***c* which is engageable with engaging claw **31***b* formed on actuating ring **31**. The length of guide groove **44***b* is set such that guide portion **41** of second movable barrel **10** remains unremoved from guide groove **44***b* of relay ring **44** even when second movable barrel **10** is translated along the optical axis. Furthermore, one end of spring **49** is fixed to the top end of arm member **21** which is fixed to second movable barrel **10**, while the other end of spring **49** is fixed to first movable barrel **9**. When second movable barrel **10** is free of external force, arm member **21** fixed to second movable barrel **10** abuts stopper **24** under the action of spring **49**.

With the present embodiment, second movable barrel **10** is maintained at a predetermined angular position relative to first movable barrel **9** by virtue of spring **49** and stopper **24**, and therefore, springs **22** and **23** in the first embodiment are not provided therein. In addition, the connection between actuating ring **31** and second movable barrel **10** is made in the present embodiment by way of engaging claw **31***b* of actuating ring **31** and engaging claw **44***c* of relay ring **44**. In the above embodiment, the amount of axial movement of second movable barrel **10** relative to first movable barrel **9** is also limited or restricted by stoppers **24** and **25**. The interval between stoppers **24** and **25** is set such that second movable barrel **10** is movable along the optical axis as much as ±2 mm for first movable barrel **9**. Furthermore, movable gear **34** is interposed between pinion gear **32** and gear portion **31***a* of actuating ring **31**, and movable gear **34** is movable in the direction of arrows A and B. When automatic focus operating switch (not shown) is opened, movable gear **34** is moved from the position shown in the Figure in the direction of arrow B to be disengaged from gear portion **31***a* of actuating ring **31**, whereby gear portion **31***a* is not driven by motor **33**.

With the above construction, manual focusing is performed in exactly the same manner as in the first embodiment. In the instant case, guide portion **41** fixed to second movable barrel **10** slides on guide groove **44***b* of relay ring **44**.

When the automatic focus operating switch (not shown) is closed, movable gear **34** is moved in the direction of arrow A to the position shown in FIG. **5** where it meshes with both pinion gear **32** and gear portion **31***a*. When motor **33** is rotated while it is controlled by an automatic focus control device (not shown), second movable barrel **10** is rotated through relay ring **44**, and thus moved along the optical axis relative to first movable barrel **9**. The amount of movement of second movable barrel **10** relative to first movable barrel **9** is restricted by stoppers **24** and **25**, as described earlier. Thus, lenses **4** through **6** held by second movable barrel **10** are moved relative to lenses **1** through **3** held by first movable barrel **9**, whereby automatic focusing is performed. In the second embodiment, automatic focus control is possible with lenses **1** through **6** being left at any position on the optical axis. Therefore, automatic focus control may be quickly performed when focusing for an object is roughly made by the manual focus control prior to changeover to automatic focus control.

When the automatic focus operating switch (not shown) is opened, motor **33** and actuating ring **31** are disconnected from each other, as described earlier, thereby causing second movable barrel **10**, relay ring **44** and actuating ring **31** to be all reset to the position as shown in FIG. **5**. With the above embodiment, motor **33** serves to rotate actuating ring **31** only in one direction. Accordingly the motor may be replaced by a spring to rotate actuating ring **31**, and the rotation of actuating ring **31** is stopped after a lapse of any desired time from the intiation of the rotation according to the output signal from an automatic focus control device.

FIG. **6** is a schematic view illustrating a distance indication scale of the second embodiment. The difference between the first and second embodiments lies only in the position of automatic focus marks **37** and **39** as seen in FIG. **3**. That is, in manual focusing mode with the second embodiment, second movable barrel **10** is spaced apart from first movable barrel **9** to the extremity of the available range along the optical axis, and second movable barrel **10** is driven from such extreme position toward first movable barrel **9** by means of an automatic focusing mechanism. Therefore, the automatic focusing mechanism can adjust the focusing of the objective for an object distance smaller than manually available. Accordingly, automatic focus marks **37** and **39** are disposed at each largest distance position of the automatically focusible range.

Shown below are the numerical examples of the relationships between the focused object distance and the amount of axial movement of second movable barrel **10** relative to first movable barrel **9** in the first and second embodiments, when the automatic focusing mechanism is actuated with automatic focus mark **37** or **39** in registry with index **36**:

In-focus distance (m)	Amount of shift (mm) First embodiment	Second embodiment
∞		
10	−1.00	AF 0.00
5	−0.73	+0.27
3	−0.47	+0.54
2	AF −0.09	+0.91
1.5	+0.40	+1.40
	+0.89	
1.2		AF +1.89
1	−0.59	+0.41
0.9	AF −0.05	+0.95
0.8	+0.32	+1.32
	+0.79	+1.79

FIG. 7 is a schematic view of an electric warning means which may be provided in the first and second embodiments. Referring to FIG. 7, switches **45** and **46** positioned on first movable barrel **9** can be closed respectively by arm member **21** fixed to second movable barrel **10** immediately before the arm member **21** abuts on stopper **24** or **25**. Warning lamps **47** and **48** provided on a camera body or inside a viewfinder light up and go out in response to the opening and closing of switches **45** and **46**, respectively. Switch **45** is closed immediately before the arm member **21** engages stopper **24**, thereby causing warning lamp **47** to light up, and conversely before the arm **21** engages stopper **25**, switch **46** is closed causing warning lamp **48** to light up.

With the above construction, it is possible to inform a photographer that second movable barrel is stopped whether in its most retracted position or most advanced position along the optical axis relative to the first movable barrel. This structure is convenient in selecting the focus adjustment range for an automatic focusing mechanism (e.g., either the range of mark **38** or that of mark **40** as shown in FIG. 3).

Furthermore, according to the first and second embodiments, even if an attachment is mounted to the front most end of first movable barrel **9**, the weight of such attachment does not affect the automatic focusing mechanism. Therefore, even in such case, the automatic focusing mechanism is capable of moving the lens group at high speed with a small power output.

FIG. **8** is a semi cross-sectional view of a third embodiment of the present invention, where the same reference numerals are used for members corresponding to those of the first and second embodiments, and the description thereof is omitted.

With reference to FIG. **8**, first movable barrel **9** supports all of lenses **1** through **6**, diaphragm blade **7** and diaphragm actuating plate **8**, and second movable barrel **10** supports no lens. Inner barrel **50** is connected by helicoid coupling to both first movable barrel **9** and second movable barrel **10**. Pin **51** carried by inner barrel **50** at the front end thereof is received by axially extending pin guide groove **12***a* formed on the inner surface of manual focusing ring **12**. Furthermore, formed at the rear end of manual focusing ring **12** is bent portion **12***b* which extends radially towards the optical axis and which is received by circumferential groove **15***b* formed circumferentially on fixed barrel **15**. With the above construction, when manual focusing ring **12** is manually rotated, the rotation thereof is transmitted to inner barrel **50**. Manual focusing ring **12** is arranged not to move along the optical axis relative to fixed barrel **15**. Further, when inner barrel **50** is otherwise translated along the optical axis, manual focusing ring **12** is not moved.

Formed on the circumference of first movable barrel **9** is projection **9***a* which is otherwise engaged by guide groove **10***c*; extending parallel to the optical axis and formed on the inner circumferential surface of second movable barrel **10**. Therefore, the rotational movement of first movable barrel **9** relative to second movable barrel **10** is restrained. In addition, second movable barrel **10** carries pin **52** which engages guide groove **15***c* extending parallel to the optical axis and formed on the inner circumferential surface of fixed barrel **15**, whereby the rotational movement of second movable barrel **10** relative to fixed **15** is restrained. Moreover, the rear of second movable barrel **10** is connected by a helicoid coupling to relay ring **44**, whose rear end is formed with recess **44***d* with which projection **31***c* of actuating ring **31** is engaged. With the third embodiment, when an automatic focus operating switch (not shown) is closed, motor **33** is driven under the control of an automatic focusing device. When the automatic focus operation switch is opened, motor **33** resets actuating ring **31** to a predetermined position and then stops its drive operation. In addition, the movement of second movable barrel **10** relative to fixed barrel **15** by the automatic focusing mechanism is restricted by stoppers **24** and **25** and arm **21** as in the first and second embodiments being provided on fixed barrel **15** and relay ring **44**, respectively.

With the above construction, motor **33** is not driven in the manual focusing mode, and second movable barrel **10** is always maintained at a predetermined position relative to fixed barrel **15**. When manual focusing ring **12** is rotated, first movable barrel **9** is translated relative to fixed barrel **15**, whereby focusing is performed.

When the automatic focus actuating switch (not shown) is closed and motor **33** is driven by the automatic focusing device (not shown), relay ring **44** is rotated through actuating ring **31**, whereby second movable barrel **10**, relay ring **44** and first movable barrel **9** are moved along the optical axis integrally with each other. In this case, it is possible to move first movable barrel **9** relative to second movable barrel **10** by manually operating manual focusing ring **12**, and consequently, the focusing effect by lenses **1** through **6** is obtained by the sum of the amount of shift of second movable barrel **10** relative to fixed barrel **15** and the amount of shift of first movable barrel **9** relative to second movable barrel **10**.

When the automatic focus actuating switch (not shown) is opened, actuating ring **31** is rotated to return to the predetermined position and remains in that position and therefore, the distance scale always indicates the distance which precisely corresponds to an object distance being manually focused.

Thus, according to the present embodiment, first movable barrel **9** supporting the lens group is moved along the optical axis both for manual focusing using a manual focusing mechanism alone, and automatic focusing using manual and automatic focusing mechanisms. This structure is advantageous when a diaphragm is provided.

With all of the above embodiments, it is possible to provide an adequate operational torque for a manual focusing mechanism, wherein grease lubrication is applied to the helicoid coupling between manual focusing ring **12**, fixed barrel **15** and first movable barrel **9**, respectively, in the first and second embodiments and the

helicoid coupling between inner barrel **50**, first and second movable barrels **9** and **10** in the third embodiment. It is also possible to move the lens group at high speed with a small output from an automatic focusing mechanism, wherein solid lubrication is applied to the helicoid coupling between relay ring **44** and second movable barrel **10** in the third embodiment.

It should be noted that the present invention is not limited to the above three embodiments, and helicoid coupling may be replaced by pin and cam-groove couplings. Also as the means for maintaining movable barrels in the predetermined positions for automatic focusing, a magnetic means may be employed which makes use of a magnet instead of springs in the preceding embodiments. Furthermore, the embodiments are shown as applied to an objective lens for a single-lens reflex camera. However, the present invention is not limited to that application but is also applicable to a lens of a coupled range finder camera.

As many apparantly widely different embodiments of this invention may be made without departing from the spirit and scope thereof, it is to be understood that the invention is not limited to the specific embodiments thereof except as defined in the appended claims.

What is claimed is:

1. An objective lens assembly for use with a camera which includes an automatic focus control device having a driving mechanism, comprising:

a manually movable focussing ring;

first and second lens groups disposed along a common optical axis, said first and second lens groups being capable of changing focus not only when said both lens groups are concurrently shifted along the optical axis but also when either one of said lens groups is shifted relative to the other along the optical axis;

a first movable barrel carrying said first lens group;

a second movable barrel carrying said second lens group, said second movable barrel being movably supported by said first movable barrel so as to be integrally moved with said first movable barrel;

first means interconnecting said manual focussing ring with said first movable barrel such that said first movable barrel is moved along the optical axis in response to the movement of said manual focussing ring, thereby moving said first and second lens groups concurrently along the optical axis; and

means for interconnecting said second movable barrel to said driving mechanism so that said second movable barrel is automatically moved, thereby said second lens group being moved relative to the first lens group along the optical axis.

2. An objective lens assembly as set forth in claim **1**, further comprising means for deenergizing said interconnecting means so that said second movable barrel is free from the control of said driving mechanism upon manual focus control and means for maintaining said second movable barrel at a predetermined position relative to said first movable barrel when said second barrel is free from the control of said driving mechanism.

3. An objective lens assembly as set forth in claim **1**, wherein said second movable barrel is rotatably engaged with said first movable barrel through a helicoid coupling, and said lens barrel further comprising means for limiting the amount of the rotational movement of said second movable barrel relative to said first movable barrel.

4. An objective lens assembly as set forth in claim **3**, further comprising electric warning means which is actuated when said second movable barrel reaches at end of rotational movement.

5. In a camera including an automatic focus electric drive motor, an objective lens comprising a pair of first and second lens groups having a common optical axis and each including at least one lens, first focusing means including a manual focusing member for manually axially shifting said first and second lens groups as an integral unit for adjusting the focus of said objective lens and second focusing means driven by said electric drive motor for axially shifting said first lens group relative to said second lens group while leaving said second lens group stationary.

6. The objective lens of claim **5** wherein said first focusing means has a greater operational resistance than said second focusing means.

7. The objective lens of claim **5** including means for alternative drive coupling and uncoupling said second focusing means with said motor.

8. The objective lens of claim **5** wherein the range of axial movement of said first lens group relative to said second lens group by said second focusing means is less than the range of axial movement of said lens groups as a unit by said first focusing means.

9. The objective lens of claim **5** further comprising a stationary member which movably supports said manual focusing member.

10. The objective lens of claim **9** further comprising an indicating means for indicating the distance of an object on which said first and second lens groups are focused by said manual focusing member.

11. The objective lens of claim **10** wherein said indicating means includes a distance scale on said manual focusing member and an index produced on said stationary member.

12. The objective lens of claim **6** wherein said first focusing means includes grease lubrication for providing a sufficient operational resistance to the operation of said manual focusing member so that a large torque is required to operate said manual focusing member.

13. The objective lens of claim **12** wherein said second focusing means includes solid lubrication for reducing the resistance of the operation of said second focusing means.

[57] **ABSTRACT**

The disclosed photographic objective includes, from front to rear, a first lens of meniscus form convex toward the front and having a positive refractive power, a second lens having a negative refractive power, a third lens having a positive refractive power, and a fourth lens of meniscus form which is concave toward the front and has a negative refractive power and whose front surface is aspheric, with the refractive power and configuration of each lens appropriately set to achieve compactness while permitting good correction of aberrations.

COMPACT PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to photographic fast wide angle objectives in which the total length of the lens system is nevertheless short and compact.

2. Description of the Prior Art

In order to minimize the bulk and size of the camera, a demand has arisen for a compact photographic objective whose length from the first lens surface to the focal plane, or the total length of the lens system, is short. Particularly desirable is an objective with a lens system whose total length is in the order of its focal length. To obtain such a lens system, it is expedient to make the front group of the lens system of a positive refractive power and the rear group of a negative refractive power, or to employ a so-called telephoto type arrangement. The telephoto type of arrangement has been used in many photographic objectives of long focal lengths with relatively narrow angular fields, but has found very little use in objectives of wider than standard angular fields. The reason is that with the power distribution of a telephoto type arrangement, as the angle of the view field increases, distortion and astigmatism increase, and they become difficult to correct.

Japanese Pat. Sho Nos. 44-10831 and 52-48011 propose photographic objectives of the telephoto type which attempt to increase the angular field. The former has a relatively narrow angular field of about 46°, and the latter, though having a relatively wide angular field at 63° is slow, with an F-number of 4.5.

On the other hand, in telephoto type wide angle objectives, the positioning error of the front lens group in a direction perpendicular to the optical axis, or so-called parallel decentering error, causes an extraordinary decrease in the imaging performance. In the paraxial region particularly, uniform coma is produced, and the intermediate zone of the field has an unsymmetrical blur, thus extraordinarily lowering the image quality over the entire area of the picture frame. In the telephoto type of lens system, therefore, it is of great importance to choose a lens configuration and a refractive power distribution which allows for the assembling error to influence the result as little as possible.

Other prior techniques of interest of the invention of the present patent application appear in Japanese Laid Open Pat. Sho Nos. 50-145226 and 50-145227 and Japanese Pat. Sho No. 56-50248.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a photographic objective with a lens system whose total length is shortened to a compactness and which is fast with a wide angular field, while still permitting the loss of the image quality due to the assembling error to be as small as possible.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a lens block diagram of Example 1 of an embodiment of the present invention.

FIGS. 2(*a*) and 2(*b*) are geometrical diagrams to explain a result from the parallel decentering error of the front group of the lens system.

FIGS. 3-*a* to *c*, to 6-*a* to *c* are graphic representations of the various aberrations of Examples 1 to 4 of specific objectives of the invention respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

One of the features of a photographic objective for accomplishing the objective of the present invention is to use, from front to rear, a first lens of meniscus form convex toward the front having a positive refractive power, a second lens having a negative refractive power, a third lens having a positive refractive power, and a fourth lens of meniscus form concave toward the front having a negative refractive power, and to satisfy the following conditions:

$$-4 < f4/f < -1.3 \quad (1)$$

$$-1.1 < \beta 4 < 1.4 \quad (2)$$

$$0.2 < D6/f < 0.3 \quad (3)$$

$$-0.5 < \frac{R6 + R5}{R6 - R5} < 0 \quad (4)$$

$$1.7 < N3 \quad (5)$$

where f is the focal length of the entire lens system;

f4 is the focal length of the fourth lens;

$\beta 4$ is the image magnification by the fourth lens;

D6 is the axial air separation between the third and fourth lenses;

R5 and R6 are the radii of curvature of the front and rear surfaces of the third lens respectively; and

N3 is the refractive index of the glass of the third lens.

Preferably, the following conditions are also satisfied: As the front surface of the fourth lens is made aspheric, an equation for that aspheric surface is defined by extending an x-axis in the optical axis, a y-axis along a direction perpendicular to the optical axis, the direction in which light advances as positive, and the vertex of the surface in the x-axis as the original point, and letting R7 denote the radius of curvature of the paraxial region of the aspheric surface, with the coefficients for the even number-order terms, bi the coefficients for the odd number-order terms and Δx the difference between the aspheric surface and a spherical surface of which the paraxial region is in common to that of the aspheric surface in a direction parallel to the x-axis, the equation being expressed in the expansion form:

$$\Delta x = \frac{(1/R7^*) \cdot y^2}{1 + \sqrt{1 - (y/R7^*)^2}} + a_1y^2 + a_2y^4 + a_3y^6 + a_4y^8 + a_5y^{10} + b_1y^3 + b_2y^5 + b_3y^7 + b_4y^9 - \frac{(1/R7)^2}{1 + \sqrt{1 - (y/R7)^2}}$$

where R7* is defined in the form of

$$R7 = \frac{1}{\frac{1}{R7^*} + 29_1}$$

Hence we have the following conditions to be satisfied:

$$-5 \times 10^{-3} < \frac{\Delta x[0.7R7]}{f} < 5 \times 10^{-3} \quad (6)$$

-continued

$$-5 \times 10^{-4} < \frac{\Delta x[0.5R5]}{f} < 5 \times 10^{-4} \quad (7)$$

where $\Delta x[0.7R7]$ and $\Delta x[0.5R5]$ are the values of Δx at the heights of $|R7| \times 0.7$ and $|R7| \times 0.5$ in the y-ordinate respectively.

Each of the above-cited conditions is explained below.

Conditions (1), (2) and (3) serve to shorten the total length of the lens system and at the same time achieve as small a loss as possible in the imaging performance due to the assembling error. In general, as the total length of the lens system is made shorter, the positive refractive power of the front lens group and the negative refractive power of the rear lens group both get stronger with an increase in the influence of the assembling error on the imaging performance. In particular the parallel decentering of the front lens group causes uniform coma in the image on the optical axis, and unsymmetric blur in the intermediate zone of the image in the picture frame area so that the resolving power and contrast are extraordinarily lowered. It is, therefore, of great importance to obtain a design of the lens system which is less sensitive to the assembling error.

Condition (1) has, because of this, to impart into the fourth lens an appropriate range of focal lengths. When a strong negative refractive power in excess of the upper limit is given, though the total length of the lens system becomes shorter, the loss in the imaging performance due to the parallel decentering of the front group is objectionably increased. Thus, such configuration is not practically acceptable from the lens manufacturing standpoint. When the lower limit is exceeded, as a weak negative refractive power results, the total length of the lens system becomes elongated, causing a lack of compactness, and further the Petzval sum is increased in a positive direction, with an increase of the field curvature in the intermediate zone of the picture area in the negative sense, causing a loss in the flatness of the image surface.

Condition (2) has, in accompaniment of condition (1), to limit the image magnification of the fourth lens so that the loss of the imaging performance due to the parallel decentering of the front group is lessened. In this connection, it should be explained by reference to FIGS. 2(*a*) and 2(*b*). FIGS. 2(*a*) and 2(*b*) illustrate an outlined configuration of the front and rear groups I and II of the invention, with FIG. 2(*a*) representing an ideal alignment of the front and rear groups I and II on a common optical axis, and FIG. 2(*b*) representing a parallel decentering of the front group I with reference to the rear group II by an erroneous difference, Δ. It is to be understood from FIG. 2(*b*) that an image formed by the front group I is made to shift perpendicularly to the optical axis by a distance equal to Δ and further that, as the image is focused by the rear group II on the film plane on an enlarged scale, the object point on the optical axis is transferred to an image point on the film plane as shifted by an amount, Δ',

$$\Delta' = \beta 4 \cdot \Delta$$

Therefore, when the front group I is parallel-decentered by the distance, Δ, the image shifts by the above-defined Δ'. This leads to a lower image quality. In other words, the parallel decentering of the front group gives rise to uniform coma in the central region of the area an the picture frame, and of unsymmetrical blurred image in the intermediate by the inclination of the image surface. In particular, the field curvature and others which are so-called longitudinal aberrations are proportional to the square of the image magnifications $\beta 4$. Accordingly, the image magnification $\beta 4$ is preferably taken at as small a value as possible. However, when the image magnification exceeds the lower limit of condition (2), the total length of the lens system is increased with consequent lack of compactness, and the Petzval sum is increased toward the positive direction so that a loss in the flatness of the image surface results. When the upper limit is exceeded, a slight parallel-decentering of the front group is occasion for a remarkable loss in the imaging performance.

Condition (3) represents a factor defining the air separation between the front and rear groups of the lens system. It is of importance to satisfy condition (3) in combination with conditions (1) and (2). When the upper limit is exceeded, the total length of the lens system is elongated with consequent lack of compactness, and the Petzval sum is increased with the loss of flatness of the image surface. When the lower limit is exceeded, while the total length of the lens system is shortened, the loss in imaging performance due to the parallel decentering of the front group becomes prominent.

Conditions (4) and (5) concern primary aberrations of the lens system.

Condition (4) represents a factor for configuration of the third lens and serves to achieve good correction of spherical aberration and coma. When the upper limit is exceeded, the spherical aberration is over-corrected, and inward coma is produced. When the lower limit is exceeded, the spherical aberration is under-corrected, and outward coma is produced.

Condition (5) involves restricting the refractive index of the glass from which the third lens is made, and serves to achieve a good correction of field curvature and astigmatism. When the refractive index N3 is not more than 1.7, the Petzval sum is increased with accompanying deterioration in the flatness of the image surface in the intermediate region of the area of the picture frame, and astigmatism is also increased.

The present invention serves, in addition to satisfying the above-described various conditions, to further make the first surface of the fourth lens aspheric with the advantage that the off-axis aberrations which would otherwise, with only a spherical system, be difficult to correct are well corrected.

Conditions (6) and (7) operate to restrict the aspheric quantity of the first surface of the fourth lens. When the upper limit of condition (6) is exceeded, it is impossible to correct positive distortion. When the lower limit is exceeded, while distortion can be corrected, over-correction of sagittal image surface results, and further inward coma is objectionably produced. Condition (7) serves to well correct aberrations in the intermediate zone of the area of the picture frame. When the upper limit is exceeded, halo is produced in the intermediate zone and under-correction of spherical aberration results. When the lower limit is exceeded, under-correction of meridional image surface results, and the astigmatic difference is increased, and inward coma is also produced.

It should be pointed out that, since, in the present invention, the first surface of the fourth lens using the aspheric surface is positioned relatively near to the

image plane, the area of the surface of the fourth lens through which the rays of light corresponding to all the image points pass is relatively small. As the surface accuracy of the fourth lens considerably is moderated, it becomes possible, instead of the glass material, to use a plastic molding and make the fourth lens inexpensively.

Also, focusing of the objective of the invention may be carried out either by manually moving the entire lens system which is the common practice in the art, or by imparting independent movement to the first to third lenses while the fourth lens remains stationary.

Four examples of specific objectives of the invention can be constructed in accordance with the numerical data given in the following tables for the radius of curvature of the i-th surface Ri counting from the front, the axial thickness or air separation Di between the i-th and (i+1)th lens surfaces, and the refractive index Ni and Abbe number Vi of the glass from which the i-th lens element counting from the front is made respectively.

What is claimed is:

1. A compact photographic objective comprising:

four lenses, from front to rear,

the first lens being a positive meniscus lens convex toward the front;

the second lens being a negative lens;

the third lens being a positive lens;

the fourth lens being a negative meniscus lens concave toward the front; and

said lenses satisfying the following conditions:

$$-4 < f4/f < -1.3$$

$$1.1 < \beta 4 < 1.4$$

$$0.2 < D6/f < 0.3$$

$$-0.5 < \frac{R6 + R5}{R6 - R5} < 0$$

$$1.7 < N3$$

wherein f is the focal length of the entire lens system;

R5 and R6 are the radii of curvature of the first and second surfaces of the aforesaid third lens;

N3 is the refractive index of the glass from which the same lens is made up;

D6 is the air separation between the aforesaid third lens and the aforesaid fourth lens;

f4 is the focal length of the aforesaid fourth lens; and

$\beta 4$ is the image magnification of the fourth lens.

2. A compact photographic objective according to claim 1, wherein said fourth lens has a first surface which is aspheric, and wherein an equation for said aspheric surface is expressed by taking an x-axis along the optical axis, a y-axis along a direction perpendicular to the optical axis, the direction in which light advances are positive, and the vertex of the surface on the x-axis as the original point, and letting R7 denote the radius of curvature of the first surface of the aforesaid fourth lens, ai the coefficients of the even number-order terms, bi the coefficients of the odd number-order terms, and Δx the difference between the aspheric surface of said fourth lens and the aspheric surface which contributes to the determination of the focal length, with the equation having the form:

$$\Delta x = \frac{(1/R7^*)\cdot y^2}{1+\sqrt{1-(y/R7^*)^2}} + a_1y^2 + a_2y^4 + a_3y^6 + a_4y^8 + a_5y^{10} + b_1y^3 + b_2y^5 + b_3y^7 + b_4y^9 - \frac{(1/R7)y^2}{1+\sqrt{1-(y/R7)^2}}$$

where R7* is defined by

$$R7 = \frac{1}{\frac{1}{R7^*} + 29_1},$$

the following conditions are satisfied:

$$-5\times10^{-3} < \frac{\Delta x[0.7R7]}{f} < 5\times10^{-3}$$

$$-5\times10^{-4} < \frac{\Delta x[0.5R5]}{f} < 5\times10^{-4},$$

and

where Δx[0.7R7] and Δx[0.5R5] are the values of the Δx at the heights of |R7|$\times$0.7 and |R7|$\times$0.5 in the y-ordinate respectively.

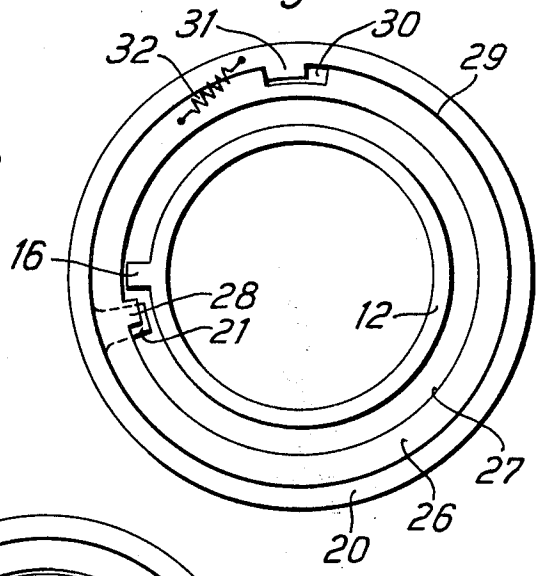

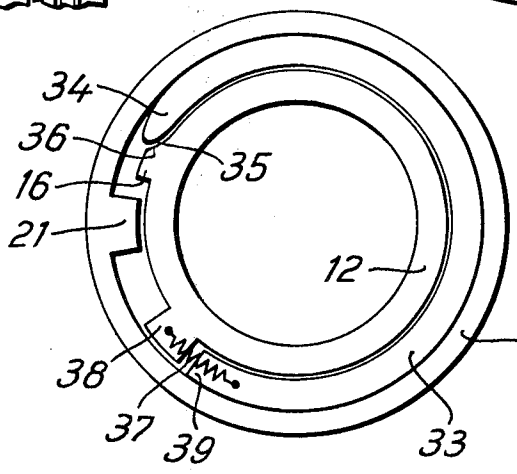

Fig. 4

APPARATUS FOR COMPENSATING FOR THE REBOUNDING OF AN AUTOMATIC DIAPHRAGM IN A PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

The present invention relates to a device for at least partially compensating for the rebound impact of an automatic diaphragm in a photographic objective having a diaphragm preselector ring with a stop for preselecting the diaphragm aperture and a diaphragm control ring for actuating or driving the leaves of the automatic diaphragm.

It is known to at least partially compensate for the rebound impact, which is defined as the recoil generated by the impact of the diaphragm control ring closing the iris diaphragm of a photographic objective upon the stop of the diaphragm preselector ring, in accordance with the laws of elastic collisions, by providing a predetermined friction in the pivot bearing of the diaphragm control ring or by transmitting the kinetic energy to the diaphragm preselector ring. It is also known to eliminate the rebound impact by using so-called catch springs or straps which act directly or indirectly on the diaphragm preselector ring.

Another known approach is to attenuate the rebound of the diaphragm control ring with the "bumper block" effect, so that the effect of the rebound impact on the diaphragm aperture remains negligibly small. All of the known devices are subject to the disadvantages that no controlled damping of the rebound impact is possible and that the manufacture of the rebound damping means is difficult.

SUMMARY OF THE INVENTION

Accordingly, it is the object of the present invention to provide an improved device for compensating for the rebound impact of an automatic diaphragm in a photographic objective.

A further object of the present invention is to provide apparatus for compensating for the rebound impact which is capable of achieving a desired or controlled compensation of the rebounding effect.

Another object of the present invention is to provide apparatus for compensating for the rebound impact which substantially avoids the manufacturing and assembly difficulties attendant to known devices.

These and other objects of the invention are achieved by providing apparatus for at least partially compensating for the rebound impact of the automatic diaphragm in a photographic objective having a diaphragm preselector ring with a stop for preselecting the diaphragm opening and a diaphragm control ring for driving the leaves of the automatic diaphragm, said compensating apparatus comprising at least one movable auxiliary mass which frictionally opposes the rebound impact.

In one preferred aspect of the invention, the auxiliary mass has the form of a cylinder, and its dimensions are selected so that the frictional forces opposing the rebounding are produced between the auxiliary mass and the diaphragm control ring.

In another preferred aspect of the invention, the auxiliary mass is a rider on the diaphragm control ring, and its dimensions are selected such that a defined frictional force is produced between the rider and the diaphragm control ring.

In yet another preferred aspect of the invention, the auxiliary mass comprises a friction riing provided with an anvil, and its dimensions are chosen such that a defined frictional force is produced between the friction ring and the diaphragm preselector ring.

In a still further preferred aspect of the invention, the auxiliary mass is movably mounted on the diaphragm with a spring for controlling its movement and produces a defined frictional clamping force in conjunction with the diaphragm control ring and the diaphragm preselector ring.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will be described in further detail with reference to the accompanying drawings, wherein:

FIG. 1 is a sectional side elevation of a photographic objective with an automatic diaphragm and a rebound impact compensating device according to the invention.

FIG. 2 is a sectional partial side elevational view of the details of an alternate embodiment of the invention.

FIG. 3 is a sectional rear detail view of a further embodiment of the invention in which the auxiliary mass is provided with an anvil.

FIG. 4 is a cross sectional rear detail view of a stll further embodiment of the invention in which the auxiliary mass produces a frictional clamping force.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

FIG. 1 schematically illustrates a photographic objective with an automatic diaphragm. For reasons of clarity, structural parts required for focusing of the objective have been omitted from the drawing.

The photographic objective comprises an objective tube **1** having an imaging system **2** mounted therein. An automatic diaphragm **3**, which closes under the force of a spring (not shown) is located behind the imaging system **2**. Automatic diaphragm **3** comprises a leaf mount **4**, diaphragm leaves **5** and a leaf guide ring **7** which moves on ball bearings **6**. The leaf guide ring **7** is provided on its surface **8** remote from the diaphragm leaves **5**, with a projection **9** having a U-shaped slot or recess **10** therein. A slide **11** of a driver **13**, which forms a unitary body with the diaphragm control ring **12**, is engaged in the U-shaped recess **10**. Slide **11** is adapted to move back and forth in slot **10** during focusing of the objective. The diaphragm control ring **12** is mounted on ball bearings **14** for easy rotation in the objective tube **1**. The diaphragm control ring **12** carries, on its side **15** opposite the driver **13**, a drive piece **16**, which drivably engages the camera (not shown) in a conventional manner.

The inner surface of the diaphragm control ring **12** is provided with a U-shaped annular groove **17**, and a suitably shaped friction ring **18** is inserted therein. The rear end **19** of the objective tube **1** carries a diaphragm preselector ring **20** with a diaphragm stop **21**, extending through a slit **20a** into the objective tube **1**. To secure the photographic objective to the camera, objective tube **1** is provided with a bayonet fitting **22**.

The operation of the above-described device is as follows:

Upon insertion of the photographic objective in a camera, the automatic diaphragm **3** is opened by the diaphragm control ring **12** which enters into driving engagement with the camera by means of drive piece **16**, and the spring (not shown) which closes the automatic diaphragm is stressed. By actuating the diaphragm preselection ring **20**, the diaphragm stop **21** is

brought into a position corresponding to a desired aperture size of the automatic diaphragm 3. When the camera is triggered, the automatic diaphragm 3 closes. The closing motion is stopped by the diaphragm stop 21, which is struck by drive piece 16. According to the laws of elastic collisions, a rebound of the diaphragm control ring 12 would now take place, whereby the diaphragm would open to an undesirable extent resulting in an erroneous exposure and in deviations in the depth of focus.

However, in the described apparatus, the rebound momentum is compensated for by friction ring 18, which works as an auxiliary mass within the diaphragm control ring 12. While the diaphragm control ring, which was accelerated by the force of the spring when the camera was triggered, is being suddenly braked, the friction ring 18, whose rotational movement is unrestricted, continues to rotate because of its inertia until it is gradually braked by the friction between it and the diaphragm control ring 12.

Turning now to FIG. 2, there is illustrated an alternate embodiment of the invention in which the diaphragm control ring 12, which moves on ball bearings 14 in the objective tube 1, is provided with a shoulder 23 and an annular groove 24 formed on its outer circumference. A friction ring 25, having a T-shaped cross section, "rides" on the diaphragm control ring 12 with the stem of the "T" received in annular groove 24. As in the case of the friction ring 18 described in connection with FIG. 1, the rotational range of friction ring 25 is unrestricted, and it functions in an analagous manner to attenuate or compensate for the rebound impact of the automatic diaphragm.

In contrast to the embodiments illustrated in FIGS. 1 and 2 in which the additional mass which compensates for the energy of the rebound impact cooperates with the diaphragm control ring 12, FIG. 3 schematically illustrates an embodiment in which the auxiliary mass cooperates with the diaphragm preselector ring 20.

For this purpose, a stop ring 26 is mounted for easy rotation within the diaphragm preselection ring 20. Stop ring 26 is provided on its inner circumference 27 with a stop nose or anvil 28. The outer circumference 29 of stop ring 26 is provided with a recess 30, which is engaged by a movement limiting cam 31 on the diaphragm control ring 20. Diaphragm preselection ring 20 and stop ring 26 are non-positively connected with each other by means of a spring 32 in such a way that the edge of the stop nose 28 adjacent to the drive piece 16 is located in front of the edge of the diaphragm stop 21.

During the closing of the automatic diaphragm 3, the drive piece 16 of diaphragm control ring 12 initially strikes the stop nose 28 of stop ring 26. Stop ring 26 is designed to have the same moment of inertia as diaphragm control ring 12. Consequently, stop ring 26 accepts all of the energy of diaphragm ring 12 and causes drive piece 16, driven by the force of the actuating spring closing the automatic diaphragm 3, to gently contact the diaphragm stop 21 of the diaphragm preselection ring 20. When automatic diaphragm 3 is returned to the "open" position, the spring 32 returns stop ring 26 to its initial position.

FIG. 4 illustrates a further embodiment of the invention in which diaphragm control ring 12 carries a spring supported auxiliary mass in the form of a cylindrical clamping piece 33. When drive piece 16 strikes the diaphragm stop 21 on diaphragm preselector ring 20, clamping piece 33 effects a clamping action. For this purpose, the end 34 of clamping piece 33 is provided with a bevel 35, while a similar bevel 36 is provided on drive piece 16. As drive piece 16 impacts against diaphragm stop 21, clamping piece 33 initially remains in motion because of its inertia and runs up with its bevel 35 on the bevel 36 on drive segment 16. In the process, it produces a clamping action between the diaphragm preselector ring 20 and the diaphragm control ring 12. The clamping action works against the recoil energy or rebound impact of the diaphgram control ring 12. The clamping action is then released by a spring 37, which extends between a nose 38 on diaphragm control ring 12 and the other end 39 of clamping piece 33.

The foregoing description of preferred embodiments has been set forth merely to illustrate the invention and is not intended to be limiting. Since modifications of the disclosed embodiments incorporating the spirit and substance of the invention may occur to persons skilled in the art, the scope of the invention is to be limited solely with respect to the appended claims and equivalents.

We claim:

1. Apparatus for at least partially compensating for the rebound impact of an automatic diaphragm in a photographic objective having a diaphragm preselector ring with a stop for preselecting the diaphragm opening and a diaphragm control ring for driving the leaves of the automatic diaphragm, said compensating apparatus comprising at least one movable auxiliary means frictionally engaging an element of said objective and set in motion in response to movement of said diaphragm control ring for counteracting said rebound impact by friction, whereby the energy of movement of said diaphragm control ring is at least partially dissipated by friction.

2. Apparatus according to claim 1, wherein the auxiliary mass has the form of a cylinder, and the dimensions of the auxiliary mass are selected so that the frictional forces which counteract the rebound impact are produced between the auxiliary mass and the diaphragm control ring.

3. Apparatus according to claim 2, wherein said auxiliary mass comprises an annular friction ring mounted for unrestricted rotation inside said diaphragm control ring.

4. Apparatus according to claim 2, wherein the auxiliary mass is disposed as a rider on the diaphragm control ring, and the dimensions of the auxiliary mass are selected such that a defined frictional force is produced between the rider and the diaphragm control ring.

5. Apparatus according to claim 4, wherein said auxiliary mass comprises an annular friction ring mounted for unrestricted rotation on a shoulder formed on the outer circumference of said diaphragm control ring.

6. Apparatus according to claim 1, wherein the auxiliary mass comprises a friction ring provided with an anvil, and the dimensions of the ring are chosen such that a defined frictional force is produced between the friction ring and the diaphgram preselector ring.

7. Apparatus according to claim 1, wherein said auxiliary mass comprises a stop ring frictionally engaging said diaphragm preselector ring, said stop ring being designed to have the same moment of inertia as said diaphragm control ring and bearing an anvil which is struck by a drive piece on the diaphragm control ring, whereby the momentum of the diaphragm control ring is transferred to the stop ring as the diaphragm control

ring contacts the stop of the diaphragm preselector ring.

8. Apparatus according to claim 1, wherein the auxiliary mass is movably mounted on the diaphragm control ring; spring means are provided to control the movement of the auxiliary mass, and the auxiliary mass produces a defined frictional clamping force in conjunction with the diaphragm control ring and the diaphragm preselector ring.

9. Apparatus according to claim 8, wherein said auxiliary mass comprises a clamping piece disposed around said diaphragm control ring, one end of said clamping piece being provided with a bevel; said clamping piece initially remaining in motion when a drive piece on the diaphragm control ring engages the stop on said diaphragm preselector ring and said bevel on said clamping piece engaging an opposing bevelled surface on said diaphragm control ring, whereby a clamping action is produced.

[57] **ABSTRACT**

A large aperture objective having a shorter physical length than 1.2 times the focal length thereof with an angular field of at least 54° and a diaphragm positioned on the image side of the rearmost lens surface. The objective comprises five elements constituting five components of which the first and second counting from the front are positive meniscus lenses of forward convexity, the third is a negative meniscus lens of rearward concavity, the fourth is a negative meniscus lens of forward concavity, and the fifth is a bi-convex lens with its rear surface of strong curvature. The objective is characterized by fulfilling the following conditions:

(1) $0.18\ f<D_1<0.28\ f$, where $D_1=d_1+d_2+d_3+d_4+d_5$

(2) $0.08\ f<D_2<0.13\ f$, where $D_2=d_7+d_8+d_9$

(3) $0.12\ f<d_6<0.15\ f$

(4) $0.35<(R_1/R_2)<0.5$

(5) $0.6<(R_7/R_8)<0.8$

(6) $|R_{10}/R_9|<0.3$

where f is the focal length of the overall lens system; R_i is the radius of curvature of the i-th surface; and d_i is the axial thickness or air separation between the i-th and (i+1)th surfaces.

LARGE APERTURE OBJECTIVE WITH BEHIND THE LENS DIAPHRAGM

BACKGROUND OF THE INVENTION

This invention relates to photographic objectives of the standard or quasi-standard angular field, and more particularly to objectives of a large aperture ratio with a diaphragm in the image space.

Lens shutter type cameras require standard objectives to be of small bulk and size with an angle of view exceeding 54°. A type of lens which has gained general acceptance for an objective having a relative aperture as large as F/2, is the diaphragm interspaced Gauss type. An example of a modified Gauss type objective is disclosed in British Pat. No. 865,530.

These diaphragm-interspaced Gauss type objectives through producing more or less flare in the intermediate to the marginal region of the image field have been proven to give good correction of field curvature for high grade imaging performance throughout the entire area of the image field.

At the present time, on the other hand, photo-electric sensing of an object distance for automatic adjustment of the objective, or so-called auto-focus mechanisms has become practical, thereby freeing many photographers from troublesome focusing operation.

Since this mechanism is powered by a tensioned spring or an electric motor as the drive source to effect focusing, the employment of the diaphragm interspaced Gauss type in the lens design leads to the necessity of moving along with the lens system, the large mass of the diaphragm device associated with a shutter and other mechanical parts. This gives rise to disadvantages, the first of which is that a strong torque is required to assure the satisfactory operation, and second is that the diaphragm, shutter and auto-focus mechanism are also made complicated. These problems have contributed to the difficulty of minimizing the bulk and size of the camera.

Arrangement of the shutter diaphragm behind the objective lens system is an effective way to solve these problems. But, as the objective becomes faster with the F-number down to as low as 2, use of the rear diaphragm arrangement creates various aberrational problems. To avoid the reduction of the image quality, therefore, a sacrifice must be made, for example, by narrowing the angular field and elongating the physical length. Even in the improved conventional objectives such as that shown in Japanese Patent Sho 41-15463 (1966), the total length from the front vertex to the image plane is limited to 1.23 times the focal length or longer, and the angle of view to 52° or less.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a photographic objective having a standard or quasi-standard angular field with the total length from the front vertex to the image plane being shortened while increasing the relative aperture.

Another object is to improve the imaging performance and to assure a high contrast over the entire area of an image field and particularly in the intermediate to the marginal region thereof for which the production of flare is prevented.

An objective of the present invention has five elements constituting five components. A diaphragm space is provided on the image side of the rear vertex of the objective. The first and second elements counting from the front are positive meniscus lenses of convex surface toward the front. The third element is a negative meniscus lens of concave surface toward the rear. The fourth element is a negative meniscus lens of concave surface toward the front. The fifth element is a bi-convex lens with the rear surface being stronger in curvatuve. Letting Ri denote the radius of curvature of the i-th lens surface counting from the front, and di the lens thickness or air spacing between the i-th and (i+1)th surfaces, the objective fulfils the following specific requirements:

(1) $0.18\ f < D_1 < 0.28\ f$, where $D_1 = d_1 + d_2 + d_3 + d_4 + d_5$

(2) $0.08\ f < D_2 < 0.13\ f$, where $D_2 = d_7 + d_8 + d_9$

(3) $0.12\ f < d_6 < 0.15\ f$

(4) $0.35 < (R_1/R_2) < 0.5$

(5) $0.6 < (R_7/R_8) < 0.8$

(6) $|R_{10}/R_9| < 0.3$

where f is the compound focal length of the entire lens system.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an optical diagram of an Example 1 of a Gauss type objective according to the present invention.

FIG. **2** is a similar diagram showing an Example 2 of the present invention.

FIG. **3** is a similar diagram showing an Example 3 of the invention.

FIG. **4** is a similar diagram showing an Example 4 of the invention.

FIGS. **5**A to **5**F are graphic representations of the various aberrations of Example 1.

FIGS. **6**A to **6**F are similar graphs of those of Example 2.

FIGS. **7**A to **7**F are similar graphs of those of Example 3.

FIGS. **8**A to **8**F are similar graphs of those of Example 4.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In order to shorten the total length of the objective to 1.2 times the focal length or thereabout within the framework of the behind-diaphragm Gauss type configuration, the first and second lenses necessarily have to be strengthened in refractive power, and the divergent lenses that follow are required to have a strengthened effect on correction of the spherical aberration. It has been, therefore, found that the sagittal image surface which is curved in a negative sense at the intermediate region of the image field is turnel rapidly to a positive curvatuve when the half-angle of view of $\omega = 25°$ is exceeded, and that the flare is objectionably increased in a region from the intermediate to the margin. Considering the fact that for the improvement of the field curvature, a great effect can be expected from the use of lens thicknesses and spacings as thin as possible, according to the present invention, the fourth lens which usually takes the form of a cemented lens of positive and negative elements is constructed in the form of a negative meniscus singlet resulting in the advantage that the lens thickness is minimized. And, as for the improvement of the flare, an air lens is provided between the second and third lenses to facilitate the improvement.

In such an arrangement, fulfilment of the specific conditions described results in an excellent objective. This is explained below. First, improvement of the image quality is made very effective by the thinning of the sum of the axial separations defined by D_i. On the other hand, such thinning makes it more difficult to impart to the first and second lenses the refractive powers necessary to shorten the total length of the objective. Accordingly, the necessity of condition (1) arises. When the upper limit of inequality (1) is exceeded, the sagittal image surface will be strongly curved in a positive sense. When the lower limit is exceeded, the lens diameter cannot be sufficiently large, so that one cannot help but to increase the F-number with a loss in lens speed, or elongate the back focal length with an increase in the total length of the objective above 1.2 times the focal length.

Thinning another sum of axial separations defined by D_2 is also effective to improve the image quality as has been mentioned above. This, on the other hand, causes increasing outward coma. Therefore, condition (2) is necessary. When the upper limit of inequality (2) is exceeded, the sagittal image surface is strongly curved at the margin. When the lower limit is exceeded, the outward coma is objectionably increased in the intermediate region of the image field to the margin.

The total length is shortened by shortening the spacing d_6. This is also advantageous for correction of inward coma of a circular zone in the intermediate region of the image field. However, when the spacing is shortened too much, the diameter of an air lens defined by r_6, r_7 and d_6 will become so small that all the axial rays at an aperture of 2 in F-number cannot pass therethrough. On this account, condition (3) is necessary. When the upper limit of inequality (3) is exceeded, inward coma of a circular zone in the intermediate region of the image field is objectionably increased, and it is difficult to shorten the total length below 1.2 times the focal length. When the lower limit is exceeded, it is difficult to achieve an increase of the lens speed to as fast as 2 in F-number.

Consideration is next given to the significances of the radii of curvature of the various lens surfaces. Bending the first lens affects the spherical aberration and distortion. In the objective aimed at by the present invention with the first lens of strong power, it is from the first lens that a strong positive distortion is produced. To suppress the increase of such distortion it is advantageous to select a large value of R_1/R_2, but this is unfavorable to suppress spherical aberration. Therefore, condition (4) is necessary. When the upper limit of inequality (4) is exceeded, good correction of spherical aberration will be difficult. When the lower limit is exceeded, positive distortion is objectionably increased.

The axial rays after their angles of inclination have been moderated by the third lens, enter the fourth lens. Therefore, the fourth lens may take the form of a negative meniscus lens of forward concavity. This offers the advantage that even when the power is relatively weak it produces, a strong effect on correction of spherical aberration. However, inward coma is also objectionably increased. Therefore, condition (5) is necessary. When the upper limit of inequality (5) is exceeded, correction of inward coma will become difficult. When the lower limit is exceeded, correction of spherical aberration will become difficult.

Bending the fifth lens has a large effect on correction of spherical aberration and astigmatism. In correction of spherical aberration, it is advantageous to select a large value for R_{10}/R_9, but astigmatism is, on the other hand, caused to increase in the marginal region of the image field. Therefore, condition (6) is important. When the upper limit is exceeded, good correction of negative astigmatism in the marginal region will be difficult to perform.

It should be noted that the front surface r_5 of the third lens also seriously affects the various aberrations, and therefore great care must be taken in configuring it. The selection of a smaller value for the radius of curvature of the lens surface r_5 can suppress the increase of the flare of the meridional circular zone and the sagittal flare of the image field to the margin, but on the other hand allows for the spherical aberration of the sagittal rays to be objectionably increased in the intermediate region of the image field so that the foci of the intermediate rays incline in a negative sense beyond the foci of the sagittal principal rays. This leads to a tendency of deteriorating the resolution of the sagittal field at or near the angle of view of $\omega = 16°$. Therefore, it is desirable that the radius of curvature of the surface r_5 lies between 0.8 and 2.2 times the focal length of the entire lens system.

The following are four examples of specific objective lens systems with the numerical data for the radii of curvature, r, the lens thicknesses or air spacings, d, the refractive indices, Nd, for the various lens elements along with the corresponding Abbe numbers, νd. The various image aberrations of the lens systems when focused at infinity are shown in FIGS. **5A–5F**, FIGS. **6A–6F**, FIGS. **7A–7F** and FIGS. **8A–8F** where S.C.: since condition; d(S): the sagittal surface of d-line; d(M): the meridional surface of d-line; g(S): the sagittal surface of g-line; and g(M): the meridional surface of g-line. As is understandable from the lists of values of the aberrational coefficients and the aberration curves, each of the examples of the lens systems is well corrected for high grade imaging performance. This reveals that the conditions set forth in the present invention are adequate for the accomplishment of the objects thereof.

(6)	0.1446	0.2255	0.20995	0.2328

What is claimed is:

1. A large aperture objective with a behind the lens diaphragm comprising five components of which the first and the second counting from the front are positive meniscus lenses of convex surface toward the front, the third is a negative meniscus lens of concave surface toward the rear, the fourth is a negative meniscus lens of concave surface toward the front, and the fifth is a bi-convex lens with its rear surface of strong curvature toward the rear, said diaphragm being positioned on the image side of said fifth lens and said objective satisfying the following conditions:

(1) $0.18\ f<D_1<0.28\ f$, where $D_1=d_1+d_2+d_3+d_4+d_5$

(2) $0.08\ f<D_2<0.18\ f$, where $D_2=d_7+d_8+d_9$

(3) $0.12\ f<d_6<0.15\ f$

(4) $0.35<(R_1/R_2)<0.5$

(5) $0.6<(R_7/R_8)<0.8$

(6) $|R_{10}/R_9|<0.3$

wherein R_i is the radius of curvature of the i-th lens surface counting from the front; di is the axial thickness or air spacing between the i-th and (i+1)th lens surfaces; and f is the focal length of the entire lens system.

2. A large aperture objective as described in claim **1**, and where said objective has, with respect to a normalized focal length of f=1, the following numerical data:

	F-number 1:1.92	Image Angle 2ω = 54.9°		
No.	r	d	Nd	νd
1	0.6358	0.083	1.77250	49.6
2	1.3917	0.002		
3	0.3486	0.109	1.77250	49.6
4	0.7814	0.016		
5	1.3183	0.024	1.75520	27.5
6	0.2607	0.136		
7	−0.4056	0.024	1.72342	38.0
8	−0.6088	0.082		
9	4.1728	0.038	1.78590	44.2
10	−0.6035			

(r=the radii of curvature; d=the lens thicknesses or air spacings; Nd=the refractive indices; and νd=the Abbe numbers).

3. A large aperture objective as described in claim **1**, and wherein said objective has, with respect to a normalized focal length of f=1, the following numerical data:

	F-number 1:2.0	Image Angle 2ω = 56.7°		
No.	r	d	Nd	νd
1	0.6676	0.080	1.77250	49.6
2	1.3831	0.003		
3	0.3610	0.114	1.77250	49.6
4	0.8351	0.022		
5	1.8175	0.025	1.74077	27.8
6	0.2741	0.133		
7	−0.3959	0.024	1.80518	25.4
8	−0.5236	0.066		
9	2.6985	0.025	1.72342	38.0
10	−0.6085			

(r=the radii of curvature; d=the lens thicknesses or air spacings; Nd=the refractive indices; and νd=the Abbe numbers).

4. A large aperture objective as described in claim **1**, and wherein said objective has, with respect to a normalized focal length of f=1, the following numerical data:

	F-number 1:2.0	Image Angle 2ω = 56.7°		
No.	r	d	Nd	νd
1	0.6775	0.084	1.77250	49.6
2	1.6702	0.003		
3	0.3248	0.099	1.77250	47.7
4	0.6876	0.014

[57] **ABSTRACT**

A wide angle objective of the retrofocus type, with an increased aperture, is disclosed. This objective comprises three lens groups of which the first counting from the front has a negative power and includes, from front to rear, a positive lens in the meniscus form convex toward the front, a negative lens in the meniscus form convex toward the front, a negative lens likewise in the meniscus form convex toward the front, a positive lens, and a negative lens in the meniscus form convex toward the front. The second lens group includes a cemented bi-convex lens, and the third lens group includes a cemented lens of positive and negative lens elements, a positive lens in the meniscus form convex toward the rear, a cemented lens of negative and positive lens elements, and a positive lens. A diaphragm is positioned in the space between the second and third lens groups. Various conditions are prescribed for every lens group, and for every lens in each group.

RETROFOCUS TYPE LARGE APERTURE WIDE ANGLE OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to retrofocus type large aperture wide angle objectives, and more particularly to a compact retrofocus type wide angle objective having a field angle of 52° or thereabout with an F-number on the order of 2.8, and which is well corrected for aberrations.

2. Description of the Prior Art

In designing wide angle objectives for single lens relfex cameras, an increase in employment of compactness and large aperture ratio is occurring. Most of these wide angle objectives have been constructed in the form of an inverted telephoto type with the advantage that the back focal distance can be generally elongated. Since, on the other hand, the lens arrangement lacks symmetry, good correction of aberrations becomes difficult to perform. This difficulty tends to be intensified more and more as the field angle and the relative aperture are increased along with a further advance in the compactness of the entire system. It is known to provide a retrofocus type wide angle objective having an increased range with an increased relative aperture as, for example, in U.S. Pat. Nos. 3,748,021, 3,976,366, 3,981,563, 4,013,350, 4,061,421, and 4,188,092.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a retrofocus type wide angle objective for single lens reflex cameras having an increased range with an increased relative aperture while nevertheless permitting the various aberrations to be well corrected, and a further minimization of the bulk and size of the entire lens system to be made possible.

The retrofocus type large aperture wide angle objective of the invention has three lens groups, the first lens group counting from the front having a negative refractive power, the second lens group having a positive refractive power, and the third lens group having a positive refractive power. And, the first lens group has two positive lenses and three negative lenses. The second lens group has a cemented bi-convex lens. The third lens group has two cemented lenses and two positive lenses. A good state of correction of aberrations has been achieved by giving the configuration, refractive power, and material of lenses in each group and the total length of the lens system prescribed various conditions.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. **1**, **2** and **3** are longitudinal sectional views of Examples 1, 2 and 3 of specific objectives according to the present invention respectively.

FIGS. **4**(*a*), (*b*), (*c*) and (*d*), **5**(*a*), (*b*), (*c*) and (*d*), and **6**(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of the objectives of FIGS. **1**, **2** and **3** respectively.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is next described in connection with embodiments thereof by reference to FIGS. **1**, **2** and **3**.

In these figures, the first lens group has a negative power, the second lens group has a positive refractive power, and the third lens group has a positive refractive power. And, the first lens group comprises, from front to rear, a positive meniscus lens of forward convexity, a negative meniscus lens of forward convexity, a negative meniscus lens of likewise or forward convexity, a positive lens, and a negative meniscus lens of forward convexity. The second lens group comprises a bi-convex doublet. The third lens group comprises, from front to rear, a doublet consisting of a positive lens and a negative lens cemented together, a positive meniscus lens of rearward convexity, a doublet consisting of a negative lens and a positive lens cemented together, and a positive lens. Positioned in the space between the second and third lens group is a diaphragm.

It is by such construction and arrangement that increases in the field angle and relative aperture and further an advance in the compactness of the lens system are achieved. For improvements of the imaging performance it is desirable to set forth the following conditions:

$$0.42 < |f_I| < 0.68, \text{ where } f_I < 0 \tag{1}$$

$$3.1 < \frac{D_T}{f} < 3.8 \tag{2}$$

$$1.3 < \frac{D_{I\,II}}{D_{III}} < 1.9 \tag{3}$$

$$f_1 > f_4 \tag{4}$$

$$|f_2| > |f_3| > |f_5|, \text{ where } f_2, f_3, f_5 < 0 \tag{5}$$

$$1.73 < \frac{N_1 + N_3 + N_5}{3} \tag{6}$$

$$\begin{matrix} 40 < \nu_1 < 65 \\ 40 < \nu_4 < 65 \end{matrix} \tag{7}$$

$$0.7 < \frac{|R_{13}|}{f} < 0.9, \text{ where } R_{13} < 0 \tag{8}$$

$$40 < \nu_7 \tag{9}$$

$$25 < \nu_6 < 32 \tag{10}$$

$$0.15 < N_9 - N_8 \tag{11}$$

$$0.25 < N_{11} - N_{12} \tag{12}$$

$$0.6 < \frac{|R_{15}|}{f} < 1, \text{ where } R_{15} < 0 \tag{13}$$

$$1.3 < \frac{R_{20}}{f} < 1.65 \tag{14}$$

where

f: the focal length of the entire system;

f_I: the focal length of the 1st lens group;

D_T: the total length of the objective;

$D_{I,II}$: the length from the first surface of the 1st lens group to the last surface of the 2nd lens group;

D_{III}: the length from the 1st surface of the 3rd lens group to the last surface;

f_1 to f_5: the focal lengths of the 1st to 5th lenses counting from front in the first lens group respectively;

N_i: the refractive index of the glass from which the i-th lens counting from front is made up;

ν_i: the Abbe number of the glass from which the i-th lens counting from front is made up; and

R_i: the radius of curvature of the i-th lens surface counting from front.

Explanation about why these conditions are given is next made below.

Conditions (1), (2) and (3) determine a basic construction and arrangement of the present invention. Condition (1) is to relatively strengthen the negative refractive power of the 1st lens group so that a sufficiently long back focal distance in view of the lens for the single lens reflex camera is secured, and the diameter of the front lens member is maintained at a minimum. When the upper limit of condition (1) is exceeded, it becomes difficult to secure a sufficiently long back focal distance and to maintain the diameter of the front lens member at minimum. When the lower limit is exceeded, the 1st lens group produces large positive spherical aberrations including higher order ones so that an increase in the relative aperture is difficult to achieve. Condition (2) is to relatively shorten the total length of the objective with an advantage of achieving compactness. When the upper limit of this condition is exceeded, an advance in the compactness is difficult to achieve. When the lower limit is exceeded, overall aberration correction becomes difficult to perform. Condition (3) has, despite the arrangement of the diaphragm at a relatively far ahead position as compared with the conventional objective under condition (2), to maintain the diameter of the front lens member at a minimum. When the upper limit of this condition is exceeded, maintenance of the minimum diameter of the front member becomes difficult. When the lower limit is exceeded, the diameter of the rear lens members becomes large, and the 3rd lens group is caused to produce large off-axis aberrations which are difficult to compensate for.

Further, in the present invention, in order to achieve good correction of aberrations, all the lens groups are individually given the following features.

The feature of the 1st lens group is that this group is constructed with a positive lens, a negative lens, a negative lens a positive lens and a negative lens and is given conditions (4), (5), (6) and (7) within the framework of condition (1). Conditions (4) and (5) define the refractive powers of all the lenses so as to almost progressively lower the heights of incidence of an off-axis ray of light on the lens surfaces as it advances through the 1st lens group while being refracted by the successive lens elements. By these conditions it is made possible to refract the off-axis ray moderately with an advantage that while distortion is corrected, the various off-axis aberrations can be well corrected, and further correction of astigmatism and coma can be achieved. Condition (6) assists in weakening the curvatures of the negative lenses in the 1st lens group. By this, the axial thickness of the 1st lens group can be made thinner so that the diameter of the front lens member can be maintained at a minimum, and at the same time it is made possible to reduce the various off-axis aberrations produced by the negative lenses. Condition (7) represents the use of glasses of large Abbe numbers in making up the two positive lenses arranged in the 1st lens group, with the advantage that color distortion and color coma produced by the positive lenses are minimized. When the lower limits of this condition are exceeded, both of the color distortion and color coma are over-corrected. When the upper limits are exceeded, under-correction of lateral chromatic aberration results.

Conditions (8), (9) and (10) are concerned with the 2nd lens group. Condition (8) compensates for the over-correction of coma by the 1st group. When the upper limit of this condition is exceeded, the compensation of the over-correction becomes difficult. When the lower limit is exceeded, the **R13** surface produces large negative spherical aberration, and an increase in the relative aperture becomes difficult to achieve. Condition (9) provides despite the configuration of the **R13** surface to a strong convex curvature for preventing the production of color coma by that surface. When this condition is violated, large color coma is produced. Condition (10) provides despite conditions (7) and (9) for preventing an under-correction of lateral chromatic aberration from tending to result, and represents the use of a glass of small Abbe number in the positive lens constituting the front element of the cemented lens of the 2nd group. When the upper limit of this condition is exceeded, under-correction of lateral chromatic aberration results. When the lower limit is exceeded, under-correction of longitudinal chromatic aberration results.

On the other hand, the residual asymmetric aberrations can be compensated for by the diverging surfaces in the 3rd lens group. But when the diverging action is strengthened, higher order aberrations are produced and it becomes difficult to achieve an increase in the relative aperture. The characteristic feature of the 3rd lens group of the invention is that this group is made to comprise a cemented lens of a positive element and a negative element, a positive lens, a cemented lens of a negative element and a positive element, and a positive lens, and, while its physical length is relatively elongated under condition (3), it is provided with many diverging surfaces, satisfying conditions (11), (12), (13) and (14). Conditions (11) and (12) represent large differences between the refractive indices of the two elements in either of the cemented lenses and cooperate with conditions (13) and (14) to impart a large diverging action. When conditions (11) and (12) are violated, a sufficient diverging action cannot be obtained even under conditions (13) and (14) thereby making it difficult to correct asymmetric aberrations. Conditions (13) and (14) represent the optimum radii of curvature of the cemented surfaces under conditions (11) and (12). When the upper limits of these conditions are exceeded, asymmetric aberrations no longer can be well corrected. When the lower limits are exceeded, higher order aberrations are produced to make it difficult to increase the relative aperture.

It is noted that the specific embodiments which will be later described employ the focusing method of moving the entire lens system forward as the object distance is shortened, while simultaneously shortening the axial air separation between the surfaces **R8** and **R9** (corresponding to that designated by **D8** in the drawings) to correct aberrations for the avoidance of lowering the imaging performance to an object at a shorter distance.

In the following, three examples of specific objectives of the invention satisfying the above-defined conditions are shown along with their numerical data, and 3rd order aberration coefficients of Example 1 objective are evaluated. Examples 1, 2 and 3 of the objective correspond to those shown in FIGS. **1**, **2** and **3** respectively. In the tables of the numerical data, Ri is the radius of curvature of the i-th surface counting from the front, Di the i-th axial thickness of air separation, and Ni and νi are the refractive index and Abbe number of the glass of the i-th lens element. Also in the table of the 3rd order aberration coefficient values, the surface numbers represent the lens surfaces numbered successively from the

front, I denotes spherical aberration, II coma, III astigmatism, P Petzval sum and V distortion.

The various aberrations of the Example 1 objective are shown in FIG. 4, the various aberrations of the Example 2 objective in FIG. 5, and the various aberrations of the Example 3 objective in FIG. 6. In these figures, M denotes the meridional focus line, and S the sagittal focus line.

In the last table, there are shown the numerical relationships of the above-described various conditions set forth to achieve the retrofocus large aperture, wide angle objective of the invention with the three examples of specific objectives cited in the present invention. It will be understood from FIGS. 4, 5 and 6 that any of the three specific objectives satisfying the conditions has a good state of correction of aberrations.

What is claimed is:

1. A large relative aperture, wide angle objective lens of the retrofocus type including, successively in the direction from front to rear, first, second and third lens groups, of which the first lens group has a negative refractive power and comprises, from front to rear, a positive meniscus lens convex toward the front, a negative meniscus lens convex toward the front, a negative meniscus lens convex toward the front, a positive lens and a negative meniscus lens convex toward the front, the second lens group has a positive refractive power and comprises a cemented bi-convex lens, and the third lens group has a positive refractive power and comprises, from front to rear, a cemented lens of a positive element and a negative element, a positive meniscus lens convex toward the rear, a cemented lens of a negative element and a positive element, and a positive lens, and a diaphragm positioned in a space between the second and third lens groups.

2. A large relative aperture wide angle objective lens according to claim 1, which satisfies the following conditions:

$$0.42 < |f_I| < 0.68 \text{ where } f_I < 0 \quad (1)$$

$$3.1 < \frac{D_T}{f} < 3.8 \quad (2)$$

$$1.3 < \frac{D_{I\,II}}{D_{III}} < 1.9 \quad (3)$$

wherein

f: the focal length of the entire system;

f_I: the focal length of the 1st lens group;

D_T: the total length of the objective;

$D_{I\,II}$: the length from the 1st surface of the 1st lens group to the last surface of the 2nd lens group;

D_{III}: the length from the 1st surface of the 3rd lens group to the last surface.

3. A large relative aperture wide angle objective lens according to claim 2, which satisfies the following conditions:

$$f_1 < f_4 \quad (4)$$

$$|f_2| > |f_3| > |f_5| \text{ where } f_2, f_3, f_5 < 0 \quad (5)$$

$$1.73 < \frac{N_1 + N_3 + N_5}{3} \quad (6)$$

$$40 < \nu_1 < 65$$
$$40 < \nu_4 < 65 \quad (7)$$

$$0.7 < \frac{|R_{13}|}{f} < 0.9 \text{ where } R_{13} < 0 \quad (8)$$

$$40 < \nu_7 \quad (9)$$

$$25 < \nu_6 < 32 \quad (10)$$

wherein

f_1: the focal length of the 1st lens counting from the front arranged in the 1st lens group;

f_2: the focal length of the 2nd lens in the 1st lens group;

f_3: the focal length of the 3rd lens in the 1st lens group;

f_4: the focal length of the 4th lens in the 1st lens group;

f_5: the focal length of the 5th lens in the 1st lens group;

N_i: the refractive index of the glass of the i-th lens counting from the front;

ν_i: the Abbe number of the glass of the i-th lens counting from the front; and

R_i: the radius of curvature of the i-th lens surface counting from the front.

4. A large relative aperture wide angle objective lens according to claim 2, which satisfies the following conditions:

$$0.15 < N_9 - N_8 \quad (11)$$

$$0.25 < N_{11} - N_{12} \quad (12)$$

-continued

$$0.6 < \frac{|R_{15}|}{f} < 1 \text{ where } R_{15} < 0 \quad (13)$$

$$1.3 < \frac{R_{20}}{f} < 1.65 \quad (14)$$

wherein

N_i: the refractive index of the glass of the i-th lens counting from the front;

ν_i: the Abbe number of the glass of the i-th lens counting from the front; and

R_i: the radius of curvature of the i-th lens surface counting from the front.

5. A large relative aperture, wide angle objective lens of the retrofocus type including first, second and third lens groups, of which the first has a negative refractive power and comprises, from front to rear, a positive meniscus lens convex toward the front, a negative meniscus lens convex toward the front, a negative meniscus lens convex toward the front, a positive lens and a negative meniscus lens convex toward the front, the second has a positive refractive power and comprises a cemented bi-convex lens, and the third has a positive refractive power and comprises, from front to rear, a cemented lens of a positive element and a negative element, a positive meniscus lens convex toward the rear, a cemented lens of a negative element and a positive element, and a positive lens, and a diaphragm positioned in a space between the 2nd and 3rd lens groups, said objective satisfying the following conditions:

$$0.42 < |f_I| < 0.68 \text{ where } f_I < 0 \quad (1)$$

$$3.1 < \frac{D_T}{f} < 3.8 \quad (2)$$

$$1.3 < \frac{D_{I\,II}}{D_{III}} < 1.9 \quad (3)$$

$$f_1 > f_4 \quad (4)$$

$$|f_2| > |f_3| > |f_5| \text{ where } f_2, f_3, f_5 < 0 \quad (5)$$

-continued

$$1.73 < \frac{N_1 + N_3 + N_5}{3} \quad (6)$$

$$40 < \nu_1 < 65$$
$$40 < \nu_4 < 65 \quad (7)$$

$$0.7 < \frac{|R_{13}|}{f} < 0.9 \text{ where } R_{13} < 0 \quad (8)$$

$$40 < \nu_7 \quad (9)$$

$$25 < \nu_6 < 32 \quad (10)$$

$$0.15 < N_9 - N_8 \quad (11)$$

$$0.25 < N_{11} - N_{12} \quad (12)$$

$$0.6 < \frac{|R_{15}|}{f} < 1 \text{ where } R_{15} < 0 \quad (13)$$

$$1.3 < \frac{R_{20}}{f} < 1.65 \quad (14)$$

wherein

f: the focal length of the entire system;

f_I: the focal length of the 1st lens group;

D_T: the total length of the objective;

$D_{I\,II}$: the length from the 1st surface of the 1st lens group to the last surface of the 2nd lens group;

D_{III}: the length from the 1st surface of the 3rd lens group to the last surface;

f_1: the focal length of the 1st lens counting from the front arranged in the 1st lens group;

f_2: the focal length of the 2nd lens in the 1st lens group;

f_3: the focal length of the 3rd lens in the 1st lens group;

f_4: the focal length of the 4th lens in the 1st lens group;

f_5: the focal length of the 5th lens in the 1st lens group;

N_i: the refractive index of the glass of the i-th lens counting from the front;

ν_i: the Abbe number of the glass of the i-th lens counting from the front; and

R_i: the radius of curvature of the i-th lens surface counting from the front.

ZOOM OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to mechanically-compensated compact zoom objectives having a large zoom ratio including a wide angle region and extending up to a telephoto region.

In a zoom objective lens system it is necessary to employ at least two lens components which move axially for varying the focal length of the entire system while maintaining a constant image plane. Recently there has been a desire to increase the zoom ratio of this type zoom objective while keeping the bulk and size to a minimum.

The zoom ratio of about two has been found practical in objectives for still cameras. Most of these objectives are constructed in the so-called short zoom form comprising two lens components of negative and positive powers as, for example, disclosed in U.S. Pat. Nos. 3,143,590, 3,848,969, 4,153,339, 4,142,779, and 4,147,410. Of these, there is known a lens system whose rear component having a positive power is divided into a plurality of parts to facilitate a remarkable increase in the zoom ratio. For example, U.S. Pat. No. 4,170,402 describes a system where the rear group comprises two positive lenses made movable independently of each other. In Japanese Patent Application Laid-Open No. Sho 53-34539, the rear group also is divided into three parts of positive, negative and positive powers of which the positive two are moved in unison with each other, while the intermediate or negative lens is moved in differential relation to the positive lenses. U.S. Pat. No. 3,771,853 describes the construction of a rear group of positive, negative and positive lenses which assume respectively different loci.

Aside from the direction of development of the art in the field of zoom objectives of the type consisting of negative and positive lens groups as described above, there is another direction of development toward an increase in the zoom ratio and the compactness based on the fundamental zoom lens design which has been widely accepted from. This development involves objectives comprising four lens components, namely, a focusing member, a variator, a compensator and a relay lens. For example, DOLS 2,833,308 describes a positive first lens group counting from the front, a negative second lens group and a positive third lens group constituting an entire system with exclusion of the relay lens. Here, the function of varying the focal length is imparted into the second and third lens groups, and both of the functions of focusing adjustment and image shift compensation are imparted into the first lens group. This achieves the objects of high zoom ratio and compactness.

To obtain a compact zoom objective of a high zoom ratio it is the common practice to strengthen the refractive power of the each individual movable lens group and narrow the air spacings between the successive lens groups. In this case, the following problems arise:

(1) The aberrational correction becomes difficult.

(2) The requirement for accuracy of adjustment in position of the movable lens group is extremely rigorous. If this is not fulfilled, the ideal optical performance cannot be obtained in completed objectives.

(3) No real solution can be found for the locus of movement of the compensator relative to the variator.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a compact zoom objective for a still camera having as high a zoom ratio as 3 with an angle of view of at least 60° in the shortest focal length positions and a total length (the distance from the front vertex to the focal plane) reduced to shorter than 1.5 times the longest focal length, while still achieving good correction of aberrations throughout the entire zooming range.

In a zoom objective according to the present invention a first lens group, a second lens group and a third lens group are arranged on a common optical axis from the front in the order stated, and the second lens group is imparted with the function of varying the size of an image of an object located at a fixed distance from the objective, the third lens group with the function of compensator, and the first lens group with not only the focusing function but also the function of a compensator, to accomplish the above-described object of the invention.

In other words, according to the present invention, as the bulk and size of the lens system is minimized by putting the second and third lens groups as near to each other as possible, in order to avoid the above-mentioned problem (3), the function of the compensator is added to the first lens group. In the zoom lens system of the present invention, therefore, when in zooming, the first and third lens groups are reciprocatingly moved along the optical axis, while the second lens group is simultaneously axially moved monotonically in one direction in the range of variation. And, the loci of movement of the first and third lens groups are made non-parallel to each other.

With the zoom lens system of the present invention when the above-described first lens has a positive refractive power, the second lens has a negative refractive power and the third lens has a positive refractive power, it the first and third lens groups preferably perform axial movements in one round of convex locus toward the front during the zooming. At that time, preferably the second lens group is axially moved monotonically from the front to the rear as the lens is zoomed from the wide angle to the telephoto settings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1A and 1B are schematic diagrams of an embodiment of a zoom objective lens system according to the present invention in two operative positions.

FIG. 2, FIG. 3 and FIG. 4 are sectional views showing three different examples of specific zoom objectives according to the present invention.

FIGS. 5A to 5C are graphic representations of the various aberrations of the zoom objective of FIG. 2 in the shortest, middle and longest focal length positions respectively.

FIGS. 6A to 6C are similar graphs of the objective of FIG. 3.

FIGS. 7A to 7C are similar graphs of the objective of FIG. 4.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIGS. 1A and 1B are block diagrams of a zoom objective of the present invention. In FIG. 1A, the lens components are positioned the wide angle end of a zooming range and in FIG. 1B at the telephoto end thereof.

The lens system of FIG. 1 is constructed with three groups as a whole of which the first I counting from the front is of positive power, the second II of negative power and the third III of positive power. When zooming, the second lens group II is moved toward the first lens group I in the wide angle settings, and toward the third lens group III in the telephoto settings. Along with this, the first lens group I and the third lens group III each perform an axial movement of small range in one round of non-parallel and convex locus toward the front. Thus, the focal length of the entire system is varied throughout the range of axial movement of the lens groups while still maintaining a fixed focal plane throughout the entire range. This makes it possible to facilitate an extreme minimization of the bulk and size of the entire system and to increase the zoom ratio up to about 3 with the inclusion of a wide angle position at one end of a zooming range, the opposite end of which is extended up to produce a telephoto effect. In more detail, as the air spacings between the successive lens groups are shorter, the use of only the third lens group as the compensator for the variator of the second lens group II would lead to give rise to the above-described problem (3). But by using two compensators of the first and third lens groups I and III the equation for defining the movements of the individual zoom lens groups can be solved. Moreover, the refractive power of each of the lens groups may be weakened, and the aberrational problem is simplified. Further, as the first lens group serves as a focusing member, the entire system can be minimized to a compact size.

FIGS. 2 to 4 are longitudinal sections of embodiments of the zoom lens system of FIG. 1 with FIG. 2 showing Example 1, FIG. 3 Example 2, and FIG. 4 Example 3. The zoom objectives shown in Examples 1 to 3 have a range of variation of the focal length, f, between 36 mm and 103 mm, with a zoom ratio of about 2.9 and an F-number of 3.5.

The numerical data of the zoom objectives shown in Examples 1 to 3 for the radii of curvature, Ri, the axial thicknesses or axial air separations, di, the refractive indices, ni, for the spectral d line, and the Abbe numbers, νi, are given in Tables 1-1 to 3-1 below. The lens block separations l1 and l2 and back focus of each of the zoom objectives shown in Examples 1 to 3 during zooming with object at infinity are given in Tables 1-2 to 3-2.

Further, the various aberrations of the zoom objective of Example 1 in three different focal length positions are shown in FIGS. 5A to 5C, those of the zoom objective of Example 2 in FIGS. 6A to 6C, and those of the zoom objective of Example 3 in FIGS. 7A to 7C.

What is claimed is:

1. A zoom objective comprising:

a first lens group, a second lens group and a third lens group arranged in the order mentioned from an objective end to an image end;

said first lens group having a positive refractive power and being axially movable forward and then rearward when zooming from a wide angle to a telephoto setting;

said second lens group having a negative refractive power and being axially movable from the objective end to the image end when zooming from the wide angle to the telephoto setting; and

said third lens group having a positive refractive power and being axially movable forward and then rearward when zooming from the wide angle to the telephoto setting.

2. A zoom objective as described in claim **1**, wherein the locus of movement of said first lens group and the locus of movement of said third lens group are non-parallel to each other during zooming.

3. A zoom objective comprising:

a first lens group, a second lens group, and a third lens group arranged in the order mentioned from an objective end to an image end;

said first lens group having a positive refractive power and focusing and compensating functions, and moving first toward the objective end and then toward the image end during zooming from a wide angle position to a tele position;

said second lens group having a negative refractive power and magnificating function, and moving only in one direction from the objective end to the image end during zooming from the wide angle position to the tele position; and

said third lens group having a positive refractive power and compensating function, and moving first toward the objective end and then to the image surface end during zooming from the wide angle position to the tele position.

[57] **ABSTRACT**

A photographic small size objective of the modified Gauss type which is well corrected for high grade imaging performance. The objective comprises, from front to rear, a first lens in a meniscus form of positive power with its convex curvature toward the front, a second lens in a similar form, a third lens in a meniscus form of negative power with its convex curvature toward the front, a fourth lens in a meniscus form of negative power with its convex curvature toward the rear, and a fifth lens of positive power with its rear surface having a strong refractive power.

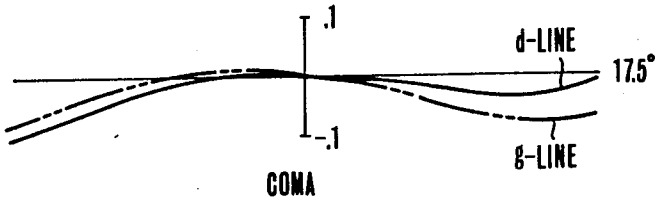

PHOTOGRAPHIC SMALL SIZE OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to photographic objectives of the modified Gauss type, and more particularly to such objectives suited to be used as the standard lens for 35 mm single lens reflex cameras. In one form the objective includes four meniscus lenses and a fifth lens having positive power and a rear surface having a strong refractive power.

2. Description of the Prior Art

In general, the Gauss type objective is, because of its having a cemented lens just in the rear of the diaphragm, feasible to achieve good correction of chromatic aberrations such as longitudinal chromatic aberration, lateral chromatic aberration and color comatic aberration. On the other hand, an objective of what may be called the modified Gauss type with five elements constituting five components is disclosed, for example, in U.S. Pat. No. 2,720,139 and Japanese Pat. No. Sho 38-12983 where the first and second counting from the front are positive meniscus lenses of forward convexity, the third is a negative meniscus lens of forward convexity followed by a diaphragm, the fourth is a negative meniscus lens of rearward convexity, and the fifth is a positive meniscus lens. This type of objective is advantageous in minimizing the bulk and size of the apparatus. It is, however, very difficult to make the lens which follows the diaphragm, which is important to provide satisfactory correction of chromatic aberrations, since this lens is a singlet.

Therefore, this residual chromatic aberration must be compensated for by the suitable design of other lenses. It is, however, impossible in the present state of the art to achieve as good a correction as when the doublet is used in the rear of the diaphragm. Such substitution of the singlet for the doublet further aggravates other aberrations such as spherical aberration and curvature of field. As compared with the six-component Gauss type objective, there is a clear distinction in the optical performance. As a result, the general trend is to reduce the angular field, or the F-number to as dark a value as F2 or less in order to preserve the image quality.

SUMMARY OF THE INVENTION

An object of the present invention is to provide good compensation for the under-correction of chromatic aberrations which is a drawback of the conventional five-component-five-element objective, without negatively influencing other aberration correction, and to provide an objective having an imaging performance equal to or higher than that of the six-component Gauss type objective. It will be seen, from embodiments of the invention to be described later, that the objective in question has an F-number increased to f/1.8 which is common to the 6-component objectives, and is suited for use as the compact standard lens of high quality for 35 mm single lens reflex cameras.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a block diagram of an Example 1 embodiment of the invention.

FIGS. **2**(*a*), (*b*), (*c*), (*d*) and (*e*) are graphic representations of the various alternatives of the objective of FIG. **1**.

FIGS. **3**(*a*), (*b*), (*c*), (*d*) and (*e*) are graphic representations of Example 2 embodiments of the invention.

FIGS. **4**(*a*), (*b*), (*c*), (*d*) and (*e*) are graphic representations of Example 3 embodiments of the invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is to provide an objective comprising, from front to rear, positive meniscus 1st and 2nd lenses each convex toward the front, a negative meniscus 3rd lens convex toward the front, a negative meniscus 4th lens convex toward the rear, and a positive 5th lens with its rear surface having a stronger curvature, and satisfying the following conditions:

$$0.04 < D_4/f < 0.06 \quad (1)$$

$$21.2 \leqq \nu 2 - \nu 3 < 28 \quad (2)$$

$$0.29 < |\psi 1| \cdot f < 0.75, \ \psi 1 < 0 \quad (3)$$

where f is the focal length of the entire system; D_4 is the axial air separation between the 2nd and 3rd lenses; $\nu 2$ and $\nu 3$ are the Abbe numbers (νd) of the 2nd and 3rd lenses respectively; and $\psi 1$ concerns with the air lens between the 2nd and 3rd lenses and is defined by $\psi 1 = (1 - N2)/R_4 + (N3 - 1)/R_5$ where N2 and N3 are the indices of refraction for d line of the 2nd and 3rd lenses respectively; R_4 is the radius of curvature of the rear surface of the 2nd lens; and R_5 is the radius of curvature of the front surface of the 3rd lens.

Each of the conditions is explained below.

Referring now to FIG. **1** condition (1) is, along with condition (2) desirable to provide amply chromatic aberration correction particularly color comatic aberration. The fact that a faster objective can be realized despite the decreased number of lens elements is largely ascribable to this condition. That is, the axial separation between the 2nd and 3rd lenses is wider than in the prior art to create an appreciable difference between the heights of incidence of off-axis rays of light from the optical axis on the surfaces R_4 and R_5. The use of a low dispersion glass in the 2nd lens and a high dispersion glass in the 3rd lens is made to increase the Abbe number difference to a considerable extent, thereby it being made possible to achieve good correction of longitudinal chromatic aberration, lateral chromatic aberration and even color comatic aberration. Further, spherical aberration and coma can be also amply corrected. When the lower limit of condition (1) is exceeded, under-correction of the color comatic aberration results. When the upper limit is exceeded, the back-focal distance can be no longer held in the prescribed value so that with the objective mounted on the single lens reflex camera when the mirror is flipped upward, the mirror will interfere with the rearmost lens element. When the lower limit of condition (2) is exceeded, not only under-correction of the color comatic aberration results, but also under-correction of the longitudinal chromatic aberration and over-correction of lateral chromatic aberration (for g line) result. When the upper limit is exceeded, the balance of the longitudinal and lateral chromatic aberrations will be broken.

Condition (3) is to amply correct spherical aberration and off-axis sagittal halo. When the lower limit is exceeded, under-correction of the spherical aberration and sagittal halo will result, which is unacceptable to the realization of as fast a lens speed as F/1.8 class.

When the upper limit is exceeded, large higher-order spherical aberrations are produced, and the spherical aberrations suddenly change from over-correction to under-correction as the aperture nears the full open, and a contrast loss result at full aperture.

To facilitate a further improvement of the overall image aberrations, it is preferred to satisfy the following conditions.

$$1.72<(N1+N2+N5)/3<1.81 \quad (4)$$

$$6.7<(1/R_6+1/|R_7|)\cdot f<8 \quad (5)$$

$$0.045<D_7/f<0.082 \quad (6)$$

$$20<\nu 3<28;\ 1.75<N3<1.93 \quad (7)$$

$$46<\nu 5<60 \quad (8)$$

where N1 and N5 are the refractive indices (for d line) of the 1st and 5th lenses respectively; R_6 is the radius of curvature of the rear surface of the 3rd lens; R_7 is the radius of curvature of the front surface of the 4th lens; D_7 is the axial thickness of the 4th lens; and $\nu 5$ is the Abbe number (νd) of the 5th lens.

Condition (4) is to provide good correction of field curvature. When the lower limit is exceeded, the Petzval sum becomes too large with an increase of the field curvature. When the upper limit is exceeded, even though the Petzval sum is improved, as the availability of existing glasses limits a range of Abbe numbers, the chromatic aberrations become difficult to correct, and, as the usable glasses are very expensive, the production cost is increased. Condition (5) is to facilitate an improvement of the sagittal halo and the coma in the intermediate zone of the picture area by limiting the curvatures of the surfaces R_6 and R_7 in front of and in the rear of the diaphragm respectively. This limitation causes the deterioration of the spherical aberration, field curvature and astigmatism, but condition (1) which strengthens the power of the air lens between the 2nd and 3rd lenses serves to effect good compensation therefor.

When the lower limit of condition (5) is exceeded, satisfactory correction of spherical aberration, field curvature and astigmatism is difficult. When the upper limit is exceeded, the production of sagittal halo and coma in the intermediate zone becomes serious. Condition (6) is to maintain a necessary back focus clearance by the limitation of the thickness of the 4th lens, and to provide ample correction of spherical aberration. That is, the 4th lens is thickened to some extent so that the back focal distance is increased, and the heights of the points from the optical axis at which a paraxial light ray crosses the both surfaces of that lens are differentiated for satisfactory correction of spherical aberration. When the lower limit is exceeded, the resultant back focus clearance and the spherical aberration are not acceptable. When the upper limit is exceeded, though the back focus clearance is kept long, the balance of the spherical aberration and astigmatism is broken, and further lateral chromatic aberration (for g line) is undercorrected.

The present invention employs a form of construction in which the lens elements that follow the diaphragm do not have a cemented surface as in the conventional 6-component standard objective of the Gauss type in order that longitudinal chromatic aberration and lateral chromatic aberration are both satisfactorily corrected. Accordingly it is required to select a glass of as low a dispersion as possible for employment in the 5th lens, and at least a range defined in condition (8) is necessitated. Again, the 3rd lens is also preferably made up of a glass of as high a dispersion as possible for the same purposes, and further this glass has to have a high refractive index for correction of spherical aberration and sagittal halo. Because of this, condition (7) is defined. Beyond these ranges, zonal spherical aberration becomes large, and the sagittal halo is largely increased so that it is difficult to achieve an increase in the imaging performance. Among the commercially available glasses, it is usual that $\nu 3$ is not less than 20, N3 is not more than 1.93, and $\nu 5$ is not more than 60. The glasses beyond these values are very expensive, and have poor chemical stability, and it is found that a photographic objective using these glasses is not practical.

Examples of specific objectives can be constructed in accordance with the following numerical data. The lens configuration of Example 1 is shown in FIG. **1**, and the spherical aberration, sine condition, astigmatism, distortion, lateral chromatic aberration and comatic aberration of the objective of FIG. **1** for infinitely distant object are represented in FIGS. **2**(*a*), (*b*), (*c*), (*d*) and (*e*) respectively. Also the various aberrations of Example 2 are represented in FIGS. **3**(*a*), (*b*), (*c*), (*d*) and (*e*) respectively, and also the various aberrations of Example 3 in FIGS. **4**(*a*), (*b*), (*c*), (*d*) and (*e*). It is to be understood from the above aberration curves particularly regarding the spherical aberration curves and comatic aberration curves for spectral d and g lines along with the lateral chromatic aberration curves that a good correction of the chromatic aberrations is achieved.

What is claimed is:

1. A photographic objective of small size consisting of five lens groups, each group having a single lens, including, from front to rear,

a meniscus 1st lens of positive power convex toward the front;

a meniscus 2nd lens of positive power convex toward the front;

a meniscus 3rd lens of negative power convex toward the front;

a meniscus 4th lens of negative power convex toward the rear; and

a 5th lens of positive power with its rear surface having a strong refractive power, and satisfying the following conditions:

$$0.04<D_4/f<0.06 \quad (1)$$

$$21.2\leqq\nu 2-\nu 3<28 \quad (2)$$

$$0.29<|\psi 1|\cdot f<0.75,\ \psi 1<0 \quad (3)$$

where:

f is the focal length of the entire system;

Ni and νi are the refractive index and Abbe number of the i-th lens counting from the front respectively;

Di is the i-th lens thickness or air separation counting from the front;

Ri is the radius of curvature of the i-th lens surface counting from the front; and

$$\psi 1=(1-N2)/R_4+(N3-1)/R_5.$$

2. A photographic objective of small size consisting of five lens groups, each group having a single lens including, from front to rear,

a meniscus 1st lens of positive power convex toward the front;

a meniscus 2nd lens of positive power convex toward the front;

a meniscus 3rd lens of negative power convex toward the front;

a meniscus 4th lens of negative power convex toward the rear; and

a 5th lens of positive power with its rear surface having a strong refractive power, and satisfying the following conditions:

$$0.04<D_4/f<0.06 \quad (1)$$

$$21.2\leqq\nu 2-\nu 3<28 \quad (2)$$

$$0.29<|\psi 1|\cdot f<0.75,\ \psi 1<0 \quad (3)$$

$$1.72<(N1+N2+N5)/3<1.81 \quad (4)$$

$$6.7<(1/R_6+1/|R_7|)f<8 \quad (5)$$

$$0.045<D_7/f<0.082 \quad (6)$$

$$20<\nu 3<28,\ 1.75<N3<1.93 \quad (7)$$

$$46<\nu 5<60 \quad (8)$$

where:

f is the focal length of the entire system;

Ni and νi are the refractive index and Abbe number of the i-th lens counting from the front respectively;

Di is the i-th lens thickness or air separation counting from the front;

Ri is the radius of curvature of the i-th lens surface counting from the front; and

$$\psi 1=(1-N2)/R4+(N3-1)/R5.$$

[57] **ABSTRACT**

The disclosed photographic objective includes, from front to rear, a meniscus first lens of positive power convex toward the front, a bi-concave second lens, a bi-convex third lens, and a negative-power fourth lens whose front surface is concave toward the front and aspherical. The form of each of the lenses, the glass material, and the air separations between the successive lenses being chosen to reduce the overall size of the objective while still permitting good correction of aberrations.

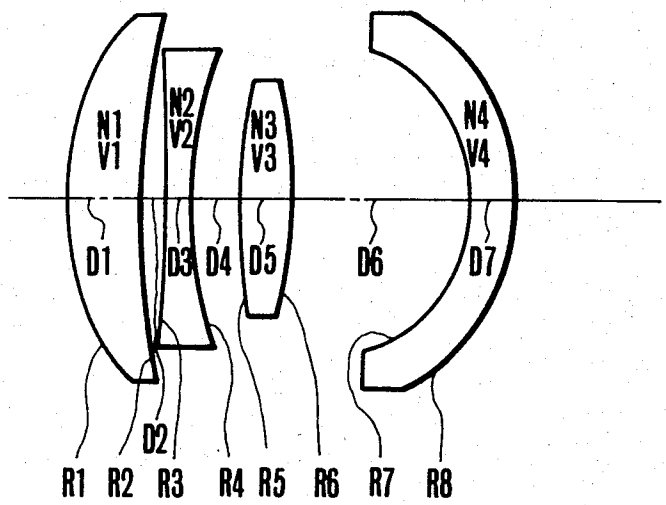

FIG.1

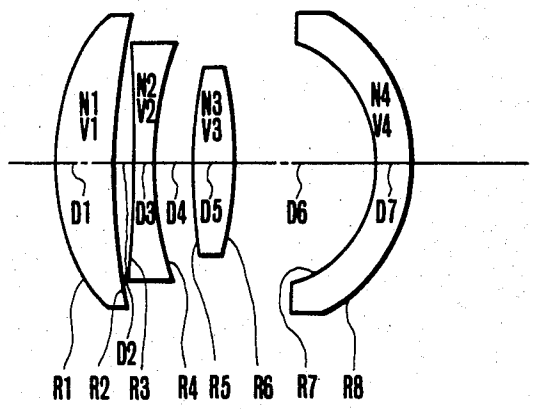

FIG.2a FIG.2b FIG.2c

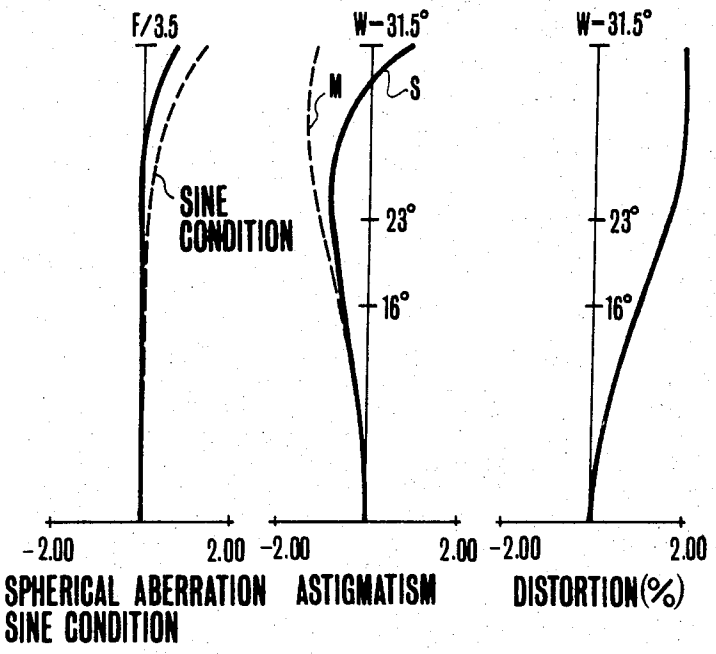

PHOTOGRAPHIC OBJECTIVE OF REDUCED SIZE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to lens systems of short total length measured from the front vertex to the focal plane, and more particularly to a small photographic objective with an angular field of about 63° and an F-number of about 3.5.

2. Description of the Prior Art

Recently, as cameras have been reduced in size, the demand has arisen for compact lenses of short focal length. Where the total length of a lens system is reduced to less than the focal length, it is desirable to distribute positive refractive power over the front group of lenses in the lens system and a negative refractive power over the rear group of lenses, or to employ a so-called telephoto-type system. Such power distribution has found many uses in long focal length lenses of narrow angular fields, but there are only a few examples of its application to wide angle objectives having angular fields of at least 60° in a short lens system with a large relative aperture.

With this type of power distribution, when the total length is reduced, and when the relative aperture is increased also, while the angular field is also widened, the distortion and astigmatism deteriorate badly or extremely large increases of coma and halo result.

U.S. Pat. No. 3,998,527 and Japanese Pat. Sho 44-10831 illustrate attempts to provide for photographic objectives of the telephoto type with increased angular fields. In the Japanese patent, the angular field is attained at a relatively narrow value, namely 46°, while the U.S. Patent illustrates a relatively wide angular field, namely 63°, but results in an F-number of 4.5.

SUMMARY OF THE INVENTION

The present applicant has proposed in Japanese Patent Application Sho 54-172405, a fast wide angle objective comprising, from front to rear, a meniscus lens of positive power, a lens of negative power, a lens of positive power and a meniscus lens of negative power with its front surface concave toward the front, said concave surface being strongly curved. Where this form of objective is employed for incorporation in a thin small-sized camera body, in order to give full play to the advantages of permitting the diaphragm mechanism to be positioned in the camera body in fixedly secured relation and the capability of lightening the weight of the movable lenses, it is desirable that the first three lenses constituting a front group be made to move for focusing purposes.

It is an object of the present invention to further improve the above-described proposal and to provide an objective lens of such construction that even when decentering of the lens groups occurs during focusing by the front group, the range of variation of the aberrations is limited to a minimum. To achieve this, the refractive power of the last lens is weakened to moderate the influence of the decentering. Though this provision leads to change the power distribution over the entire system, to cope with this change, the lens elements are formed that the various aberrations are well corrected.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a longitudinal sectional view of an embodiment of an objective according to the present invention.

FIGS. **2***a*, **2***b* and **2***c* are graphic representations of the aberrations of the objective of FIG. **1**.

DESCRIPTION OF PREFERRED EMBODIMENTS

In an embodiment of the present invention, the photographic objective has, as shown in FIG. **1**, from front to rear, a meniscus first lens of positive power convex toward the front, a second lens of bi-concave form, a third lens of bi-convex form and a meniscus fourth lens of negative power concave toward the front in strong curvature, the front lens surface of the fourth lens being aspherical. The equation for the aspherical surface is expressed by:

$$\Delta X = \frac{(1/R^*)Y^2}{1+\sqrt{1-(1/R^*)}} + A_1Y^2 + A_2Y^4 + A_3Y^6 \ldots + B_1Y^3 + B_2Y^5 + \ldots - \frac{(1/R)Y^2}{1+\sqrt{1-(Y/R)^2}}$$

where

ΔX, assuming that the optical axis is taken as X-axis, the direction perpendicular to the optical axis as Y-axis, the direction in which light advances as positive and the cross-point between the vertex of the objective and the optical axis at the original point, it is the difference along the X-axis between the aspherical surface and the extrapolation of a spherical surface contributing to the determination of the focal length;

R: the radius of curvature of the paraxial region;

R*: the radius of curvature of the lens standard spherical surface defined in $R^*=R/(1-2RA_1)$

Ai=the spheric even coefficients

Bi=the aspheric odd coefficients.

An example of a specific objective of the invention can be constructed in accordance with the following numerical data as related to a focal length F of 100 millimeters.

F = 100 F-number = 1:3.5 Image Angle 2ω = 63°

	Radius of Curvature	Thickness & Separation	Refractive Index (Nd)	Abbe Number (νd)
R1 =	28.32	D1 = 8.59	N1 = 1.77250	ν1 = 49.6
R2 =	86.00	D2 = 2.66		
R3 =	−159.52	D3 = 2.86	N2 = 1.80518	ν2 = 25.4
R4 =	43.65	D4 = 5.33		
R5 =	69.12	D5 = 5.44	N3 = 1.60342	ν3 = 38.0
R6 =	−69.12	D6 = 20.51		
R*7 =	−16.56	D7 = 4.58	N4 = 1.49171	ν4 = 57.4
R8 =	−22.20			

Aspherical Coefficients

A1 = -0.17023×10^{-2}	B1 = -0.54318×10^{-4}
A2 = 0.65538×10^{-5}	B2 = 0.73458×10^{-7}
A3 = -0.74579×10^{-7}	B3 = 0.15509×10^{-8}
A4 = 0.28740×10^{-9}	B4 = -0.13024×10^{-10}
A5 = 0.11786×10^{-12}	

By giving various dimensions to the above-listed values it is made possible to achieve a remarkable reduc-

tion in the size of the photographic objective while still permitting good correction of aberrations since the various aberrations vary to an extremely small extent even when the lens groups are decentered from each other during focusing by moving the front lens group.

What is claimed is:

1. A photographic objective of reduced size including the following various conditions:

from front to rear;

a first lens in the form of a positive meniscus lens convex toward the front;

a second lens in the form of a negative lens;

a third lens in the form of a positive lens;

a fourth lens with the front surface concave toward the front, said concave surface being aspheric and said aspheric surface being figured by the following equation:

$$\Delta X = \frac{(1/R^*)Y^2}{1+\sqrt{1-(Y/R^*)^2}} + A_1Y^2 + A_2Y^4 + A_3Y^6 + \ldots + B_1Y^3 + B_2Y^5 + \ldots - \frac{(1/R)Y^2}{1+\sqrt{1-(Y/R)^2}}$$

where the axial direction is taken as the X-axis, the direction perpendicular to the optical axis as the Y-axis, the direction in which light advances as positive, and the intersection of the vertex and the X-axis at the original point, and the difference along the X-axis direction between the aspheric surface and the surface obtained by extrapolating the spherical surface contributing to the determination of the focal length is denoted by ΔX, the radius of curvature of the paraxial region by R, the radius of curvature of the standard spherical surface of the lens defined as $R^*=R/(1-2RA_1)$, the aspheric even coefficients by Ai and the aspheric odd coefficients by Bi;

and being characterized by the following numerical values for the radii of curvature of the lens surface Ri numbered the i-th from the front, the lens thicknesses and axial air separations Di, the refractive indices for spectral d lines of the glasses of the lens elements Ni, and Abbe numbers νi of the glasses of the lens elements as related to a focal length of the entire lens system f=100:

F = 100 F-number = 1:3.5 Image Angle 2ω = 63°

Radius of Curvature	Thickness & Separation	Refractive Index (Nd)	Abbe Number (νd)
R1 = 28.32	D1 = 8.59	N1 = 1.77250	ν1 = 49.6
R2 = 86.00	D2 = 2.66		
R3 = −159.52	D3 = 2.86	N2 = 1.80518	ν2 = 25.4
R4 = 43.65	D4 = 5.33

[57] **ABSTRACT**

The objective disclosed includes, from front to rear, a positive meniscus lens of forward convexity, a negative lens, a positive lens, and a negative meniscus lens having an aspheric front surface concave toward the front, and fulfills the following requirements:

$$-1.5f < fA < -0.5f$$

$$4.5 \times 10^{-4} < \left| \frac{\Delta x(0.7r_7)}{f} \right| < 4.0 \times 10^{-3}$$

$$6.5 \times 10^{-5} < \left| \frac{\Delta x(0.5r_7)}{f} \right| < 1.0 \times 10^{-3}$$

where

f is the focal length of the entire system;

fA is the focal length of the air lens defined by the opposing surfaces of the first and second lenses counting from the front; and

$$x(y) = \frac{(1/r_7^*)y^2}{1 + \sqrt{1 - (y/r_7^*)^2}} + a_1y^2 + a_2y^4 + a_3y^6 + \ldots + b_1y^3 + b_2y^5 + \ldots - \frac{(1/r_7)y^2}{1 + \sqrt{1 - (y/r_7)^2}}$$

wherein

r_7 is the paraxial radius of curvature of the front surface of the 4th lens; and

r_7^* is the radius of curvature of the lens reference spherical surface defined by

$$r_7 = \frac{1}{1/r_7^* + 2a_1}$$

COMPACT PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to lens systems of short total length (from the first surface of the lens to the focal plane) and more particularly to compact wide angle photographic objectives.

2. Description of the Prior Art

Recently, the trend toward minimizing the bulk and size of the camera has increased demands for compact lenses or objective lenses with shortened total lengths. When the total length of a lens system is reduced to less than one times the focal length, it is particularly desirable to make the front lens group of the lens system of a positive refractive power and the rear lens group of a negative refractive power. Such power distribution has found many uses in long lenses with narrow angular fields of view. However, there are a few examples of the application of this principle to objectives having wide angles at least 60° with large aperture ratios and short total lengths.

The reason for this deficiency is that this type of refractive power distribution increases the residual distortion and astigmatism objectionably, or produces extremely large comas and halo, as the total length decreases, the relative aperture increases and the angular field of view widens.

Japanese Patent Application Publication No. Sho 44-10831 discloses a lens system using this type of power distribution. However, the system described therein exhibits a field angle of 46°, that is, in the order of a standard lens. If an attempt is made to increase the angular field, the astigmatic difference will increase. U.S. Pat. No. 3,998,527 (Japanese Patent Application Publication No. Sho 52-48011) discloses a similar lens system. However, here the F number is 1:4.5.

SUMMARY OF THE INVENTION

It is an object of the present invention to minimize the number of constituent lens elements and shorten the total length of lens systems and to provide a compact faster wide angle objective lens with four elements constituting four components. In embodiments of the present invention to be described more fully later, an angular field of view of 59.7° with F/2.8 and 63.4° with F/3.5 has been achieved.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a longitudinal sectional view of an embodiment of an objective according to the present invention.

FIGS. 2(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of Example 1 of the objective.

FIGS. 3(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of Example 2 of the objective.

FIGS. 4(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of Example 3 of the objective.

FIGS. 5(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of Example 4 of the objective.

FIGS. 6(*a*), (*b*), (*c*) and (*d*) are graphic representations of the various aberrations of Example 5 of the objective.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The present invention is to provide an objective comprising, from front to rear, a positive meniscus 1st lens component convex toward the front, a negative 2nd component, a positive 3rd component and a negative meniscus 4th component with its front aspheric surface concave toward the front, wherein letting f denote the focal length of the entire system and fA the focal length of the air lens forms in a separation between the 1st and 2nd components, the following requirement (1) is fulfilled:

$$-1.5f < fA < -0.5f \tag{1}$$

Further, taking the axial direction as the x-axis and the direction perpendicular to the optical axis as the y-axis, stipulating that the quantity measured in a direction in which the light progresses shall have the positive sign, and locating the original point at the intersection of the vertex of the front surface of the 4th component and the x-axis, the difference Δx between the aspheric surface and a spherical surface assumed to have a radius of curvature equal to that of curvature of the paraxial region of the aspheric surface which contributes to the determination of the focal length is expressed by the following formula:

$$\Delta x = \frac{\left(\frac{1}{r_7^*}\right) y^2}{1 + \sqrt{1 - \left(\frac{y}{r_7^*}\right)^2}} + a_1 y^2 + a_2 y^4 + a_3 y^6 + \ldots + b_1 y^3 + b_2 y^5 + \ldots - \frac{\left(\frac{1}{r_7}\right) y^2}{1 + \sqrt{1 - \left(\frac{y}{r_7}\right)^2}}$$

where r_7 is the radius of curvature of the paraxial region of the front surface of the 4th lens component;

r_7^* is the radius of the curfature of the reference spherical surface of the lens defined by the following formula:

$$r_7 = \frac{1}{\frac{1}{r_7^*} + 2a_1}$$

ai is the coefficient of the i-th even-numbered power term; and

bi is the coefficient of the i-th odd-numbered power term. Then, letting $\Delta x(0.7r_7)$ denote the value of Δx at the height $r_7 \times 0.7$ in y coordinate and $\Delta x(0.5r_7)$ the value of Δx at the height $r_7 \times 0.5$, the following requirements (2) and (3) are fulfilled

$$4.5 \times 10^{-4} < \left| \frac{\Delta \times (0.7r_7)}{f} \right| < 4.0 \times 10^{-3} \tag{2}$$

$$6.5 \times 10^{-3} < \left| \frac{\Delta \times (0.5r_7)}{f} \right| < 1.0 \times 10^{-3} \tag{3}$$

In this embodiment the 1st to 4th lens components take the form of a positive meniscus lens, a bi-concave lens, a bi-convex lens and a negative meniscus lens respectively.

The significance of each of these inequalities is as follows. When the lower limit of inequality (1) is ex-

ceeded, under-correction of spherical aberration results, and the astigmatic difference also increases, resulting in strong inward coma, and the transverse chromatic aberration also increases in the negative sense. When the upper limit is exceeded, over-correction of sagittal image surface results and the astigmatic difference also increases, resulting in strong halo, and the longitudinal chromatic aberration also increases in the negative sense. Therefore, in order to obtain a compact lens system which is well corrected for spherical aberration and astigmatism while keeping coma and halo and further longitudinal and transverse chromatic aberrations to a minimum, it is, of importance to fulfil requirement (1).

Requirement (2) has a particular concern with aberration correction of the marginal zone of the angular field of view.

A lens system with the negative meniscus lens at a rear position as in the present invention, is subject to deterioration of astigmatism in the negative sense as a result of this negative meniscus lens. This causes the production of positive distortion, inward coma and halo. Requirement (2) is to compensate for such deterioration of astigmatism, positive distortion, inward coma and halo. That is, when $|\Delta x(0.7r_7)/f|$ exceeds the lower limit, though the positive distortion and halo can be compensated for, over-correction of sagittal image surface results and strong inward coma is also produced. When the upper limit is exceeded, though correction of coma is possible, sufficient correction of positive distortion becomes impossible. To achieve a good state of correction of the aberrations at the marginal zone of the angular field of view, therefore it is important to fulfil requirement (2).

Requirement (3) concerns aberration correction particularly in the middle zone of the angular field of view.

That is, when $|\Delta x(0.5r_7)/f|$ exceeds the lower limit, under-correction of meridional image surface results and the astigmatic difference also increases, thereby causing strong inward coma. When the upper limit is exceeded, under-correction of spherical aberration results and halo is produced at the middle zone of the angular field of view. To achieve a good state of correction of the aberration at the middle zone, therefore, it is important to fulfil requirement (3).

The use of synthetic resin in making the 4th or aspherical lens can provide an inexpensive photographic objective.

Fulfillment of the following additional requirements (I) and (II) facilitates a shortening of the lens system while simultaneously maintaining the good state of correction of the image aberrations.

$$0.6 < \frac{F_{123}}{|F_4|} < 1.1 \quad \text{(I)}$$

$$0.1 < \frac{D_6}{f} < 0.25 \quad \text{(II)}$$

where

F_{123} is the overall focal length of the 1st, 2nd and 3rd lens components;

F_4 is the focal length of the 4th lens component; and

D_6 is the axial air separation between the 3rd and 4th lens components.

When the lower limit of inequality (I) is exceeded, the refractive power of the front group of the 1st, 2nd and 3rd lens components becomes too strong relative to the refractive power of the rear group, composed of the 4th lens component to shorten the back focal length. Therefore, the total length of the lens system cannot be shortened. When the upper limit is exceeded, under-correction of spherical aberration results, and the astigmatic difference also increases, thereby causing the production of strong halo.

With the total length of the lens system shortened, when the lower limit of inequality (2) is exceeded, sagittal image surface is over-corrected in the marginal zone and under-corrected in the middle zone, and the astigmatic difference also increases. This causes strong inward coma. When the upper limit is exceeded, spherical aberration is under-corrected, which causes the production of extremely large halo.

Five examples of specific objectives can be constructed in accordance with the numerical data given in the following tables. Example 1 of the specific objective is depicted in longitudinal section in FIG. 1. The spherical aberration, astigmatism, distortion and lateral aberration of the objective of FIG. 1 are graphically represented in FIG. 2. Examples 2 to 5 have these aberrations shown in FIGS. 3 to 6 respectively.

In the tables, r are the radii of curvature of the paraxial regions of the various lens surfaces; r_7* the radius of curvature of the reference spherical surface for the aspheric surface satisfying the following equation: $r_7 = 1/(1/r_7^* + 2a_1)$; d the axial thicknesses and air separations between the successive lens surfaces; n the indices of refraction for the spectral d-line of the glasses of which the various lens elements are made up; ν the Abbe numbers of the glasses of which the various lens elements are made up; ai the even coefficients of the aspheric surface; and bi the odd coefficients of the aspheric surface.

	$\lvert\Delta \times (0.5r_7)/f\rvert = 9.3780 \times 10^{-4}$

What is claimed is:

1. A compact photographic objective comprising:

from the front,

a first positive meniscus lens convex toward the front and forming a surface toward the rear,

a second negative lens forming a surface toward the front,

a third positive lens,

a fourth negative meniscus lens having a surface concave toward the front, the concave surface being aspheric,

said first, second, third, and fourth lenses together forming a system having an axial direction and a focal length f,

the opposing surfaces of the first and second lenses forming an air lens having a focal length fA, the values f and fA being related so that

$$-1.5f < fA < -0.5f,$$

taking the axial direction an an x-axis, a direction perpendicular to the optical axis as a y-axis, the forward direction of the light as positive, and the intersection of the vertex of one of the lenses and the x-axis as an origin, the aspheric surface being defined by the following formula for the x-axis directional difference Δx between the aspheric surface and an ideal spherical surface, the latter of which contributes to the determination of the focal length:

$$\Delta x = \frac{\left(\frac{1}{r_7^*}\right) y^2}{1 + \sqrt{1 - \left(\frac{y}{r_7^*}\right)^2}} + a_1 y^2 + a_2 y^4 + a_3 y^6 + \ldots$$

$$+ b_1 y^3 + b_2 y^5 + \ldots - \frac{\left(\frac{1}{r_7}\right) y^2}{1 + \sqrt{1 - \left(\frac{y}{r_7}\right)^2}}$$

where r_7 is the radius of curvature of the paraxial region of the front surface of the 4th lens; r_7^* is the radius of curvature of the reference spherical surface of the lens defined by $r_7 = 1/(1/r_7^* + 2a)$; ai are the even coefficients of the aspheric surface; and bi are the odd coefficients of the aspheric surface, whereby letting $\Delta x\ (0.7r_7)$ denote the value of Δx at the height $r_7 x 0.7$ in y coordinate, and $\Delta x(0.5r_7)$ the value of Δx at the height of $r_7 x 0.5$, and the condition

$$4.5 \times 10^{-4} < \left| \frac{\Delta x(0.7r_7)}{f} \right| < 4.0 \times 10^{-3}$$

$$6.5 \times 10^{-5} < \left| \frac{\Delta x(0.5r_7)}{f} \right| < 1.0 \times 10^{-3}$$

$$0.1 < \frac{D_6}{f} < 0.25$$

being satisfied.

2. A compact photographic objective according to claim 1, wherein said second lens is a negative lens in bi-concave form, and the said third lens is a positive lens in bi-convex form.

3. A compact photographic objective according to claim 1, wherein said fourth lens is made of a synthetic resin.

4. A compact photographic objective according to claim 1, further satisfying the following conditions:

$$0.6 < \frac{F_{123}}{|F_4|} < 1.1$$

where F_{123} is the overall focal length of the 1st lens, said 2nd lens and said 3rd lens; F_4 is the focal length of said 4th lens; and D_6 is the axial air separation between said 3rd and said 4th lenses.

5. An objective as in claims 1, 2, 3, or 4, wherein the origin is the intersection of the vertex of the front surface of the fourth component and the x-axis.

[57] **ABSTRACT**

The variable-focal-length objective for motion-picture cameras and especially color television cameras comprises two movable groups of lens elements placed between two stationary groups of lens elements and capable of displacement so as to produce a variation of the focal distance. In this objective, the two movable groups each take part in the total variation of magnification; each elementary magnification has a minimum and maximum absolute value during the variation, such that the ratio of maximum value to minimum value is higher than 1:1. However, only one of the two movable groups which does not pass through a magnification of unity performs both a magnification function and an additional focusing function. On the other hand, the other movable group which may pass through a position corresponding to a magnification of unity performs only a magnification function.

VARIABLE-FOCAL-LENGTH OBJECTIVE

This invention relates to variable-focus objectives comprising several groups of lens elements which are respectively movable and stationary, the characteristics of these groups being such that the displacement of the movable groups in accordance with a predetermined optical law makes it possible to obtain a continuous variation of the focal length of the corresponding objective.

In more exact terms, the invention relates to variable-focus objectives of the most common type, namely those comprising at least four groups of lens elements, viz:

- a first group which is stationary when the object is placed at infinity but is displaced along the axis in order to adjust the focusing on objects located at a finite distance;
- second and third groups which are movable and permit displacement along the axis in order to vary the magnification produced by these two groups, thus producing a variation in focal length of the system;
- a final stationary group having the principal function of producing the image on a suitable scale.

However, the fact that the front group of lens elements is movable in order to adjust the focusing is subject to a certain number of disadvantages. One of the main disadvantages lies in the fact that objectives of this type have a substantial overall length by reason of the range of travel to be provided for said front group of lens elements.

In consequence, the center of gravity of the objective is located at a distance from the camera, which is a disadvantage since it is usually fixed in an overhung position. Provision must accordingly be made for reinforced fixing means.

Furthermore, by reason of the mobility of the first group of lens elements, steps must be taken to ensure that said elements have a relatively large useful diameter since they are moved to a distance away from the pupil. However, the size and diameter of lenses are attended by a certain number of drawbacks including in particular the weight and cost of fabrication of lenses.

The aim of the present invention is therefore to circumvent these disadvantages by maintaining in a fixed position the first group of lens elements of a variable-focus objective of the type recalled in the foregoing and by carrying out adjustment of focusing by additional displacement of one of the two groups which take part in the variation of magnification.

To this end, the invention is directed to a variable-focal-length objective consisting of two groups of movable lens elements which are capable of displacement along the axis and placed between a group of stationary lens elements at the front end and another group of stationary lens elements at the rear end. An essential feature of the invention lies in the fact that one of the two groups of movable lens elements does not pass through a magnification of unity and performs both a function of variation of magnification and an additional focusing function whilst the other group of movable lens elements which can pass through a position corresponding to a magnification of unity performs solely a function of variation of magnification.

This particular feature makes it possible to solve one of the most difficult problems presented by an objective of this type. In fact, if a movable group which passes through a magnification of unity were employed for performing the additional focusing function, the displacements of said movable group would in that case be excessive with respect to the dimensions of the objective itself. The objective in accordance with the invention overcomes this disadvantage by virtue of the fact that the additional focusing function is assigned to a movable group which does not pass through a magnification of unity.

The design concept of the objective under consideration is such as to provide a certain number of advantages over the variable-focus objectives at present in use.

Thus, irrespective of the focusing distance, the fixity of the first group of lens elements of said objective results in a reduction in diameter of the lens elements of this group by approximately 20%.

In point of fact, this reduction in dimensions secures the following advantages:

- higher relative precision of the active surfaces of the lenses as a result of reduction of deformations under the action of gravity and arising from contact of said lenses with the mechanical support components;
- reduction of the weight of the objective, thus making it easier to fix the objective on a motion-picture camera;
- the center of gravity of the objective is brought nearer to the camera, thus making it easier to balance the objective-camera assembly and permitting greater mobility of the assembly.

Furthermore, the fact that an additional displacement is applied for the purpose of focusing to a group which is already movable makes it possible to dispense with all the guiding means at the level of the front group which is then completely stationary.

In addition, the volume of the objective remains constant irrespective of the focusing distance, thereby limiting gaseous exchanges between the interior and the exterior of the objective while thus reducing any danger of condensation of steam.

In an advantageous embodiment:

- the movable group which takes part solely in the variation of magnification is the group located nearest the stationary element on the object side, said movable group being divergent;
- whilst the other movable group which ensures part of the variation of magnification and permits focusing is divergent.

Moreover, the different components of the objective under consideration comply with a certain number of predetermined conditions which make it possible to obtain a satisfactory objective, the function of these conditions being explained in detail hereinafter.

Thus:

- the absolute value of the focal distance f_1 of the first stationary group is within the range of one-half to double the sum of absolute values of the focal distances f_2 and f_3 of the two movable groups

$$0.5(|f_2|+|f_3|)<|f_1|<2(|f_2|+|f_3|)$$

- the absolute value of the focal distance f_3 of the second movable group is within the range of one to three times the absolute value of the focal distance f_2 of the first movable group

$$|f_2|<|f_3|<3|f_2|.$$

Furthermore, the first movable group satisfies the following conditions:

the group comprises in sequence three divergent lenses and one convergent lens;

the refractive index of these four lenses at a wavelength $\lambda=588$ nm is within the range of 1.60 to 1.85

$$1.60<n_d<1.85$$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$$20<\nu_d<35$$

the absolute value of the radius of curvature of the convergent lens located nearest the preceding divergent lens is within the range of one-half to double the absolute value of the focal distance f_2 of said movable group

$$0.5|f_2|<|R|<2|f_2|$$

the absolute value of the radius of curvature R nearest the object of the first divergent lens is comprised between the absolute value of the focal distance f_2 of said movable group and four times its absolute value

$$|f_2|<|R|<4|f_2|$$

In regard to the second movable group, this latter satisfies the following conditions:

said group comprises in sequence two divergent lenses and one convergent lens;

the refractive index of these three lenses at a wavelength $\lambda=588$ nm is within the range of 1.60 to 1.85

$$1.60<n_d<1.85$$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$$20<\nu_d<35$$

the absolute value of the radius of curvature of the convergent lens nearest the preceding divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$$0.5|f_3|<|R|<2|f_3|$$

the absolute value of the radius of curvature nearest the object of the first divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$$0.5|f_3|<|R|<2|f_3|.$$

Finally, the first convergent stationary group preferably comprises in sequence two divergent lenses, one convergent lens, a cemented doublet consisting of a divergent lens and a convergent lens, and two convergent lenses:

the absolute value of the radius of cementing of the doublet is within the range of one-half to three times the absolute value of the focal distance of said stationary group

$$0.5|f_1|<|R|<3|f_1|$$

the absolute value of the radius of curvature nearest the object of the first divergent lens is within the range of one-half to three times the absolute value of the focal distance of said stationary group

$$0.5|f_1|<|R|<3|f_1|$$

One example of construction of a variable-focal-length objective in accordance with the invention is described hereinafter with reference to the accompanying drawings which are given by way of indication and in which:

FIGS. 1A and 1B are the two complementary portions of an axial sectional view of the different groups of lens elements of the objective under consideration, these two portions being joined together along the line A-B which passes through the plane of the diaphragm of said objective;

FIGS. 2A to 2D show the curves of spherical aberration, the curves of field curvature and of distortion in respect of four positions of the movable groups corresponding to overall focal distances of the objective of 18, 50, 120 and 270 mm.

Below air spacings values e13, e20, e25 in the proposed example, in relationship with the four focal distances values F=18, F=50, F=120, and F=270, for which residual aberration curves are given.

	F = 18	F = 50	F = 120	F = 270
e13	0.288 mm	61.951 mm	96.069 mm	113.520 mm
e20	114.323 mm	47.646 mm	18.800 mm	29.742 mm
e25	30.000 mm	35.014 mm	29.742 mm	6.550 mm

The above values correspond to focussing at infinity.

The objective illustrated in the drawings comprises four groups of lens elements, namely two movable groups II and III placed between two stationary groups I and IV.

The three first groups I, II and III are placed in front of the diaphragm D whilst the fourth group IV is placed behind said diaphragm. This fourth and last group is stationary and has the function of forming an image having the desired size at a given distance which is relatively substantial with respect to the overall focal distance in order to make provision for a beam-splitting prism for spectral analysis of light in the particular application of camera shooting for color television and in order to perform corrections for aberrations introduced by the preceding groups. It should be noted in this connection that the fixity of this group and its arrangement behind the diaphragm constitute a particularly advantageous solution. In fact, this combination makes it possible to ensure fixity of the exit pupil of the objective, which is advantageous when the image produced by the objective is processed by another optical system such as a beam-splitting prism P or an optical relay, for example.

Of the two movable groups II and III, the group which is placed in front, namely group II, has the sole function of variation of the focal length of the objective. This group, however, is intended to pass through a magnification of unity.

On the other hand, the design concept of the system is such that the second movable group III does not pass at all through a magnification of unity. In accordance with the invention, this group possesses both a function

of variation in focal length of the objective and an additional function of focusing of the system.

Finally, the stationary front group I has the intended function of producing a real image of the object which is variable both in position and in magnification according to the position of the object 1.

The first group I, which is stationary, comprises seven lens elements, namely a divergent meniscus lens whose convex face is directed towards the object, a biconcave divergent lens, a convergent meniscus lens, a cemented doublet constituted by a divergent lens and a biconvex convergent lens, a biconvex convergent lens and a convergent meniscus lens whose convex face is directed towards the object.

In regard to the first movable group II, this group is made up of four lens elements, namely a divergent meniscus lens whose convex face is directed towards the object, a divergent lens, a doublet constituted by a biconcave divergent lens and a convergent lens.

So far as the second movable group III is concerned, this group is made up of three lens elements, namely a biconcave divergent lens, a doublet constituted by a biconcave divergent lens and a biconvex convergent lens.

Finally, the fourth group, which is stationary, can comprise eleven lens elements, namely two biconcave convergent lenses, a doublet constituted by a biconvex convergent lens and a divergent lens, a doublet constituted by a convergent lens and a divergent lens, a convergent lens, a convergent meniscus lens, a biconcave divergent lens, and two convergent lenses.

The table given hereinafter will in any case specify the values of the different radii of curvature of the lenses of these different groups as well as the values of the air spaces and thicknesses of lenses. The references R1, R2 and R3 designate the radii of curvature of the lenses and are followed by the + sign when their convex faces are directed towards the front and by the − sign in the contrary case. However, this table also indicates the other applied characteristics of the lenses Thus the reference n_d indicates the refractive index relating to each lens in respect of the spectral line d (λ=588 nm) whilst the reference ν_d designates the value of the Abbe number.

On the basis of the values thus established, the focal distances f1, f2 and f3 of the first three groups are respectively as follows: f1=131.143, f2=−45.384 and f3=−79.526.

In consequence, it can be observed that the objective herein described by way of example fully satisfies the different supplementary conditions which were set forth earlier.

The following inequalities may in fact be noted:

(1) $0.5|f1|-|R1|<3|f1|$

(2) $0.5|f1| < |R8| < 3|f1|$
(3) $1.60 < nd21\ 1.85$
(4) $20 < \nu_d < 35$
(5) $|f2| < |R14| < 4|f2|$
(6) $0.5|f2| < |R19| < 2|f2|$
(7) $0.5|f3| < |R21| < 2|f3|$
(8) $0.5|f3| < |R24| < 2|f3|$
(9) $0.5(|f2| + |f3|) < |f1| < 2(|f2| + |f3|)$
(10) $|f2| < |f3| < 3|f2|$

where R1 to R24 define in sequence the radius of curvature of the constituent surfaces of the lens elements of the objective which are numbered from the surface nearest the object.

n_d and ν_d represent the refractive indices for the wavelength $\lambda = 588$ nm and the Abbe number of the lens elements constituting the two movable groups.

The respective functions of the different conditions given above are as follows:

Condition (1) is necessary for correcting the distortion when the objective is employed at short focal distances.

Condition (2) is necessary for correcting spherical aberration and chromatic aberration when the objective is employed at long focal distances.

Condition (3) is necessary for correcting the Petzval curvature as well as the residual spherical aberration of the front stationary group.

Condition (4) is necessary for correcting the residual longitudinal chromatic aberration of the front stationary group.

Condition (5) is necessary for correcting the distortion of the objective.

Condition (6) is necessary for correcting the residual spherical aberration of the objective as well as part of the longitudinal chromatic aberration.

Condition (7) is necessary for correcting the residual distortion of the objective.

Condition (8) is necessary for correcting the residual spherical aberration of the objective as well as part of the longitudinal chromatic aberration.

Condition (9) is necessary for fabricating an objective having small overall size and weight.

Condition (10) is necessary for correcting the Petzval curvature throughout the positional variation of the two movable groups.

It should be noted that the objective in accordance with the invention is not limited solely to the embodiment which has been described in the foregoing and which constitutes only an example.

Thus the first movable group can be constituted in a different manner. Instead of comprising in sequence three divergent lenses and one convergent lens, said group could be constituted in sequence by: two divergent lenses, one convergent lens and one divergent lens.

So far as the second movable group is concerned, this group could comprise in sequence one divergent lens, one convergent lens and one divergent lens instead of being constituted by two divergent lenses and one convergent lens.

What is claimed is:

1. A variable-focal-length objective consisting of two movable groups of lens elements which are capable of displacement along the axis and placed between two other stationary groups of lens elements, the displacement of said two movable groups and solely of said two groups being such as to produce a variation of the focal distance and to maintain the image in a fixed plane in respect of any object located at distances chosen at will between finite values and infinity or focusing distance in front of the first stationary group of lenses, wherein:

the two movable groups are divergent and each takes part in the total variation of magnification, each elementary magnification being such as to have a minimum and maximum absolute value during the variation, the ratio of maximum value to minimum value being higher than 1:1;

only one of the two movable groups which does not pass through a magnification of unity performs both a magnification function and an additional focussing function;

the other movable group which may pass through a position corresponding to a magnification of unity performs only a magnification function, said other movable group being nearest the stationary element on the object side;

each movable group comprises at least three lens elements in the case of one group and two lens elements in the case of the other group.

2. A variable-focal-length objective according to claim **1**, wherein the respective focal values:

f_1 of the first stationary group
f_2 of the first movable group
f_3 of the second movable group

satisfy the following two conditions:

the absolute value of the focal distance f_1 of the first stationary group is within the range of one-half to double the sum of absolute values of the focal distances f_2 and f_3 of the two movable groups

$$0.5(|f_2| + |f_3|) < |f_1| < 2(|f_2| + |f_3|)$$

the absolute value of the focal distance f_3 of the second movable group is within the range of one to three times the absolute value of the focal distance f_2 of the first movable group

$$|f_2| < |f_3| < 3|f_2|$$

3. A variable-focal-length objective according to claim **2**, wherein the first movable group satisfies the following conditions:

said first movable group comprises in sequence three divergent lenses and one convergent lens;

the refractive index for the wavelength $\lambda = 588$ nm of the four lenses aforesaid is within the range of 1.60 to 1.85

$$1.60 < n_d < 1.85$$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$$20 < \nu_d < 35$$

the absolute value of the radius of curvature of the convergent lens which is nearest the preceding divergent lens is within the range of one-half to double the absolute value of the focal distance f_2 of said movable group

$$0.5|f_2| < |R| < 2|f_2|$$

the absolute value of the radius of curvature R nearest the object of the first divergent lens is comprised between the absolute value of the focal distance f_2 of said movable group and four times its absolute value

$|f_2| < |R| < 4|f_2|$

4. A variable-focal-length objective according to claim 2, wherein the first movable group satisfies the following conditions:

said first movable group comprises in sequence two divergent lenses, one convergent lens and one divergent lens;

the refractive index for the wavelength $\lambda = 588$ nm of the four lenses aforesaid is within the range of 1.60 to 1.85

$1.60 < n_d < 1.85$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$20 < \nu_d < 35$

the absolute value of the radius of curvature of the convergent lens located nearest the following divergent lens is within the range of one-half to double the absolute value of the focal distance f_2 of said movable group

$0.5|f_2| < |R| < 2|f_2|$

the absolute value of the radius of curvature R nearest the object of the first divergent lens is comprised between the absolute value of the focal distance f_2 of said movable group and four times its absolute value

$|f_2| < |R| < 4|f_2|$

5. A variable-focal-length objective according to claim 2, wherein:

the second movable group comprises in sequence two divergent lenses and one convergent lens,

the refractive index for the wavelength $\lambda = 588$ nm of the three lenses aforesaid is within the range of 1.60 to 1.85

$1.60 < n_d < 1.85$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$20 < \nu_d < 35$

the absolute value of the radius of curvature of the convergent lens located nearest the preceding divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$0.5|f_3| < |R| < 2|f_3|$

the absolute value of the radius of curvature nearest the object of the first divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$0.5|f_3| < |R| < 2|f_3|$

6. A variable-focal-length objective according to claim 2, wherein:

the second movable group comprises in sequence one divergent lens, one convergent lens and one divergent lens;

the refractive index for the wavelength $\lambda = 588$ nm of the three lenses aforesaid is within the range of 1.60 to 1.85

$1.60 < n_d < 1.85$

and the Abbe number ν of the convergent lens is within the range of 20 to 35

$20 < \nu_d < 35$

the absolute value of the radius of curvature of the convergent lens located nearest the following divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$0.5|f_3| < |R| < 2|f_3|$

the absolute value of the radius of curvature nearest the object of the first divergent lens is within the range of one-half to double the absolute value of the focal distance f_3 of said movable group

$0.5|f_3| < |R| < 2|f_3|$

7. A variable-focal-length objective according to claim 2, wherein the first convergent stationary group comprises in sequence two divergent lenses, one convergent lens, one cemented doublet constituted by a divergent lens and a convergent lens, and two convergent lenses:

the absolute value of the radius of cementing of the doublet is within the range of one-half to three times the absolute value of the focal distance of said stationary group

$0.5|f_1| < |R| < 3|f_1|$

the absolute value of the radius of curvature nearest the object of the first divergent lens is within the range of one-half to three times the absolute value of the focal distance of said stationary group

$0.5|f_1| < |R| < 3|f_1|$

[57] **ABSTRACT**

A still camera with a fold up cover, a retracting objective and a drive connection between these components acting within the light tight camera space on the objective mount so that the objective is advanced when the cover is opened and retracted when the cover is shut.

The camera has the following features:

(a) the drive connection is divided into outer drive links (**4–5, 6, 7**) and inner drive links (**10, 11**);

(b) the outer drive links (**4–5, 6, 7**) are connected with the cover (**3**) so as to positively control the cover;

(c) the inner drive links (**10, 11**) are connected with the objective mount (**2**) so as to positively control the mount; and

(d) the connection between the outer and inner drive links consists of a round shaft (**8**) supported in a bore (**9**) of the housing (**1**) with a light tight snug fit.

STILL CAMERA WITH RETRACTING OBJECTIVE

CROSS REFERENCE TO RELATED APPLICATION

Applicant claims priority under 35 USC 119 for application P 30 20 340.8, filed May 29, 1980 in the Patent Office of the Federal Republic of Germany.

BACKGROUND OF THE INVENTION

The present invention relates to a still camera having a flip open cover and a retractable objective connected with the cover so that the objective is pulled out as the cover is folded open and is retracted when the cover is folded shut.

In the prior art still cameras of this kind, the light tightness is a special problem. This problem is solved for simple cameras by inserting a bellows between the objective seat and the camera housing, where this bellows can be folded together.

However, this kind of design is unsuited for small cameras with solid housings and where because of compactness the objective in the retracted position is fully sunk into the housing and thereby comes to rest directly on the film plane. The latter characteristic makes it impossible to implement a direct operational connection between the cover and a mount remaining outside for the retracted state, which otherwise would ensure light tightness. Only such an operational connection is possible, which on the one hand acts on the objective mount in the light tight camera space and on the other hand acts on the cover outside this light tight space. This necessitates a passageway through the housing wall in order to arrive from the outside cover to the inside mount by means of one or several drive links in order that, if possible at all, the objective be moved from its inside limit position into its picture taking position by one opening motion of the cover. This passageway must be light tight itself.

SUMMARY OF THE INVENTION

Having in mind the limitations of the prior art, it is an object of the present invention to provide such a passageway which shall be simple in design and construction and therefore easily manufactured and nevertheless absolutely light tight.

This object is achieved by the present invention for a camera having the following features:

(a) the operational connection between the flip cover and the objective mount is divided into outer and inner drive means;

(b) the outer drive means are connected to the cover so that they will be positively controlled by it;

(c) the inner drive means are connected with the objective mount so that it will positively control them; and

(d) the connection between the outer and inner drive means consists of a round shaft supported in a housing bore with a light tight fitted seat.

The passageway from the outer space into the light tight camera inner space therefore consists in accordance with the present invention solely of a round bore within which rotates a round shaft. This bore can be easily made commercially, and the bore and the shaft can easily be implemented with such respective fits that no light shall reliably enter the camera inner space. For increased safety the shaft moreover may be provided with an offset, a collar or the like which together with a matchingly shaped bore offset would form a labyrinth.

In a particular embodiment of the concept leading to the solution, the outer drive means are a four link device of which the fixed link is formed by the camera housing and of which the coupler is so connected to the swinging member by an elongated slot in this swinging member that the drive means, due to spring support when the cover is flipped shut, arrives at a top dead position where the cover is firmly resting against the housing by spring action.

The inner drive means consist of a plain swing lever comprising an elongated slot at its free end to act on a pin fixed into the objective mount. If the lever is pivoted, the objective is moved to and fro by this pin/elongated slot connection.

The present invention provides a further embodiment in the form of a locking system for the objective when in its front picture taking position, where the system cooperates with the swing lever. The system consists of a locking lever pivotably supported in the rear, light tight camera inside space and snapping into position under spring pressure by means of a locking surface behind the pin fixed to the objective mount.

The locking lever itself comprises a fixed pin cooperating by means of a bevel with the free end of the swing lever. Due to this cooperation, first the locking lever is lifted out of its locking position at the beginning of the fold in motion of the cover, before the retraction motion of the objective begins. To that end the elongated slot in the swing lever is somewhat widened at this location so that the swing lever at the beginning of motion moves through an idle path with respect to the objective mount, during which course it is lifted out of the locking position. Only the pin will thereafter be at the objective mount and hence the entire objective is carried along in the retraction motion.

BRIEF DESCRIPTION OF THE DRAWINGS

The appended drawings illustrate the present invention in relation to one embodiment, wherein:

FIG. **1** is a schematic section through a still camera with the retracting objective system of the present invention;

FIG. **2** is a schematic section through a camera as in FIG. **1** but with the extended objective; and

FIG. **3** is a front view of the camera shown partly in section.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

With particular reference to FIG. **1**, the camera housing is designated by **1** and holds at its front side an objective in a mount **2** which is displaceably supported. A light sealing element, for instance a felt strip, a rubber ring or the like is inserted in known manner between the front side and the objective mount, so that it is feasible to move the objective through the front side without light penetrating the camera inside space.

A cover **3** covers the objective at the camera front side and this cover pivots around a shaft **4** fixed to the housing.

A lever **6** is pivotably connected to the cover at point **5** and is connected at its other end in rotational manner to a lever **7**. This lever **7** is fixed to a point in the camera housing but is capable of rotation by means of a shaft.

The lever arms between the shaft **4** and the point **5** at the cover **3**, the lever **6** and the lever **7** are the outer

drive links of a drive linkage mounted between the cover **3** and the objective mount **2** and effecting the advance of the objective when the cover is folded open and the retraction of the objective when the cover is folded shut, as described further below.

In terms of linkages, these outer drive links form a four link structure, where the spacing between the shaft **4** and the point **5** represents the crank, the lever **6** the coupler and the lever **7** the swing means.

The motion of the lever **7** is transmitted by the shaft **8** to the inside drive links of the side drive linkage. This shaft **8** projects through a bore **9** (FIG. **3**) into the light tight camera inner space. The bore thus represents the transition from the light permeable outer space into the light tight inner space. As the bore and the shaft are round, they are easy to make commercially and for a sufficiently tight snug fit between shift and bore they provide a wholly light tight passageway.

The inside drive links consist of a swing lever **10** solidly connected at one end to the shaft **8**, and of a pin **11** which is fixed to the objective mount. The swing lever **10** at its free end is provided with an elongated slot **12** surrounding the pin **11**.

Due to the solid connection between the swing lever **10** and the shaft **8**, the swing lever is moved along with every shaft rotation and pivoted. If, therefore the cover **3** is folded open or shut, the outer drive links perforce are displaced and hence the swing lever **10** also is pivoted to and fro between two end positions. Therefore, the objective through its mount **2** also is advanced or retracted by means of the elongated slot **12** and the pin **11**.

As shown by FIG. **3**, the outer and inner drive links are present in duplicate, on each side of the objective mount **2** in a symmetrical arrangement to this mount. Therefore, the displacing force acts symmetrically on the objective mount and tilting of the objective during the displacement is prevented on account of the shaft **8** which is common to the swing levers **10** mounted on both sides of the objective.

In order that the cover **3** when in its folded shut position shall also always rest securely against the camera housing, the rotational connection between the levers **6** and **7** is designed in a special manner. To that end the lever **7** is provided with a small elongated slot within which the lever **6** can easily slide to and fro by means of a pin. Moreover, a compression spring **13** is mounted between the levers **6** and **7**. The arrangement is such that for the shut position of the cover **3**, the lever **6** arrives at a sort of top dead point position into which it is pressed by spring **13**. Accordingly, the cover **3** always rests under some stress against the housing **1** when in the closed position.

In the picture taking position of the objective, the mount **2** rests by means of a collar **2***a* against the inside of the front housing wall (FIG. **2**). This stop position is precisely defined. It is adjusted to the back lens/image distance of the objective. The objective also must be locked in this position so it cannot be accidentally displaced during picture taking. A locking lever **14** is provided for that purpose which is pivotably supported at **15** in the rear area of the light tight camera inside space and is stressed by a compression spring **16**. When now the objective is advanced by means of the swing lever **10**, then the pin **11** fixed to the mount slides underneath a slanted surface **14***a* of the lever **14** which thereby is raised against the force of the spring **16**. When the forward objective position is reached, the lever **14** with its slanted surface **14***b* falls behind the pin **11** of the objective and locks it into the picture taking position.

When it is desired to fold shut the cover **3** and hence to retract the objective, then first the locking lever **14** must be lifted out of its locked position. This takes place at the beginning of the pivoting motion of the lever **10** by means of a slanted surface **10***a* fashioned at the lever **10** and cooperating with a pin **17** which is firmly seated on the locking lever **14**. At the beginning of the fold shut motion of the cover **3**, this slanted surface—still before the objective mount **2** starts moving—impacts the pin **17** and raises the lever **14** and only then does the retraction of the mount **2** begin.

To make this possible, the elongated slot **12** is kept somewhat wide in this area. The swing lever **10** therefore at the beginning of the retraction first passes through a short idle path relative to the pin **11**. During this idle course the locking lever **14** is lifted against the force of the spring **16**, so that thereafter the objective together with its mount **2** is retracted.

I claim:

1. In a still camera having a housing, a fold up cover, a retracting objective and a drive connection between these components acting within the light tight camera space on an objective mount so that the objective is advanced when the cover is opened and retracted when the cover is shut, the improvement comprising the following features in combination:

(a) said drive connection divided into outer drive links (**4–5, 6, 7**) and inner drive links (**10, 11**);

(b) said outer drive links (**4–5, 6, 7**) connected with said cover (**3**) so as to positively control said cover;

(c) said inner drive links (**10, 11**) connected with said objective mount (**2**) so as to positively control said mount; and

(d) a connection between the outer and inner drive links consisting of a round shaft (**8**) supported in a bore (**9**) of said housing (**1**) with a light tight snug fit.

2. The still camera of claim **1**, wherein said round shaft (**8**) is provided with at least a first offset and said bore (**9**) comprises identically shaped second offsets which together with said first offset define a light tight labyrinth.

3. The still camera of claim **1**, wherein outer drive links consist of a four link mechanism comprising a crank (levers **4-5**) supported on a pivot shaft (**4**) of said cover (**3**) and a swing member (lever **7**) supported by said round shaft (**8**) extending into the camera inside.

4. The still camera of claim **3**, wherein a lever (**6**) is connected in rotational manner to said swing member (**7**) and to said crank (**4-5**) and a compression spring is mounted between said lever (**6**) and said swing member (**7**) which for said cover (**3**) folded shut effects a tilting of said lever (**6**) in an elongated slot in said swing lever into a top dead center position and thereby insures a firm rest of said cover (**3**) against said housing.

5. The still camera of claim **1**, wherein said inner drive links consist of a swing lever (**10**) solidly connected to said round shaft (**8**) for the purpose of common rotation and of a pin (**11**) fixed to said objective mount (**2**) and subjected to the action of said swing lever (**10**) by means of an elongated slot (**12**) therein.

6. The still camera of claim **2**, provided with a spring-loaded locking lever (**14**) in the light tight camera inside space to act on said objective mount (**2**) when it is in the picture taking position, said locking lever being pivotably supported in a rear camera space and being pro-

vided at its front end with a slanted locking surface (**14***b*) that engages behind a first pin (**11**) fixed to said objective mount when in the locked state and with a second pin (**17**) cooperating with a swing lever (**10**).

7. The still camera of claim **6**, wherein said swing lever (**10**) is provided with a slanted surface (**10***a*) against which rests said second pin (**17**) fixed to said locking lever when said objective is in the advanced position, where the slope of said slanted surface is such that at the beginning of the cover folding shut motion said locking lever (**14**) is first raised out of its locking position by said slanted surface (**10***a*) and said second pin (**17**).

[57] **ABSTRACT**

In the device disclosed, eight elements form a Gauss type wide or large aperture objective. The first element counting from the front is a positive meniscus lens of forward convexity, the second is a positive lens of convex curvature toward the front, the third is cemented to the second and is a negative lens of concave curvature toward the rear, the fourth is a negative lens of concave curvature toward the front, the fifth is cemented to the fourth and is a positive lens of convex curvature toward the rear, the sixth is a positive meniscus lens of rearward convexity, the seventh is a bi-convex lens with the rear surface of stronger curvature, and the eighth is a positive lens. The front surface of the second lens is aspherical so that as the distance from the optical axis increases, the deviation of the surface from the spherical surface of paraxial radius increases in a direction toward the front.

GAUSS TYPE LARGE APERTURE PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to large, or wide, aperture photographic objectives, particularly in the 50 mm focal length, F/1.2 class, and more particularly, to objectives using an aspherical surface for maintaining a long back focus and providing extremely good correction for flare at the fully open aperture, and also providing good correction for spherical aberration, field of curvature, and coma.

2. Description of the Prior Art

A Gauss type lens produces flare (sagittal flare) mainly because the forward and rearward lens surfaces adjacent the diaphragm are strong in negative curvature. However, limiting the curvature of these surfaces causes rapid deterioration in quality due to spherical aberrations and field curvature.

The index of refraction of the positive lens may be increased to facilitate aberrational corrections. However, optical glasses having the high refractive indices required for this purpose are not available at the present time. Therefore, in F/1.2 class lenses, effective removal of flare at fully open aperture, spherical aberration, and curvature of field becomes difficult with a spherical system.

An objective which corrects for flare and various aberrations using an aspherical surface is disclosed in Japanese Patent Publication No. Sho 47-19386, assigned to the assignee of the present invention.

SUMMARY OF THE INVENTION

The present invention makes the first surface of the second lens aspherical like in the above-cited Japanese Patent Publication No. Sho 47-19386. The aspherical surface is configured so that proceeding radially outwardly from the optical axis, the positive power is weakened. This makes possible extremely good compensation for the deteriorated spherical aberration due to the weakening of the negative curvature of the lens surfaces forwardly and rearwardly adjacent to the diaphragm. Further the use of a positive lens made up of a higher refractive index glass than that used in the above-described lens makes it possible even to correct the field of curvature properly. This achieves good correction of flare at the fully open aperture and the various aberrations.

The main feature of the present invention is, as will be described later, to provide a Gauss type eight-element objective with a wider image angle than was in the prior art while nevertheless solving the aberrational problem by satisfying the following conditions.

$$1.24 < \frac{D3 + D4}{D6 + D7} < 1.4 \quad (1)$$

$$1 < \frac{L}{f} < 1.1 \left(L = \sum_{i=1}^{13} Di \right) \quad (2)$$

$$1.78 < \frac{N1 + N2 + N5 + N6 + N7}{5} < 1.89 \quad (3)$$

$$2.17 < \frac{f}{R5} < 2.56 \quad (4)$$

-continued

$$2.44 < \frac{f}{|R6|} < 2.7 \quad (5)$$

$$f6 < f7 < f8 \quad (6)$$

$$0.08 < n2 - n3 < 0.22 \quad (7)$$

$$0.1 < \frac{f}{R4} < 0.5 \quad (8)$$

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a lens block diagram of an embodiment of the present invention.

FIGS. **2** and **3** are aberration curves of Example 1 of the present invention.

FIGS. **4** and **5** are aberration curves of Example 2 of the present invention.

FIGS. **6** and **7** are aberration curves of Example 3 of the present invention.

FIGS. **8** and **9** are aberration curves of Example 4 of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

An embodiment of an objective according to the present invention comprises, from front to rear, a positive first lens of meniscus shape of convex curvature toward the front, a positive second lens of convex curvature toward the front, a negative third lens of concave curvature toward the rear, a negative fourth lens of concave curvature toward the front, a positive fifth lens of convex curvature toward the rear, a positive sixth lens of meniscus shape of convex curvature toward the rear, a bi-convex positive seventh lens with its rear surface of stronger curvature, and a bi-convex eighth lens, the 2nd and 3rd lens being cemented together, the 4th and 5th lenses being cemented together, and a diaphragm being arranged in a space between the 3rd and 4th lenses. Letting **R1** to **R14** denote the radii of curvature of the various lens surfaces, **D1** to **D13** the axial thicknesses of the various lenses and the axial separations between the successive lenses, **N1** to **N8** the indices of refraction (for d-line) of the various lenses, ν**1** to ν**8** the Abbe numbers of the various lenses, f the focal length of the entire system, **f6**, **f7** and **f8** the focal lengths of the 6th, 7th and 8th lenses respectively, and the first surface of the 2nd lens being an aspherical surface of such configuration that as is farther distant radially outwardly of the optical axis, the amount of deviation of the surface from the spherical surface of paraxial radius of curvature increases in a direction toward the front, the Gauss type large aperture photographic objective is characterized by satisfying the following conditions:

$$1.24 < \frac{D3 + D4}{D6 + D7} < 1.4 \quad (1)$$

$$1 < \frac{L}{f} < 1.1 \left(L = \sum_{i=1}^{13} Di \right) \quad (2)$$

$$1.78 < \frac{N1 + N2 + N5 + N6 + N7}{5} < 1.89 \quad (3)$$

$$2.17 < \frac{f}{R5} < 2.56 \quad (4)$$

-continued

$$2.44 < \frac{f}{|R6|} < 2.7 \quad (5)$$

$$f6 < f7 < f8 \quad (6)$$

$$0.08 < n2 - n3 < 0.22 \quad (7)$$

$$0.1 < \frac{f}{R4} < 0.5 \quad (8)$$

Thus, the objective of the present invention is of the Gauss type with eight elements, and provides good correction for the various aberrations and particularly flare over the extended range of the image angle without stress when the various afore-mentioned conditions are satisfied. These various conditions are next described in greater detail.

Condition (1) serves for maintaining the necessary back focus. Below the lower limit, when the back focus becomes longer than necessary, and the diameter of the rear lens is increased, thus increasing the bulk and size of the objective. If the entire length is maintained constant, it also becomes a cause of increasing the diameter of the diaphragm.

Conversely, above the upper limit, when the back focus becomes too short, the mirror up function of the camera now becomes too difficult to perform.

Condition (2) defines the total length of the objective. The more compact the objective, the more convenient for portability. Below the lower limit, it is difficult to properly remove the flare at the fully open aperture. Above the upper limit, in order to assure a sufficient marginal amount of light, the diameters of the front and rear lenses are both required to be increased, thus increasing the bulk and size of the objective as the total length is also increased.

Condition (3) is a condition for using a high refractive index glass particularly in the positive lens of strong power. Below the lower limit, it becomes difficult to correct both flare and field curvature. And, the upper limit represents the maximum refractive index value in the glasses available on the market at the present time.

Conditions (4) and (5) when combined with condition (3) to well remove the flare (mainly the sagittal flare) while maintaining good correction of field curvature. Above the upper limit, the negative curvature of each of these surfaces is strong so that the flare removal effect is too weak. Conversely below the lower limit, when the negative curvature becomes too weak, although the flare at the fully open aperture only can be effectively removed, the Petzval sum becomes too large to prevent the deterioration of the field curvature. This makes it difficult to achieve an increase in the performance.

Condition (6) when combined with condition (1) serves to reduce the diameter of the rear lens to a necessary minimum or thereabout (the diameter determined by the fully open F-number light bundle), while maintaining the necessary amount in back focus. That is, of the 6th, 7th and 8th positive lenses, the refractive power is made stronger in the order nearer to the diaphragm so that as the light bundle of the maximum image angle after having passed through the diaphragm is first refracted toward the optical axis by the 6th lens of strong refractive power, and then proceeds to the 7th and 8th lenses successively, the diameter of the rear lens can be decreased without difficulty. Also since the gentle passage of the light bundle is possible, spherical aberration and coma can be corrected with ease. When the conditions are not satisfied, an increase in the diameter of the rear lens and deterioration of the spherical aberration and coma result and an increase in performance becomes difficult to achieve.

Condition (7) prevents the field curvature from increasing when the range of image angles is extended and minimizes the Petzval sum by defining, for the cemented second and third lenses, somewhat of a difference in refractive indices. Below the lower limit, the Petzval sum deteriorates. Above the upper limit, no combinations of glasses for use in the positive and negative lenses corrected for chromatic aberrations is available at the present time and an under-correction of longitudinal chromatic aberration (g-line) results.

Condition (8) when combined with condition (7) and the aspherical configuration facilitates good correction of both astigmatism and distortion. That is, the first or aspherical surface of the second lens produces over-corrected astigmantism and barrel type distortion, a part of which must be compensated for by the cemented surface R4, and somewhat refractive power must be had. Also, for ease of correction, a concentric configuration to the diaphragm is preferred. When this condition is not satisfied, the balance of the astigmatism and distortion is broken, and it becomes difficult to properly correct both of them. Further a problem arises in selecting glasses for use in the second and third lenses to correct chromatic aberration.

By satisfying the conditions as above, it is possible to provide a photographic large aperture objective with an image angle of 46° where F-number = 1.2 which has flare limited to an extremely low level at the fully open aperture, and moreover, is properly corrected even for spherical aberration, curvature of the field and coma as will be seen from the examples of practical objectives of the invention.

Further, focusing of the objective in the embodiment of the present invention is performed by moving the 1st to 7th lenses only, while the 8th lens remains stationary. Hence, excellent image quality can be maintained throughout the focusing range. Particularly, when the range of variation of coma and astigmatism can be reduced to zero.

It is noted that the above-mentioned aspherical configuration may be expressed by the following formula:

$$X = R\{1-(1-H^2/R^2)^{\frac{1}{2}}\} + AH^2 + BH^4 + OH^6 + DH^8 + EH^{10}$$

where

R: the radius of curvature in the paraxial region.

H: the height from the optical axis.

X: the axial deviation of the surface at the height H from the optical axis with reference to the vertex of the surface (the direction in which the light advances is taken as plus)

A–E: aspheric coefficients.

In the following, the numerical data of examples of specific objectives of the invention are given. Table 1 shows the values of the factors in the above-described various conditions for Examples 1 to 4 of the invention.

What is claimed is:

1. A Gauss type large aperture photographic objective comprising eight elements of which:

the first is a positive meniscus lens of convex curvature toward the front,

the second is a positive lens of convex curvature toward the front,

the third is a negative lens of concave curvature toward the rear,

the fourth is a negative lens of concave curvature toward the front,

the fifth is a positive lens of convex curvature toward the rear,

the sixth is a positive meniscus lens of convex curvature toward the rear,

the seventh is a bi-convex positive lens with its rear surface of stronger curvature, and

the eighth is a positive lens,

said second and third lenses being cemented together,

said fourth and fifth lenses being cemented together,

the first surface of said second lens being aspherical, its aspherical configuration being such that as the distance from the optical axis increases, the deviation of the surface from the spherical surface of paraxial radius of curvature increases toward the front, and said objective being characterized by satisfying the following conditions:

$$1.24 < \frac{D3 + D4}{D6 + D7} < 1.4 \quad (1)$$

-continued

$$1 < \frac{L}{f} < 1.1 \left(L = \sum_{i=1}^{13} Di \right) \quad (2)$$

$$1.78 < \frac{N1 + N2 + N5 + N6 + N7}{5} < 1.89 \quad (3)$$

$$2.17 < \frac{f}{R5} < 2.56 \quad (4)$$

$$2.44 < \frac{f}{|R6|} < 2.7 \quad (5)$$

$$f6 < f7 < f8 \quad (6)$$

$$0.08 < n2 - n3 < 0.22 \quad (7)$$

$$0.1 < \frac{f}{R4} < 0.5 \quad (8)$$

wherein

R1, R2, . . . , R14 are the radii of curvature of the various lens surface,

D1, D2, . . . , D13 are the axial thicknesses of the various lenses and the axial separations between the successive lenses,

N1, N2, . . . , N8 are the indices of refraction of the various lenses (d-line),

ν1, ν2, . . . , ν8 are the Abbe numbers of the various lenses,

f is the focal length of the entire system,

f6, f7 and f8 are the focal lengths of the 6th, 7th and 8th lenses respectively.

[57] **ABSTRACT**

A television camera objective has a driving mechanism for adjusting components of its optical system and is adapted selectively replaceably to receive either a servo control driving unit or a manual control driving unit. Either type of driving unit has a driving shaft that engages with a rotary transmission shaft that remains in place on the driving mechanism. To prevent the transmission shaft from rotating in the absence of a driving unit, the transmission shaft has a flange against which a sliding sleeve is spring urged into braking frictional engagement. The introduction of the driving unit pushes back this sleeve to disengage the frictional surfaces and release the transmission shaft for rotation. In addition, the sleeve can be manually pulled back and rotated to lock it in a disengaged position, so as intentionally to free the transmission shaft for rotation in the absence of a driving unit.

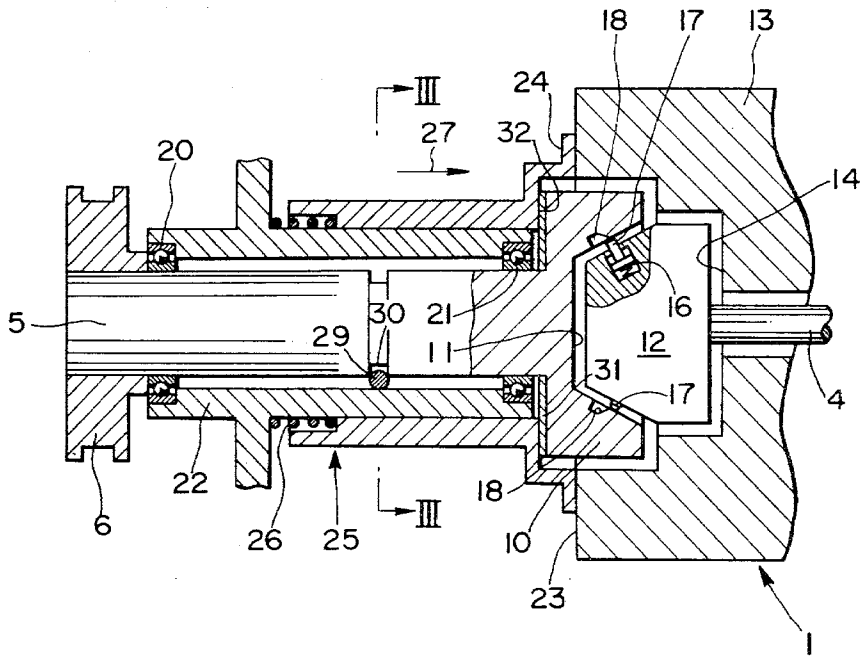

FIG. 1

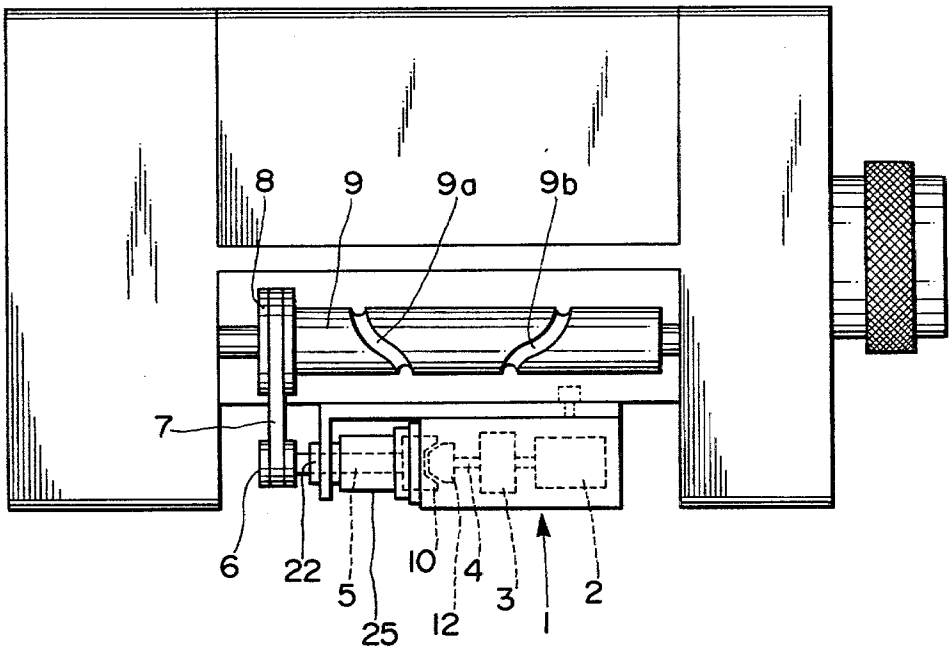

FIG. 2

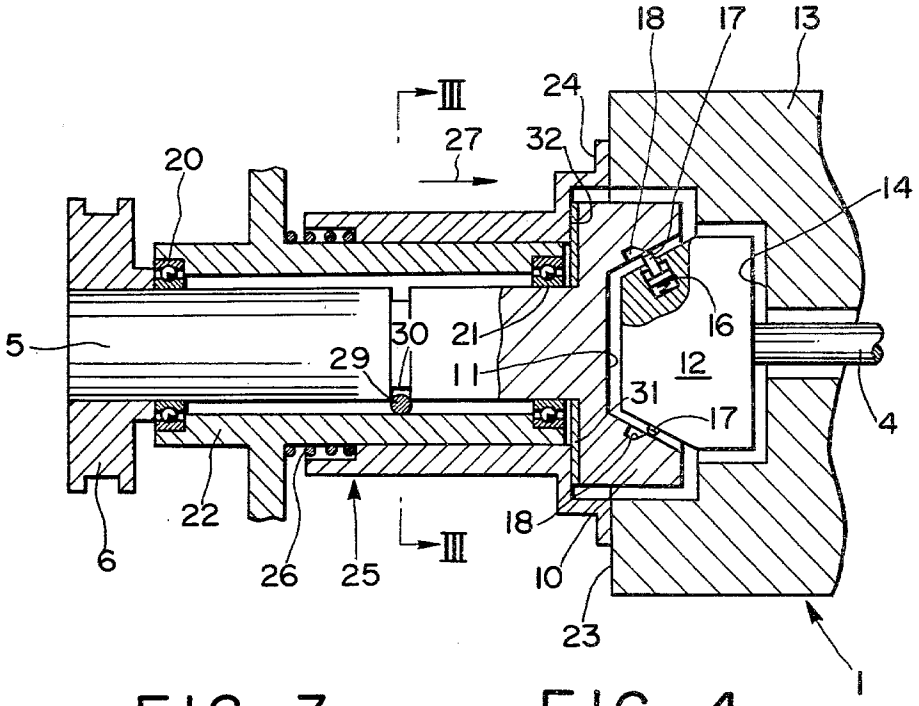

FIG. 3

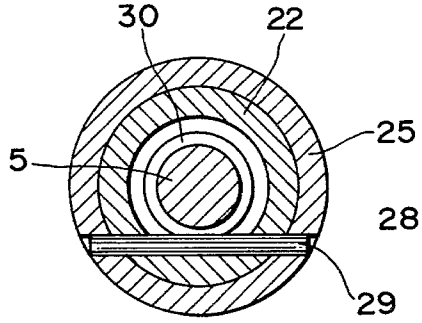

FIG. 4

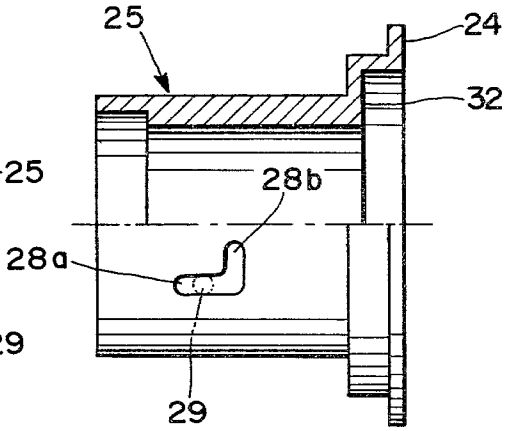

TELEVISION CAMERA OBJECTIVE HAVING DRIVING MECHANISM FOR ADJUSTING COMPONENTS OF ITS OPTICAL SYSTEM

BACKGROUND OF THE INVENTION

The present invention relates to a television camera objective having a driving mechanism for adjusting components of an optical system, and more particularly relates to such an objective including an engaging mechanism for preventing a transmission shaft from rotating in the absence of a driving unit for controlling focusing components.

In usual television camera objectives having a driving mechanism for adjusting components of an optical system, a controlled displacement of at least one component of the optical system is caused by a driving force which, in turn, is transmitted from a driving unit to a lens component displacing mechanism through a transmission shaft. In zoom lenses, in which the focal length is variable, correlative displacements of lens components for varying the focal length and for compensating are attended by variations of magnification ratio. On the other hand the focusing control of an objective is performed by an axial displacement of focusing lens components. In standard television camera objectives, there are provided driving force transmission mechanisms on which driving units identical in their construction are detachably mounted for zooming control and focusing control.

There are two well known types of driving units. One of them is a servo control driving unit, or so-called servo module, into which a servo motor is built for motor-operated zooming control or motor-operated focusing control. The other is a manual control driving unit, or so-called manual module, having a flexible cable through which zooming or focusing control commands are manually given by an operator. Such driving units are a servo module or a manual module are selectively mounted on the driving force transmission mechanism according to the contemplated mode of operation.

Such driving units as described hereinbefore are usually demounted from the driving force transmission mechanism during shipment from the factory or during transportation from one studio to another. Generally, objectives for use with television cameras have an optical system with a large aperture number and components which are quite heavy in weight. Consequently, upon the objective without driving units being inclined, one or more movable lens components can shift in position. Such motions of these movable lenses finally cause the guide pin of a movable lens holder to come into collision with the end of a cam slot formed on a camming cylinder. As a result of that, the guide pin and/or cam slot can be damaged, and the movable lenses can break by impact of the guide pin and movable lens holder.

OBJECTS OF THE INVENTION

It is accordingly a principal object of the present invention to provide a television camera objective having a driving mechanism for adjusting components of an optical system, in which at least one movable lens component is prevented from accidentally moving in the absence of a driving unit on a transmission shaft.

Another object of the present invention is to provide a television camera objective having a driving mechanism for adjusting components of an optical system and which is adapted to allow or obstruct the rotation of a transmission shaft, depending on whether or not a driving unit is mounted on the transmission shaft.

Finally, it is an object of the present invention to provide a television camera objective having a driving mechanism for adjusting components of an optical lens system, in which an engaging member for obstructing the rotation of a transmission shaft can be selectively moved to a position in which the engaging member allows the transmission shaft to rotate.

SUMMARY OF THE INVENTION

The objects of the invention described above are achieved by the provision of a television camera objective which has a detecting member adapted to be displaced from a first position to a second position by the operation of coupling a driving unit with a transmission shaft and an engaging member which is forced to shift by the displacement of the detecting member. The engaging member is adapted to prevent the transmission shaft from rotating by its engagement with a part of the transmission shaft when the detecting member is in the first position but to allow the transmission shaft to rotate upon its disengagement therefrom when the detecting member is in the second position. The engaging member comes into contact with and brakes the transmission shaft to obstruct the rotation thereof. Although the engaging member and the detecting member are referred to as two separate members, it is desirable to unite these two as one member.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects, features and advantages of the present invention will become apparent from a consideration of the following description, taken in conjunction with the accompanying drawings, in which:

FIG. **1** is a side elevational view, with the cover removed, of a preferred embodiment of the present invention;

FIG. **2** is a sectional view illustrating the principal parts of the present invention;

FIG. **3** is a cross-sectional view taken along line III—III in FIG. **2**; and

FIG. **4** is a side view, the upper half in section, of the engaging member.

DETAILED DESCRIPTION OF THE INVENTION

Referring now to the drawings in greater detail, in FIG. **1** there is shown a television camera objective with the side cover removed, including a driving unit, for example a servo module driving unit **1** having a servo motor **2** therein, which is detachably mounted on the objective. The driving force produced by the servo motor **2** is transmitted to a driving shaft **4** through a reduction gear **3** and causes a transmission shaft **5** to rotate. A belt pulley **8** fixed to the end of a cylindrical shaft **9**, which in turn is formed with two curved cam slots **9***a* and **9***b* on its outer surface, is rotated by a drive belt **7** and a pulley **6** fixed to the end of the transmission shaft **5**.

Upon the camming cylinder **9** rotating, two lens holders (not illustrated), on which two movable lens components are mounted separately and each of which is slidably engaged with respective ones of the cam slots on the camming cylinder **9**, are caused to be displaced axially with these followers guided by a straight guide

provided on a fixed cylinder (not illustrated). Consequently, two movable lens components such as a lens of variable focal length and a compensating lens (not illustrated, nor are the other lens components comprising a zoom lens system) are correlatively displaced along an optical axis a distance corresponding to the amount of rotation of the camming cylinder shaft **9**, so as properly to vary the focal length. Such an assembly of camming cylinder shaft **9**, lens holders and a fixed cylinder comprise a well-known lens displacement control mechanism.

Referring now to FIG. **2**, on the end of the transmission shaft **5** opposite pulley **6**, a coupling head **10** similar to a flange is provided. The coupling head **10** of the transmission shaft **5** is provided with a frusto-conical depression **11** which coacts with a complementarily shaped coupling head **12** on the end of driving shaft **4**. The coupling head **12** is accommodated in a recess **14** on a housing **13** of the servo module **1**. A plurality of engaging pins **17** are urged by biasing coil compression springs **16** so as to retractably project from the truncated conical surface of the coupling head **12**. Therefore, as the coupling head **12** of the driving shaft **4** is inserted into the frusto-conical depression **11** of the coupling head **10** of the transmission shaft **5**, the interconnection between these two shafts **4** and **5** is completed by pins **17** seating in recesses **18** formed on the truncated conical surface of the frusto-conical depression **11** of the transmission shaft **5**.

The transmission shaft **5** is rotatably carried by a cylindrical fixed rigid member **22** through ball bearings **20** and **21** interposed therebetween as shown in FIG. **2**. The cylindrical rigid member **22** is surrounded by an engaging member **25** the rear end of which has a flanged portion **24** adapted to come into abutment against a front wall **23** of the housing **13**, the engaging member **25** being biased in the direction of the arrow **27** as shown in FIG. **2** by means of a coil compression spring **26** and being axially slidable and rotatable through only a portion of one turn.

As shown in FIG. **4**, the engaging member **25** is restricted in its sliding movements by an axial slot **28***a* formed thereon and a rigid rod **29** described hereinafter coacting with the slot **28***a*. The engaging member **25** is further restricted in rotation by a peripheral slot **28***b* formed thereon and by the rigid rod **29**.

Turning now to FIG. **3**, the cylindrical rigid member **22** holds fixedly and rigidly the rod **29** which is fitted into an annular groove **30** on the transmission shaft **5** and is further selectively engaged with slots **28***a* or **28***b* so as to restrict the sliding or rotating motion of the engaging member.

On the front face of the coupling head **10** of the transmission shaft **5** an annular member **31** having a relatively high frictional resistance is secured. The annular member **31** serves to prevent the transmission shaft from rotating when member **31** frictionally engages with the surface **32** of the engaging member **25**. Obviously, the same result is achieved if the annular frictional member **31** is instead secured to the opposed engaging surface of the engaging member **25**.

In the operation of a television camera objective embodying the present invention, as illustrated in FIGS. **1** and **2**, the housing is formed along one of its rectangular surfaces with a slot (not shown) adapted to receive a bayonet lug (see FIG. **1**) on the casing of servo module **1**, whereby the module casing may be emplaced in its socket by transverse and longitudinal motion to introduce the lug into the slot while connecting the driving shaft **4** with the transmission shaft **5** through coupling heads **10** and **12**. Longitudinal advancement of the servo module **1**, in the direction opposite to that of arrow **27** in FIG. **2**, causes the engaging member **25** to move axially against the biasing force of spring **26** with its guide slot **28***a* engaging with the rigid rod **29** secured to the cylindrical rigid member **22**.

At the end of the longitudinal advance of the servo module **1**, the driving shaft **4** and the transmission shaft **5** are interconnected with each other through the engagement between guide pins **17** and bores **18**. After the completion of the interconnection of the servo module **1** and the transmission shaft **5**, engaging surface **32** of the engaging member **25** is spaced from the annular frictional member **31** so that the driving force produced by the servo motor **2** is allowed to be transmitted to the transmission shaft **5** through coupling **10** and **12** without obstruction by the engaging member **25**. Consequently the zoom lens system is servo-controlled to vary its focal length by the servo module **1**.

Upon the servo module being required to be demounted, it may be enough to displace the casing from its socket by longitudinal (toward the arrow **27** shown in FIG. **2**) and transverse motion to withdraw the lug from the slot while disconnecting the driving shaft **4** from the transmission shaft **5** through disengagement between coupling heads **10** and **12**. On this occasion, the engaging member **25** is gradually moved in the direction of arrow **27** under the influence of the force of the biasing spring **26** with the withdrawing of servo module **1** and finally the surface **32** of the engaging member **25** will come into contact with the annular frictional member **31** secured to the coupling head **10** of the transmission shaft **5**.

Thereafter, the cylindrical rigid member **22**, with the axial slot **28***a* engaged by the rigid rod **29**, prevents the engaging member **25** from rotating, so that the transmission shaft is prevented from rotating, thanks to the frictional engagement between surface **32** and member **31**.

As is apparent from the above description, even though a television camera objective without driving units is tilted by mistake during its shipment from the factory or transportation or the like, the movable lens components will be prevented from falling by gravity due to the fact that the engaging member **25** is in contact with the annular frictional member **31**.

Furthermore when it is required to manually operate a television camera objective for zooming control without a servo module driving unit, that is, when it is desirable to adjust the focal length of the optical system through the transmission shaft **5** being operated manually and directly by an operator, the engaging member **25** is slid with axial and circumferential motion along slots **28***a* and **28***b* and locks in slot **28***b* against the force of the biasing spring **26**, with the result that the engaging member **25** is kept disengaged from the transmission shaft **5**. Consequently, the transmission shaft **5** can rotate under an extremely light load.

While the preferred embodiment of the present invention described above is explained with reference to a television camera objective with a servo module driving unit, the present invention can be applied to a television camera objective using a manual module driving unit in the same way as a servo module driving unit. And the present invention can be applied not only to a zooming control mechanism but also to a focusing control mechanism of a television camera objective. the

latter being, as a matter of course, identical in design and results, no matter whether the driving unit is a servo module or a manual module.

Naturally, the invention is not limited to the specific details described and illustrated but may be modified in various respects without departing from the spirit and scope of the invention as defined by the appended claims.

What is claimed is:

1. In a television camera objective having a transmission shaft to which a driving unit is adapted to be detachably connected and a driving mechanism for axially displacing at least one lens component of an optical system upon rotation of said transmission shaft; the improvement comprising:

means movable from a first position when said driving unit is dismounted from said transmission shaft to a second position when said driving unit is mounted on said transmission shaft, and

means releasably interconnecting said first-named means and said transmission shaft for preventing said transmission shaft from rotating upon said first-named means being in said first position but allowing said transmission shaft to rotate upon said first-named means being in said second position.

2. A television camera objective as claimed in claim **1**, in which said first-named means is moved from said first position to said second position by engagement with said driving unit upon connection of said driving unit to said objective.

3. A television camera objective as claimed in claim **1**, and spring means biasing said first-named means toward said first position.

4. A television camera objective as claimed in claim **1**, said first-named means engaging a portion of said transmission shaft in said second position to prevent rotation of said transmission shaft.

5. A television camera objective as claimed in claim **4**, said first-named means and said transmission shaft having surfaces that frictionally engage each other in said second position to brake said transmission shaft.

6. A television camera objective as claimed in claim **1**, and means for selectively locking said first-named means in said second position.

7. A television camera objective having a driving mechanism for axially displacing at least one lens component of an optical system by driving force transmitted from a detachable driving unit, said driving mechanism including a rotatable transmission shaft for receiving and transmitting driving force from said driving unit, a coupling element on one end of said transmission shaft selectively engageable with a complementary coupling element of said driving unit, a fixed member supporting said transmission shaft for rotation, engaging means slidably surrounding said fixed member, means on said transmission shaft engageable with said engaging means in a first position of said engaging means to prevent rotation of said transmission shaft, spring means yieldably urging said engaging means toward said first position, said engaging means being engageable with a said driving unit upon attachment of said driving unit to said objective to move said engaging means from said first position to a second position in which said engaging means is spaced from said engageable means on said transmission shaft, and means preventing rotation of said engaging means in said first position.

8. A television camera objective as claimed in claim **7**, said rotation preventing means comprising pin and slot means between said engaging means and said fixed member.

9. A television camera objective as claimed in claim **7**, said driving unit having a driving shaft, said driving shaft and said transmission shaft having enlarged adjacent ends which detachably couple together upon mounting of said driving unit on said objective.

10. A television camera objective as claimed in claim **9**, said engaging unit being engageable with said enlarged end of said transmission shaft in said first position.

11. A television camera objective as claimed in claim **9**, said enlarged ends of said shafts having complementary frusto-conical surfaces that mate to transmit rotation from said driving shaft to said transmission shaft.

12. A television camera objective as claimed in claim **11**, said enlarged end of said transmission shaft having a friction surface on its side opposite its said frusto-conical surface, said friction surface frictionally engaging said engaging means to brake said transmission shaft in said first position.

13. A television camera objective as claimed in claim **7**, said engaging means having frictional engagement with an enlarged portion of said transmission shaft to brake said transmission shaft in said first position.

14. A television camera objective as claimed in claim **7**, and means for selectively locking said engaging means in said second position in the absence of a said driving unit.

15. A television camera objective as claimed in claim **14**, said engaging means comprising a cylindrical sleeve, said locking means comprising pin and slot means that act between said sleeve and said fixed member, said slot means having a portion that extends peripherally of said sleeve to lock said engaging means in said second position and a portion that extends parallel to the axis of said sleeve to receive said pin and to prevent rotation of said sleeve in said first position.

REFLEX CAMERA HAVING A FOCAL PLANE SHUTTER AND AN INTERCHANGEABLE VARIABLE SHUTTER OBJECTIVE

The present invention relates to a reflux camera having a focal plane shutter, a time adjuster associated with the focal plane shutter and which can be set to a particular position "C", and an interchangeable variable shutter objective which has a segment system which, in the basic position, fully clears the lens aperture of the objective and is mounted so as to be able to pivot backwards and forwards. The objective also has a time adjuster which has a set position "F" with "B" function, and a diaphragm which, before the segment system commences its operating movement, approaches a specific working aperture, which is preselectable by means of a diaphragm adjuster.

A reflex camera is already known which, because it does not itself have a shutter system, can only use that type of interchangeable objective which has a central interlens shutter and diaphragm, the diaphragm concept and arrangement being selected so that the diaphragm blades open fully when the shutter is cocked and move to a preselected aperture width in an automatically controlled manner upon the release of the shutter and before the central shutter opens and closes again.

A reflux camera is also alread known which is provided with a focal plane shutter and to which interchangeable objectives of various types are selectively attachable, these objectives in fact being both interchangeable objectives which have only one diaphragm and interchangeable objectives of the above described type having a central shutter and diaphragm.

Interchangeable objectives of the first-mentioned category, which merely have a diaphragm and consequently may also only be used with focal plane shutter cameras, are, as is well known, of such a technical concept that, when the camera is released, the diaphragm blades spring from the fully open position towards the aperture width which corresponds to a manually preselected value and retain this aperture for the duration of the operating movement of the focal plane shutter in order to return again to the fully open position immediately afterwards, whereby the objective passage for observing the image is completely clear again.

If, however, an interchangeable objective which has a central shutter and diaphragm is in fact attached to a reflex camera which is fitted with a focal plane shutter, and if the camera user intends to take flash photographs with an extremely short exposure time, which photographs presuppose the use of an electronic flash device using the central shutter on the objective then, as explained in German Patent Specification No. 2 001 406, before taking the picture, he firstly has to set the time adjuster, which is on the camera body and which is provided with an additional set position "C" (central shutter), for the focal plane shutter correspondingly to this position "C". With this setting operation an electromechanical control device is actuated which, after the camera has been released, clears the focal plane shutter prematurely for the full aperture and permits it to return to the closed position only after the central shutter has functioned. If, however, the camera user wishes to take photographs which require the use of the focal plane shutter, then he has first to set the time adjuster of the central shutter to the particular set position "F" with "B" shutter function. This setting operation in turn acts upon the electromechanical control device in such a way that the movement procedure of the focal plane shutter is delayed until the central shutter has reached the fully open position, from which it returns again to the closed position.

When taking photographs with such a camera provided both with a central shutter and with a focal plane shutter, it is disadvantageous to the camera user if the central shutter on the objective always fully closes again at the end of the exposure to fulfil its function, while the diaphragm remains at its set value, since the camera user does not have at his disposal a ground-glass screen image until the camera is again ready to take photographs by actuating the cocking mechanism and, as a result thereof, the central shutter has again been transferred to the open position.

The object of the invention is to eliminate the disadvantage discussed above of a variable shutter objective which is provided with a diaphragm and central shutter, i.e. to modify such a shutter in such a way that:

(a) as in the case of interchangeable objectives provided only with a diaphragm, the ground-glass screen image is available again through the focal plane shutter directly subsequent to the exposure operation, and

(b) with a low cocking moment and with regular use of the focal plane shutter and central shutter, a long service life is insured for the camera and the objective shutter.

According to the present invention there is provided a reflex camera having a focal plane shutter, a time adjuster associated with the focal plane shutter and which can be set to a particular position "C", and a variable shutter objective, which has a shutter segment system which, in the basic position, fully clears the lens aperture of the objective and is mounted so as to be able to pivot backwards and forwards, and a time adjuster associated with the objective shutter which can be set to a particular position with "B" function, and a diaphragm which, before the shutter segment system commences the operating movement, approaches a specific working aperture which is preselectable by means of a diaphragm adjuster, wherein by setting the time adjuster associated with the central shutter of the objective to the set position "F" which effects an "B" function, a lock is operated which blocks the closure drive for the shutter segment system.

Compared with known shutters of this type, an objective shutter having this feature according to the present invention enjoys the advantage that the ground-glass screen image is available again immediately after the exposure operation has ended. It is also advantageous if, on the one hand, by not involving the central shutter in the operating procedure of the camera when taking photographs through the focal plane shutter, an additional tensioning moment for transferring the central shutter to the cocked condition does not need to be applied and, on the other hand, the service life of the central shutter can be extended because of the consequential lack of stress and the resultant sparing of the central shutter from extra operating wear to which it would be otherwise subjected.

In a preferred embodiment of an objective shutter arrangement according to the present invention, which is advantageous from the design point of view and insures an absolutely problem-free use of the camera, the objective shutter can have an adjuster which is provided with radial cams which serve to clear a spring-loaded feed lever, which acts upon the diaphragm in the

closing direction, and to clear and return a further return lever, which is likewise spring-loaded and acts upon the diaphragm in the opening direction, to the initial position. The return lever may have a lock which keeps it in the initial position and can be driven out of the locked position by the adjuster after a first phase of motion (α), i.e. and a short intermediate stop, i.e. in motion, necessary for the functioning of the focal plane shutter on the camera body, in a second phase of motion (β), i.e. beta.

Further, for the manual actuation of the diaphragm for the purpose of observing the depth of focus, the radial cam, which releases the feed lever into the initial position, may be disposed on a pin-mounted lever and this lever may be disposed on the adjuster so as to be resiliently flexible. Consequently, the camera user is then able to change the diaphragm manually from the fully open position to the preselected aperture width and/or to view the object while judging the depth of field.

An arrangement which positively excludes operating errors and is also easy to handle for the manual adjustment of the diaphragm can be achieved according to the present invention, in that the pin-mounted lever, which is provided with a radial cam, may have a push-button or the like which serves to actuate the feed lever manually.

In order to prevent an unintentional setting of the time adjuster, belonging to the central shutter, to the set position "F" which, from the point of view of its functional significance, differs basically from the other scale values, and to secure the time adjuster in the set position "F" so that a return from this position can only ever be effected deliberately by the camera user, a lock mechanism is preferably provided with the time adjuster for the central shutter, so that a setting of the adjuster to the set position "F" or correspondingly a return from this position to a time value can only be effected after a previous actuation of the lock mechanism, whereby incorrect settings of the camera can be avoided in a simple manner and also with absolute certainty.

A preferred embodiment of the lock mechanism, which is both structurally simple and reliable in operation, is achieved if this mechanism is designed according to the present invention as a spring-loaded, double-armed lever which is actuated by a push-button and cooperates with an annular groove, corresponding to the extent of the time range of the time adjuster, and with a specific additional recess which fixes the time adjuster in the set position "F".

The present invention will be described further, by way of example, with reference to the accompanying drawings, in which:

FIG. 1 shows the diaphragm drive of a variable shutter in the initial position;

FIG. 2 shows the diaphragm set to the preselected aperture width after completion of the α , i.e. alpha, phase of motion;

FIG. 3 shows the diaphragm returned to the initial position or correspondingly the open position after the completion of the α and β, i.e. alpha and beta, phases of motion;

FIG. 4 shows the unactuated push-button for setting the diaphragm manually to a preselected aperture width;

FIG. 5 shows the push-button of FIG. 4 after it has been actuated into the locked position;

FIG. 6 shows a variable shutter objective and the front portion of a reflex camera seen from above;

FIG. 7 is a partial view of the time adjuster of the camera of FIG. 6 set to the position "F"; and

FIG. 8 is a partial cross-section through the variable shutter objective along the section line I—I indicated in FIG. 7.

In the drawings, the reference numeral **1** denotes the base plate of a central shutter which is suitable for installation in a variable objective and is provided with a cocking and releasing member which, when the variable objective or variable shutter is attached to the housing of a reflex camera by way of a shaft, can be disengaged from the transmission of the cocking and releasing mechanism on the camera body by removing the objective or shutter. Positively connected to the annular cocking and releasing member, which is rotatably mounted on the rear side of the base plate **1**, and of which only one coupling part **2** can be seen in the drawing, is an adjuster **3** on which a radially directed arm **3***a*, which engages with the part **2**, is disposed.

The adjuster **3** is rotatably mounted in a conventional manner on a concentric extension **1***a* of the base plate **1**. It serves specifically to control a backward and forward movement of the iris ring or diaphragm ring **5**, which is likewise mounted on the extension **1***a* and is effectively connected to diaphragm blades **7** rigidly mounted at **9** in a conventional manner by means of a slot and pin connection **7***a*, **8**. For reasons of clarity, only one diaphragm blade **7** is shown, of which there are usually five in number, and which are distributed around the aperture and, as shown in the drawing, are disposed beneath the base plate **1**.

On the side facing the viewer, the iris ring **5** is provided with a driving pin **12** which is drivingly connected to one end of a feed lever **11**, which is mounted on the base plate **1** by means of pin **10** and is designed as an angled lever, the lever arm **11***a*, which is fork-shaped at the free end, positively embracing the pin **12** for this purpose. The end of the other lever arm **11***b* is in turn provided with a stop pin **13**, which cooperates with a radial cam **14** which, in FIGS. **1** to **3** is indicated by dash-dot lines and, is presettable by means of a diaphragm adjuster which is manually actuable, but is not shown fully in these views. This occurs in such a way that, due to the effect of the driving spring **16**, which is supported at one end on a tab **11***c* and at the other end on a rigid pin **15** on the base plate **1** with an initial tension, the feed lever **11**, which in the position of rest lies on a supporting part which is more fully described hereinafter, experiences an anticlockwise rotational movement about the bearing pin **10** with the simultaneous driving of the iris ring **5**, this rotational movement continuing until the stop pin **13** meets the radial cam **14**. This in turn signifies that, depending upon the relative set position of the radial cam **14**, the feed lever **11** passes through a greater or smaller angle of rotation range and thereby sets the diaphragm blades **7** to a specific aperture width, as shown, for example in FIG. **2**, by way of the iris ring **5**, from the fully open position shown in FIG. **1**.

The feed lever **11** could per se be supported by a radial cam which is securely disposed on the adjuster **3** and engages with the tab **11***a* but, in order to enable an intermediate observation of the depth of field, provision is made for the radial cam **17***a* to be disposed on a lever **17** which, for its part, is rotatably mounted on the adjuster **3** by means of a bearing pin **18** and abut the tab

11*a* of the feed lever **11** under the influence of a spring **19** which is under relatively high initial tension.

The object of the control lever **17** is to support the feed lever **11** in the initial position so that the feed lever **11** also retains its position under the compression force of the spring **16** which acts upon it. The initial tension of the spring **19** must therefore be selected to be higher than that of the spring **16**. It follows from this that, when the adjuster **3**, driven by the cocking and releasing member, leaves the initial position shown in FIG. **1** and the radial arm **3***a* passes through the α, i.e. alpha, phase of motion as far as an intermediate stop located at the end thereof, the feed lever **11** follows the radial cam **17***a* and thereby sets the diaphragm blades **7** to the preselected aperture width fixed by the position of the diaphragm radial cam **14**. Once the end of the α, i.e. alpha, phase of motion is reached, the operating movement of the adjuster **3** is interrupted for an interval of time within which the focal phase shutter in the camera body opens exposing the film material at the set diaphragm aperture width. After the operation of the focal plane shutter, the adjuster **3**, again driven by the cocking and releasing member, continues its rotational movement, whereby a driving pin **20**, disposed on the adjuster **3***a*, approaches a locking catch **22**, which is rotatably mounted on the base plate **1** by means of pin **21** and drives this catch **22** against the action of a spring **23** associated with the catch **22** and thereby releases a multi-armed lever **25** which acts as a return lever for the diaphragm blades **7**.

The return lever **25**, which was previously supported by its arm **25***a* against the locking catch **22**, is now under the tensioning effect of a spring **27** which now acts with the lever arm **25***b* upon a driving pin **29** located on the iris ring **5**, and drives this driving pin **29** along with it, thereby returning the diaphragm blades **7** into the open position shown in FIG. **3**. The adjuster **3** thus passes through the β, i.e. beta, phase of motion entirely and stops at the end thereof.

If, subsequent to the above described movements the cocking transmission on the camera body is actuated, a torque is applied via the shaft connection which rotates the adjuster **3** counter-clockwise and acts upon the cocking and releasing member of the shutter, this member being disposed on the shutter side. During the return of the adjuster **3**, a fixed radial cam **3***b* on the adjuster **3** approaches a pin **30** on the free end of a lever arm **25***c*, disposed on the return lever **25**, whereby the return lever **25** is displaced progressively from the position shown in FIG. **3** towards the cocked position shown in FIG. **1**. This cocked position is reached when the locking catch **22** is again located under the bent-over tab of the lever arm **25***a* under the tensioning effect of the spring **23**, as indicated in FIG. **1**. Once the end position of the adjuster **3** has been reached, the radial cam **17***a* (cf. FIGS. **2** and **3**), as can also be seen from FIG. **1**, adopts a position relative to the feed lever **11**, in which position the tab **11***a* of the feed lever **11** is actually located on the cam **17***a*.

The prerequisite for achieving the above described mode of operation is, however, that the time adjuster **35** of the central shutter, indicated only symbolically in FIGS. **1** to **3**, has been set, as shown, before the release of the camera to an additional set position denoted, for example, by "F" (focal shutter). If this happens, a radial cam **35***a*, which is also only indicated in the drawing which and is nonrotationally connected to the time adjuster **35**, receives such a setting relative to a rigidly mounted locking lever **36** that this locking lever can engage with a driving tab **37**, which is disposed on the shutter segment ring of the shutter, and can thus prevent the central shutter from fulfilling its function. For this purpose, the radial cam **35***a* is provided with a radial recess **35***b* which enables the locking lever **36** to enter the locked position.

In order to give the camera user the opportunity of making an intermediate observation so as to judge the depth of focus with the preselected diaphragm aperture in the set position "F" of the time adjuster **35** with the above described arrangement of diaphragm mechanics, a push-button **45** is provided which is disposed securely, but resiliently flexibly, on a lever **46** which sits on a bearing pin **47** inserted in the base plate **1**. In this case, the resiliently designed push-button **45** is guided in a slot-like recess **48***a* of the shutter housing **45**, which is merely indicated in FIGS. **4** and **5**, this being so that, when the push-button **45** is pressed down and the spring **49**, which engages therewith, is overcome, the outer end of the lever **46** acts upon an adjusting pin **50**, which is disposed on the control lever **17**.

In turn, this adjusting pin **50** transfers the compression force to the control lever **17** which executes a rotational movement in a counter-clockwise direction about the bearing pin **18**, resulting in the feed lever **11** losing its support. In this case, under the pressure of the pretensioned spring **16**, the feed lever **11** follows the control lever **17** until such time as the stop pin **13** comes to rest on the radial cam **14**. Consequently, in turn, the diaphragm blades **7**, which participate in the adjusting movement of the feed lever **11** via the iris ring **5**, have reached the aperture width corresponding to the preselected diaphragm valve.

In order to be able to keep the push-button **45** in the active position for undertaking further setting manipulations which have to be effected on the camera, a locking edge **45***a* is provided thereon which, as shown in FIG. **5**, engages with the housing **48***a* at the end of the push-button actuation and consequently locks the button **45** until such time as it is able to return again into the initial position, shown in FIG. **4**, by a transversely directed pressure stress, causing lateral deflection to be exerted upon the button **45**. With the return of the push-button **45**, the pressure is absorbed by the control lever **17**, this pressure acting upon the feed lever **11** under the influence of the relatively strong spring **19** by way of the tab **11***a* and consequently returning the diaphragm blades **7** again from the pre-selected aperture width to the fully open position according to FIG. **1**.

FIG. **6** shows the housing **51** of a reflex camera which comprises a focal plane shutter with a time adjusting ring **52** and a variable shutter objective **53** which can be detachably attached to the camera housing **51** by means of a bayonet connection, the objective being designed with a central shutter and provided with a diaphragm mechanism and a segment system, i.e. of shutter segments, which is mounted so as to pivot backwards and forwards, and which is preferably driven mechanically. Disposed concentrically to the objective barrel are rotatably mounted adjuster rings **54** and **35** of which one adjuster, denoted by **54**, serves to pre-select the diaphragm aperture width and the other serves to set the exposure time.

As can be seen from FIG. **6**, the time adjuster **52**, belonging to the focal plane shutter, is provided additionally with a particular set position "C" (central shutter) in addition to the actual time scale **52***a*, and the time

adjuster 35, belonging to the central shutter, is provided with a particular set position "F" (focal shutter), i.e. which effects a "B" function, in addition to the time setting scale 35*a*. The purpose of this is to enable the camera user to be in a position to expose one or other shutter arrangement, depending upon the selection of one or other set position "C" or "F", respectively.

If, as shown in FIG. 6, the focal plane shutter time adjuster 52 on the camera side is set to the particular set position "C" opposite the fixed mark 56, and if the camera is released, the film exposure is effected through the central shutter in the objective with the exposure time pre-set at its central shutter time adjuster 35. If, however, the central shutter time adjuster 35 on the objective side is set to the additional set position "F" opposite the fixed mark 57, as is shown in FIG. 7, then the focal plane shutter in the camera body exposes the film with the exposure time pre-selected at the focal plane time adjuster 52 when a photograph is taken.

Since the set position "F" in respect of its functional significance differs basically from that of the scale values of the central shutter time adjuster 35, precautions are to be taken to avoid incorrect settings, such precautions, on the one hand, preventing the camera user from setting the central shutter time adjuster 35 unintentionally to the particular set position "F" and, on the other hand, not permitting an inadvertent unintentional return of the time adjuster to one of the scale values of the time scale 35*a*.

To effect this precautionary measure, the central shutter time adjuster 35 is provided with a locking mechanism. This locking mechanism includes a manually actuable push-button 58 and a double lever 60 which is rotatably mounted on an axle 59, one end of which lever 60 is loaded by a spring 61, preferably a leaf spring, and the other end of which lever 60 cooperates with the push-button 58 and engages in a groove-like recess 58*a* of the push-button 58. As can be seen especially from FIG. 8, the locking mechanism, which at one end is provided with a locking tooth 60*a*, cooperates with a recess 62*a* which is disposed on a rigid part 62, preferably the barrel, of the objective. Because of the positive and constant engagement of the locking tooth 60*a* in this recess 62*a*, the time adjuster 35 is protected from unintentional actuation after being set to the particular set position "F".

Opposite the recess 62*a*, defined by a material shoulder 62*b*, an annular groove 62*c* is incorporated into the barrel of the objective and its length corresponds at least to the extent of the time setting range of the time adjuster 35. If the camera user wishes to set the time adjuster 35 to the set position "F" shown in FIG. 7, or to change it from this position to a time value corresponding to the time scale 35*a*, both setting manipulations always presuppose the previous positive releasing actuation of the push-button 58 of the positive locking mechanisms 58–61 which permits the range change.

We claim:

1. Reflex camera of the type having a focal plane shutter, comprising:

an objective containing a lens aperture and provided with a variable central shutter of the type adapted for operation between a basic open shutter position in which the lens aperture is fully open and a closed shutter position, and a central shutter drive for effecting opening and closing shutter operating movement, the central shutter being arranged for mounting a shutter segment system for operating movement adjustably backwards and forwards for opening and closing the lens aperture and which in the basic open shutter position fully clears the lens aperture,

a focal plane time adjuster associated with the focal plane shutter and arranged for setting to a particular central shutter position "C" for operating the central shutter,

a central shutter time adjuster associated with the central shutter and arranged for setting to a particular focal plane shutter position "F" which effects a "B" function for operating the focal plane shutter while the central shutter is in the basic open position,

a diaphragm and a diaphragm preselecting adjuster arranged such that, before commencement of the operating movement of the central shutter, the diaphragm approaches a specific working aperture which is preselectable by means of the diaphragm preselecting adjuster, and

a central shutter lock arranged such that upon setting the central shutter time adjuster to the focal plane shutter position "F" which effects a "B" function, the lock operates to block the central shutter drive from effecting closing shutter operating movement of the central shutter whereby to permit the focal plane shutter to be operated while the central shutter is in the basic position.

2. Camera according to claim 1 wherein the diaphragm is adjustable in an opening direction and in a closing direction, a spring loaded feed lever is provided for acting under a feed force upon the diaphragm in the closing direction, a spring loaded return lever is provided for acting under a return force upon the diaphragm in the opening direction, the central shutter is provided with a diaphragm cam adjuster having radial cams for urging the feed lever in the opposite direction against such feed force to an initial position for opening the diaphragm and for urging the return lever in the correspondingly opposite direction against such return force to an initial position for reloading the return lever, and a return lever lock is provided for locking the return lever in its initial position and which is drivable out of the locking position by the cam adjuster after a first phase of motion and a short intermediate stop in motion, as required for the functioning of the focal plane shutter in the camera, in a following second phase of motion.

3. Camera according to claim 2 wherein the corresponding radial cam for urging the feed lever to such initial position is disposed on a pin mounted cam lever which is resiliently flexibly disposed on the cam adjuster.

4. Camera according to claim 3 wherein a cam lever push button or the like is arranged for controlling the pin mounted cam lever for permitting manual actuation of the feed lever.

5. Camera according to claim 1 wherein the central shutter time adjuster is provided with a time value adjustment scale corresponding to the extent of the time setting range of said time adjuster, and an actuatable central shutter time adjuster releasable lock mechanism arranged for permitting a setting of said time adjuster to the set position "F", or correspondingly a return from such set position "F" to a time value of the corresponding adjustment scale at another set position thereof, to be effected only after a previous releasing actuation of said lock mechanism.

6. Camera according to claim 5 wherein the lock mechanism is provided as a spring loaded double armed lever, which is arranged for actuation by a time adjuster push button, and which cooperates with an annular groove corresponding in extent to the extent of the time setting range of the central shutter time adjuster, and which also cooperates with a selective specific additional recess for releasably fixing said time adjuster in the set position "F".

7. Reflex camera of the type having a focal plane shutter, comprising:

an objective containing a lens aperture and provided with a central shutter of the type adapted for operation between a basic open shutter position in which the lens aperture is fully open and a closed shutter position, and central shutter drive means for opening and closing shutter operating movement,

a focal plane time adjuster associated with the focal plane shutter and arranged for setting to a particular central shutter control position for operating the central shutter,

a central shutter time adjuster associated with the central shutter and arranged for setting to a particular focal plane shutter control position which effects a "B" function for operating the focal plane shutter while the central shutter remains in the basic open position,

a diaphragm and diaphragm aperture preselecting adjustment means arranged for adjusting the diaphragm to a preselected working aperture before commencement of the operating movement of the central shutter, and

central shutter drive lock means arranged, upon setting the central shutter time adjuster to the focal plane shutter control position which effects a "B" function, for blocking the central shutter drive means from effecting closing shutter operating movement of the central shutter whereby to permit the focal plane shutter to be operated while the central shutter remains in the basic open position.

8. Camera according to claim 7 wherein the diaphragm is adjustable in an opening direction and in a closing direction, diaphragm closing means are provided for resiliently urging the diaphragm in the closing direction under a closing force, diaphragm opening means are provided for resiliently urging the diaphragm in the opening direction under an opening force, diaphragm control adjustment means are provided for effecting operating phases of motion for correspondingly urging the diaphragm closure means in the opposite direction against the closing force to relieve the diaphragm from such closing force and for correspondingly urging the diaphragm opening means in the correspondingly opposite direction against the opening force to a basic cocked position to relieve the diaphragm from such opening force, and diaphragm opening means catching lock means are provided for releasably locking the diaphragm opening means in the basic cocked position, said diaphragm control adjustment means also being arranged such that, after a first operating phase of motion in which the diaphragm control adjustment means are released from urging the diaphragm closure means and from urging the diaphragm opening means while the diaphragm opening means remains locked in the basic cocked position, and after a short intermediate stop in motion corresponding to that required for the functioning of the focal plane shutter, said diaphragm control adjustment means in turn release the catching lock means in a following second phase of motion to permit the diaphragm opening means to urge the diaphragm in the opening direction.

9. Camera according to claim 8 wherein the diaphragm control adjustment means are operatively releasably connected with the diaphragm closing means, and manually controlled releasing means are provided for operatively disconnecting the diaphragm control adjustment means from the diaphragm closing means to permit manual control of the diaphragm closing means.

10. Camera according to claim 7 wherein the central shutter time adjuster is provided with a time value adjustment scale corresponding to the extent of the time setting range of said time adjuster, and a manually controlled releasable positive lock mechanism is arranged for permitting a setting of said time adjuster to the focal plane shutter control position which effects a "B" function, or correspondingly a return from said control position to a time value of the corresponding adjustment scale at another set position thereof, to be effected only after the preliminary positive releasing actuation of said locking mechanism.

[57] **ABSTRACT**

A front component of a varifocal camera objective, axially shiftable for focusing purposes, is provided with a lens mount held by an axially extending guide rod which is slidably received in an inner annular flange and an end wall of a lens barrel. The lens mount has a pin projecting through an axial guide slot in the lens barrel into a camming groove in a surrounding milled setting ring. A rearward extension of the guide rod, nonrotatable but axially slidable with reference thereto against the force of a tension spring, is provided with male threads engaged by a drive nut held captive in the end wall, the nut being provided with outer gear teeth meshing with a pinion which is driven by a reversible electric motor via a slipping clutch. Upon retraction of the threaded extension by the drive nut, the tension spring holds the pin of that lens mount against the rear edge of its camming groove; the width of that groove and the axial length of the guide slot are sufficient to let the motor drive the lens mount over at least part of the available focusing range in a given position of the setting ring.

FOCUSING MECHANISM FOR CAMERA OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a photographic or cinematographic camera whose objective includes one or more lenses that are axially shiftable for focusing purposes.

BACKGROUND OF THE INVENTION

Conventional cameras with focusable objectives are provided with an outer, axially fixed setting ring rotatably mounted on a lens barrel and provided with female threads engaging male threads of an inner guide ring which is held against rotation and is rigid with a lens mount supporting the shiftable lens or lenses, the latter usually constituting a front component of the objective. The two rings are centered on the objective axis and are therefore of a rather large diameter, resulting in considerable friction along their threaded contact surfaces.

In commonly owned U.S. Pat. No. 3,482,500 there has been disclosed a control mechanism for manual and automatic focusing in which a lens mount is supported by several axially extending guide rods, one of these rods having threads engaged by a nut which is integral with the shiftable lens mount. It has also been proposed to provide a shiftable lens support with an axially extending rack engaged by a rotatable worm; see German Pat. No. 1,101,801.

In commonly owned U.S. patent application Ser. No. 894,031, filed Apr. 6, 1978 by Karl-Heinz Holderbaum, now U.S. Pat. No. 4,200,377, there has been disclosed and claimed a focusing mechanism comprising a guide rod which is fastened to a shiftable lens mount and is slidably but nonrotatably held in stationary bearings inside a lens barrel, this guide rod extending parallel to the optical axis of the objective and terminating within a camera housing in a threaded rear extremity which is engaged by a captive drive nut. The nut is provided with external gear teeth in mesh with a motor-driven pinion and also with a manually rotatable toothed wheel, the latter being rigid with a scale-carrying setting ring projecting from the housing. A slipping clutch inserted between the motor and its pinion allows the lens mount to be manually displaced even if the motor is of the self-locking (e.g. stepping) type remaining stationary when not energized. That system is advantageous for its low frictional resistance and for the accurate guidance given to the movable lens mount.

OBJECTS OF THE INVENTION

An object of my present invention is to provide a modified focusing mechanism, generally similar to the above-identified Holderbaum application, which retains the aforementioned advantages of that system while allowing greater flexibility in the positioning of the manually operable setting ring.

Another object is to provide means in such a system for enabling a manual preselection of a distance range and automatic focusing or scanning within that selected range.

SUMMARY OF THE INVENTION

In accordance with my present invention, a guide rod similar to that referred to, fastened to a lens mount and extending rearwardly therefrom parallel to the optical axis while being slidably and nonrotatably held in internal bearing means of a lens barrel, coacts with a threaded member forming a coaxial rearward extension thereof, this member being nonrotatably held in the camera housing with freedom of axial displacement and being engaged by a threaded drive element such as a captive nut. The guide rod and its extension, which are relatively axially shiftable, are urged by biasing means such as a contractile spring into a predetermined relative axial position so as to constitute, in effect, a lost-motion link which converts a rotation of the drive element into an axial motion of the lens mount; such rotation is brought about by a reversible motor having a pinion in mesh with gear teeth of the drive element, preferably with interposition of a slipping clutch as in the system of the Holderbaum application. A manually rotatable setting ring, carried on the lens barrel in an axially fixed position, has a camming groove registering with an axially extending slot in the lens barrel, the shiftable lens mount being provided with a pin or similar radial projection which extends through the slot into engagement with the camming groove but is received therein with sufficient play to enable an axial shift of the lens mount by the motor independently of the position of the setting ring; conversely, the lens mount is axially entrainable via its projection by the setting ring against the force of the biasing means for the manual establishment of a selected focusing position.

In this way, as more fully explained hereinafter, the projection of the lens mount is held by the biasing means against an edge of the camming groove when the threaded extension of the guide rod is retracted by the drive motor, this edge defining one of the limits (usually the more remote one) of a selected distance range within which the lens mount can be displaced by operation of the motor. The extent of that range is determined by the width of the camming groove.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing the sole FIGURE of which illustrates, somewhat diagrammatically and in axial section, a motion-picture camera with a varifocal objective focusable by a mechanism according to my invention.

SPECIFIC DESCRIPTION

The camera shown in the drawing comprises a varifocal or zoom-type objective, generally designated **1**, and a camera body, generally designated **2**. The objective **1** is provided with a lens barrel **10** which projects from the camera housing **33** and is centered on an optical axis O. Also centered on this axis are several lens members constituting a positively refracting front component **3**, two negatively refracting intermediate components **4**, **5** and a stationary rear component **6**; the latter, disposed outside lens barrel **10** within housing **33**, consists of a plurality of lenses not illustrated individually.

As is well known per se, an axial shifting of the second component **4** changes the focal length of lens assembly **3** - **6** and must be accompanied by a compensatory displacement of the third component **5** in order to keep the image plane of the objective coincident with the sensitive surface of a film **7**. The concurrent shifting of components **4** and **5** is brought about by the rotation of a sleeve **34**, provided for this purpose with a knob **35**, which has camming grooves **31**, **32** engaged by respective pins that pass through an axially extending slot **36**

of the lens barrel 10 and are rigid with their respective lens mounts 37, 38. The lens mounts are slidably supported by axially extending guide rods not shown.

Front component 3, here shown as a compound lens, is provided with a lens mount 8 which is axially movable between an infinity position (full lines) and a closeup position (dot-dash lines), independently of lens mounts 37, 38, for focusing the objective upon an object to be photographed, either manually or automatically under the control of a conventional distance finder. Lens mount 8 is cantilevered on an axially extending guide rod 14 that is slidably and nonrotatably received in an inner annular flange 26 of lens barrel 10 and has a rear extremity sliding in a bore 19 of an extension member 18 which is guided in a bearing block 27 forming part of a rear wall 28. A transverse pin 20 of guide rod 14 engages in an axial slit 39 of member 18 to prevent relative rotation of the two relatively axially shiftable members 14 and 18. Member 18 terminates beyond bearing block 27, thus within camera housing 33, in a threaded stem 21 matingly engaged by a captive nut 22 which is held against axial displacement by the block 27 and by an extension 28' of end wall 28. A tension spring 16, anchored to rod 14 at 16 and to member 18 at 17, tends to contract the extensible link 14, 18 by urging these members into a limiting position in which the end of rod 14 abuts the bottom of the bore 19.

Nut 22 carries external gear teeth in mesh with a pinion 23 driven, via a slipping clutch 24, by a reversible electric motor 25 which is energizable (e.g. as described in my commonly owned U.S. Pat. No. 3,165,044) from a nonillustrated power supply. The automatic displacement of lens mount 8 by motor 25 via nut 22 and lost-motion connection 14–21, under the control of the aforementioned distance finder for example, is limited by the edges of a camming groove 13 formed in a milled setting ring 12 which is held against axial displacement on the front end of lens barrel 10, the groove 13 being engaged by a pin 9 on lens mount 8 penetrating an axially extending slot 11 of the lens barrel. With motor 25 arrested in a position in which member 18 is retracted to tension the spring 15, pin 9 is held against the rear edge of groove 13. Manual rotation of setting ring 12 thus establishes the remote limit of a distance range within which fine focusing can be carried out automatically. Ring 12 is provided with a distance scale (not shown) coacting with a stationary pointer.

In order to hold the lens mount 8 against rotation, and to prevent jamming or canting, I provide that lens mount with an ancillary guide rod 29 also slidable in flange 26 and terminating short of end wall 28. The two parallel rods 14 and 29 are fixedly interconnected, inside lens barrel 10, by a bracing ring 30 fastened to the rear end of rod 29 by a screw 35 and frictionally fitted onto an intermediate portion of the driven guide rod 14. It will be observed that ring 30 lies between the cam tracks 31 and 32 of components 4 and 5 so as not to interfere with their displacement by sleeve 34. Such a precaution, however, will not be necessary if the shifting of these components for zooming purposes is controlled by a camming sleeve of smaller diameter lodged inside ring 30. In either case, lens mount 8 forms with the two diametrically opposite rods 14 and 29 as well as ring 30 a rigid cage insuring precise axial movement of component 3 upon rotation of drive 22 or setting ring 12.

With pinion 23 of smaller diameter than nut 22, a favorable transmission ratio exists between motor 25 and guide rod 14 so that the frictional resistance encountered by the motor is small, its energy consumption is low and precise focusing is possible, e.g. under the control of an electronic comparator measuring contrasts between adjacent image points against a locally generated reference parameter. Other known distance meters usable for automatic focusing control operate with emitters of infrared radiation or radar pulses and corresponding receivers on the camera.

Though the combination of manual and automatic adjustability of lens mount 8 by setting ring 12 and drive motor 25 makes available a large focusing range, it may be desirable to restrict that range in certain positions of the zooming-control sleeve 34. Thus, focusing upon nearby objects may not yield sharp images with larger focal lengths. Sleeve 34 and ring 12 may therefore be provided with coacting formations, such as a lug 40 and a pin 41, limiting the excursion of front component 3 from its infinity position at the telephoto end of the varifocal range.

It will be apparent that more than a single component of an objective—possibly the entire lens assembly thereof—can be axially shifted for focusing purposes by the mechanism according to my invention.

I claim:

1. In a camera provided with a housing and an objective projecting forwardly from said housing, said objective including a lens barrel centered on an optical axis and a plurality of lenses in said lens barrel, at least one of said lenses being provided with an axially shiftable lens mount,

the combination therewith of:

stationary bearing means in said lens barrel;

a guide rod slidably and nonrotatably held in said bearing means, said guide rod being fastened to said lens mount and extending rearwardly therefrom parallel to said optical axis;

a threaded member forming a coaxial rearward extension of said guide rod nonrotatably held in said housing with freedom of axial displacement, said guide rod and said member being relatively axially shiftable;

a threaded drive element matingly engaging said member, said element being provided with gear teeth and being held against axial displacement in said housing;

a reversible motor provided with a pinion in mesh with said gear teeth;

a manually rotatable setting ring carried on said lens barrel in an axially fixed position, said setting ring being provided with a camming groove registering with an axially extending slot in said lens barrel, said lens mount being provided with a projection extending through said slot into engagement with said camming groove; and

biasing means urging said guide rod and said member into a predetermined relative axial position, said camming groove and said slot receiving said projection with sufficient play to enable an axial shift of said lens mount by said motor independently of the position of said setting ring, said lens mount being axially entrainable by said setting ring via said projection against the force of said biasing means.

2. The combination defined in claim 1 wherein said biasing means comprises a contractile spring anchored to said guide rod and to said member, said spring hold-

ing said projection onto a rear edge of said camming groove in a retracted position of said member.

3. The combination defined in claim 1 wherein said element is a captive nut.

4. The combination defined in claim 1, further comprising a slipping clutch interposed between said motor and said pinion.

5. The combination defined in claim 1, further comprising an ancillary rod parallel to said guide rod and shorter than the latter, said bearing means including an internal annular flange of said lens barrel close to said lens mount, said ancillary rod being slidably guided in said flange.

6. The combination defined in claim 5, further comprising annular bracing means rigidly connecting the rear end of said ancillary rod with a portion of said guide rod ahead of said member.

7. The combination defined in claim 1 or 2 wherein said one of said lenses is part of a front component of the objective, said lenses further forming additional components provided with control means for axially shifting same to vary the focal length of the objective.

8. The combination defined in claim 7 wherein said control means and said setting ring are provided with coacting formations limiting the displaceability of said lens mount in certain positions of said additional components.

Fig. 2

STILL CAMERA WITH A RETRACTABLE OBJECTIVE

BACKGROUND OF THE INVENTION

The present invention relates to still cameras, advantageously miniature cameras, with a viewfinder, an extensible and retractible objective, and a reversible electric motor which during its rotation in one direction is coupled with an objective-displacing device and during its rotation in the opposite direction is coupled with a film transport transmission and a film take-up spool, wherein a switching device is provided for reversing the motor.

Cameras of the above-mentioned general type are known in the art. In cameras of the above described construction, it is possible that overlapping of the picture field for individual pictures in the film gate of the camera takes place, as a result of the film pulling action on the film take-up spool.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the present invention to provide a camera in which during the displacement of the objective and simultaneous uncoupling of the film take-up spool from the motor, no overlapping of the picture fields for the individual pictures takes place in the film gate of the camera.

In keeping with this object, and with others which will become apparent hereinafter, one feature of the present invention resides, briefly stated, in a photographic camera in which locking means is provided for the film take-up spool and coupled with the motor switching means, so that when the electric motor is switched for rotation in a direction for displacing the objective and coupled with the objective-displacing device, the film take-up spool is locked against rotation, and when the electric motor is reversed and uncoupled, the film take-up spool is released. When the photographic camera is designed in accordance with the present invention, the above-mentioned overlapping of the picture fields for individual pictures cannot take place.

The novel features which are considered characteristic for the present invention are set forth in particular in the appended claims. The invention itself, however, both as to its construction and its method of operation, together with additional objects and advantages thereof, will be best understood from the following description of specific embodiments when read in connection with the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** is a view showing a photographic camera in accordance with the present invention in direction toward the objective and the film plane with a removed housing, wherein parts located one behind the other are shown for the sake of clarity as located partially one below the other; and

FIG. **2** is a plan view of the photographic camera of FIG. **1**.

DESCRIPTION OF THE PREFERRED EMBODIMENT

A photographic camera, preferably a miniature photographic camera, is shown in the drawing. Its housing is removed for the sake of clarity.

The camera has an objective or an objective mount which is identified by reference numeral **2**. A viewfinder is arranged laterally adjacent to the objective **2** in the upper part of the housing. The viewfinder has an inlet opening or a front lens which is identified by reference numeral **3**. A cover plate **4** is movably arranged in front of the objective **2** and is insertable or pivotable behind the front side of the camera housing. When the camera is not used, the cover plate **4** is displaced so that it is located in front of the objective **2**, and the latter is protected against damage and dirtying. The front lens **3** of the viewfinder is arranged in a cavity of the front side of the camera. A cover slider **5** is arranged displaceably so that it moves between one end position in which it covers the front lens **3** of the viewfinder and another end position in which it releases the same.

There is a possibility that a user displaces only the cover slider **5** to the working position shown in dotted lines and, since he can now look through the viewfinder, forgets that the objective **2** is still closed by the cover plate **4**. In order to avoid this, the cover slider **5** is formed as a handle for joint displacement of the cover slider **5** of the viewfinder and the cover plate **4** of the objective to their working positions, for example **4'**, or their closed positions.

In FIG. **2**, the objective **2** is shown in its nonworking position, in which it is inserted into the camera, as shown in solid lines. For the use of the camera, the objective **2** is displaced out of the camera housing to the working position shown in dotted lines, after withdrawing of the cover plate **4**. The joint movement of the cover slider **5** of the viewfinder, the cover plate **4** of the objective, and the objective itself is performed with the aid of an electric motor **12** which can alternately rotate in opposite directions for driving a film take-up spool **80** and a film transport of the film **59**, on the one hand, and for the displacement of the objective, on the other hand. For this purpose, a drive coupling is provided between the motor **12** and a motor pinion **12*b'*** or between a spool gear **80*a*** and a spool **80** at respective locations. The drive coupling acts only in a direction of film take-up on the spool **80** so that the spool can be taken along only in the winding direction when the motor **12** rotates in a direction which is opposite to the objective-displacement direction.

The motor **12** is provided with a rotary switch **12*a*** which changes polarity in the event of rotation from the position shown in FIG. **2** for film transporting by an angle of 90°. A pin **12*b*** of the rotary switch **12*a*** engages in a slot **6*c*** of a strip **6*d*** of a slider **6**, whereby the pin **12*b*** and the slot **6*d*** are so arranged that during movement of the slider **6** from its one end position to its other end position, the motor changes the polarity. Simultaneously, during the movement of the slider **6** in its position which corresponds to the working position of the viewfinder **3** and the cover plate **4** of the objective **2**, not only the motor changes the polarity relative to its position corresponding to the film transport position, but it is also simultaneously switched on. The cover slider **5** of the viewfinder has a control slot **5*b*** which is formed as a large recess with two oppositely running identical control curves **5*c*** and **5*d***. The pin **6*a*** of the slider **6** abuts against the control curves **5*c*** and **5*d*** under the action of a spring **13**. The cover plate **4** of the objective and a driving part **6*b*** are so arranged that during the movement of the cover slider **5** of the viewfinder in direction of the arrow **9**, the slider **6** first moves in direction of the arrow **14** and thereby pivots the cover plate **4** of the objective into its working position **4'**

shown in dotted lines. In this position, the slider **6** and the cover plate **4** are locked, as will be described hereinbelow. During further displacement of the cover slider **5** of the viewfinder into its position which releases the viewfinder **3**, the motor **12**, **12***a* changes its polarity in the above-described manner and is switched on, and the slider **6** locked with the interval is released by the control curve **5***c* to allow return to its inoperative position.

A known gear transmission with a one-way coupling (not shown in the drawing) is provided between the motor **12** and the objective **2** or its mount. As a result of this, a gear **15** can be driven only in the clockwise direction. The gear **15** is connected with an eccentric disk **16**, **16***a*. The eccentric disk has two recesses **16***b* which are offset by 90° relative to an eccentric pin **16***a* and arranged diametrically opposite to one another. The objective mount **3** is provided with a carrier plate **7** which is displaceable along an axis **15** extending parallel to the axis of the objective and has a groove **17***a* normal to the axis **18**. An eccentric pin **16***a* engages in the groove **17***a*.

When the eccentric rotates by 180° by the slider **6** when the motor **12** is switched on, the objective **2** is displaced from the position shown in solid lines in FIG. **2** to the position shown in dotted lines outwardly of the camera, after removal of the cover plate **4**. The latter position is identified by reference numeral **2'**. The pin **6***a* and the slot **6***c* are so dimensioned that the motor **12**, **12***a* is first switched on when the cover plate **4** fully releases the objective **2**. When the cover slider **5** of the viewfinder thereby moves opposite to the direction of arrow **9** for closing the camera, the slider **6** is moved in direction of the arrow **14** through the control curve **5***c* and changes the polarity of the motor from its condition corresponding to the film transport position and switches on the same. In this case, the eccentric **16***a* rotates in the counterclockwise direction by 180° further and displaces back the objective **2** into the housing of the camera.

After the movement of the slider **6** in the direction of arrow **14**, despite the preparatory release of the slider **6** by the respective oppositely running curves **5***c*, **5***d* during opening of the camera or closing of the same, the slider **6** holds the switch **12***a* in the changed-pole closed position until the objective **2** is completely withdrawn from or inserted into the camera, the slider **6** will be temporarily locked in its position in direction of the arrow **14**. For this purpose, the slider **6** has a raised strip **6***e*, and a projection **20***a* of a lever **20** pivotable about an axle **21** abuts against the strip **6***e* in the non-working position of the slider **6**. The lever **20** is pulled against the strip **6***e* under the action of a spring **22** so that the projection **20***a* lowers behind the strip **6***e* when the slider **6** reaches its end position in direction of the arrow **14**. Finally, a lever **25** is provided which is displaceable under the action of a spring **23** on an axle **24**. The lever **25** has a lever arm **25***a* which is pulled under the action of a spring **26** against the outer surface of the eccentric disk **16** or its recesses **16***b*.

When the eccentric disk **16** rotates by approximately 180° after the extension or retraction of the objective **2**, the lever arm **25***a* engages in the directly passing recess **16***b* and is displaced by the same against the action of the spring **23** on the axle **24**. Thereby, a projection **25***b* takes along the lever **20** in clockwise direction so that its projection **20***a* is lifted from the strip **6***e*. The slider **6** is released for return to its non-working position against the direction of the arrow **14** and runs down under the action of the spring **13**. The switch **12**, **12***a* displaces in clockwise direction to its open initial position shown in FIG. **2**. Approximately near the end of its return movement, the slider **6** acts by its edge **6***f* on the lever arm **25***b* of the lever **25** and rotates the same in clockwise direction to the position shown in FIG. **1**. During this rotation, the lever arm **25***a* runs out of engagement with the recess **16***b* and somewhat moves back under the action of the spring **23** to the position shown in FIG. **2**, so that it again lies above the eccentric disk **16**; compare FIG. **1**. During the next actuation of the cover slider **5** and the slider **6**, the lever arm is again released by the edge **6***f* for abutting against the eccentric disk **16** or engaging in a recess **16***a*.

During return movement of the slider **6** against the direction of arrow **14** after the release by the lever **20**, the slider **6**, **6***b* releases at the end of its movement also the cover plate **4** for displacement to its position in which the cover plate **4** closes the objective **2**. When in the respective position of the slider **6**, as a result of the release of the viewfinder **3** by the cover slider **6**, the objective is extended out of the camera, the cover plate **4** abuts against the objective mount and is thereby held in its open position. The viewfinder and the objective are in their preparatory positions. When the slider **6** assumes its returned position after the movement of the cover slider **5** of the viewfinder in which the viewfinder is closed, the cover plate **4** is released from the objective inserted into the camera and pivots under the action of the spring **10** in front of the objective **2** so as to close the latter. An abutment **30** fixedly connected with the housing is provided for the closed position of the cover plate **4** of the objective.

Since during the motor-driven movement of the objective out of and into the housing of the camera the spool **80** is not coupled with the motor **12**, it can rotate during this phase under the pulling action of the film. This leads to displacement of the film **59** in the film gate of the camera and to overlapping of individual pictures. Because of this, the take-up spool **80** must be secured against rotation during the movement of the objective by the motor **12**.

For this purpose, an arm **87***a* of a lever **87** rotatable about an axle **88** abuts against the end of the slider **6**. Another arm **87***b* of the lever **87** abuts against a locking lever **85** with a locking tooth **85***a*. Its spring **86** pulls the locking tooth **85***a* out of engagement with the gear **80** and thereby holds the arm **87***a* in abutment against the slider **6**.

When the movement of the objective is performed by displacing the cover slider **5** in one of its two possible directions of movement, the slider **6** moves in the direction of arrow **14** and pivots via the lever **87** the locking tooth **85***a* into engagement with the gear **80***a*, so that the take-up spool **80** is secured against rotation and thereby the film **59** is secured in its position. Since the slider **6** assumes this position at the end of the movement of the objective, the spool **80** remains locked by the locking tooth **85***a* until the end of each movement of the objective and change of polarity of the motor **12** in the film transport position. When at the end of the movement of the objective—either for extension from the camera or retraction into the camera—the slider **6** is released for return to its shown initial position and thereby the motor **12** is reset to its film transport position, the lever arm **87** follows under the action of the spring **86**. The locking lever **85** also follows the same under the action of the spring **86**, so that the locking tooth **85***a* is lifted out of the gear **80***a* and it rotates during renewed actua-

tion of the motor **12** in a take-up direction of the take-up spool.

Thus, during the rotation of the motor in one direction for the transport of the objective and in the other direction for driving of the film spool, it is guaranteed that the film spool and thereby the film cannot assume during the movement of the objective not moving and damaging intermediate positions.

It is to be understood that a slider can be utilized instead of the levers, and an interengaging coupling can be utilized instead of the frictional coupling, and vice versa. Instead of the cover slider **5** for reversing the motor **12**, a special switching handle can be utilized for cooperating with the slider **6**.

It will be understood that each of the elements described above, or two or more together, may also find a useful application in other types of constructions differing from the types described above.

While the invention has been illustrated and described as embodied in a photographic camera, it is not intended to be limited to the details shown, since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features that, from the standpoint of prior art, fairly constitute essential characteristics of the generic or specific aspects of this invention.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims:

1. A photographic camera, comprising a housing; a viewfinder; an objective displaceable between extended and retracted positions relative to said housing; means for displacing said objective between said extended and retracted positions; film transporting means; and film take-up spool; an electric motor rotatable in two opposite directions and arranged so that when said electric motor rotates in one of said directions it is coupled with said objective displacing means and when said electric motor rotates in the other of said directions it is coupled with said film transporting means and said film take-up spool; switching means for reversing said electric motor; and locking means for said film take-up spool, coupled with said switching means so that when said electric motor is switched for rotation in said one direction for displacing said objective and is coupled with said objective displacing means said film take-up spool is locked against rotation, and when said electric motor is reversed and uncoupled said film take-up spool is released.

2. A photographic camera as defined in claim **1**; and further comprising means for coupling said electric motor with said objective displacing means, on the one hand, and said film transporting means and said film take-up spool, on the other hand, said coupling means including a transmission and one-way clutch means.

3. A photographic camera as defined in claim **1**, wherein said switching means includes a switching element displaceable between two different positions in dependence upon the switching of the electric motor to a respective one of said directions of rotation, said locking means including a locking element connected with said switching element of said switching means.

4. A photographic camera as defined in claim **3**, wherein said locking element of said locking means is connected with said switching element of said switching means in a frictional manner.

5. A photographic camera as defined in claim **3**, wherein said locking element of said locking means is connected with said switching element of said switching means in interengaging manner.

6. A photographic camera as defined in claim **3**, wherein said switching element of said switching means is formed as a slider, said locking element of said locking means being formed as a lever connected with said slider.

7. A photographic camera as defined in claim **3**, wherein said switching element of said switching means is formed as a lever, said locking element of said locking means being formed as a slider connected with said lever.

8. A photographic camera as defined in claim **1**; and further comprising a cover movable relative to said viewfinder between closed and open positions so as to cover and expose said viewfinder, respectively, said switching means being connected with said cover so that when said cover moves between said closed and open positions, said objective is displaced between said retracted and extended positions.

9. A photographic camera as defined in claim **8**; and further comprising a further switching means arranged so that after terminating the displacement of said objective said first mentioned switching means is returned to its condition in which it is coupled with said film transporting means.

10. A photographic camera as defined in claim **8**, wherein said cover of said viewfinder is formed as a handle.

11. A photographic camera as defined in claim **1**, wherein said film take-up spool has a transmission including a toothed wheel, said locking means having a displaceable member provided with a locking tooth which is engageable with said toothed wheel of said transmission of said film winding spool.

12. A photographic camera as defined in claim **11**, wherein said displacing member of said locking means is formed as a lever, said locking tooth being provided on said lever.

13. A photographic camera as defined in claim **11**, wherein said displaceable member of said locking means is formed as a slider, said locking tooth being provided on said slider.

VARIABLE-FOCAL-LENGTH OBJECTIVE AND AN OPTICAL SYSTEM EQUIPPED WITH OBJECTIVES OF THIS TYPE FOR THE PRODUCTION OF SPECIAL EFFECTS ON FILM

This invention relates to a variable-focal-length objective as well as to optical systems equipped with said objective for producing special effects on unexposed films.

Optical systems designed for the production of special effects on an unexposed film by superimposing at least one previously exposed film on this latter are commonly designated as "optical printers" or as "caption stands", depending on whether the camera which unwinds the unexposed film and the objectives of the device move respectively in a horizontal or in a vertical direction. A fixed-focal-length objective is associated with each projector; an optical printer can thus comprise a main projector, an aerial-image projector and a beam-splitter projector for producing a 90° deviation with respect to the axis of the camera.

Known systems are equipped with a mechanical combination which makes it possible to displace the camera, camera objective and aerial projector objective as well as the projector in a horizontal direction in order to obtain either an enlargement or a reduction according to the direction of displacement, this being achieved while maintaining the focus on the plane of the unexposed film throughout the range of travel of the objective.

In the case of caption stands, the principle is the same; in this case, the camera dolly moves in the vertical direction and the plane of sharpness is located on the table of the stand.

However, it proves virtually impossible to eliminate the mechanical play which exists in optical systems of this type. In consequence, the focus does not remain constant and may be displaced either to the front or to the rear with respect to the plane of the unexposed film on which the films mounted on the projectors are to be combined. The aim of the invention is to overcome these disadvantages by replacing the fixed-focal-length objectives of conventional optical printers and caption stands by automatic-focusing varifocal objectives.

In accordance with the invention, the variable-focal-length objective which is intended to equip optical printers and caption stands for the production of special effects on films is constituted by four groups of lenses, viz:

a first convergent group of four lenses,
a second divergent group of four lenses,
a third convergent group of six lenses,
a fourth convergent group of two lenses,

the first and third groups being coupled together and movable.

This objective has a well-determined lens formula or silhouette, the numerical characteristics of which will be given in the following description.

The optical system for the production of special effects on an unexposed film, constituting an optical printer or a caption stand according as the movable elements undergo either a horizontal or a vertical displacement, comprises at least one objective associated with means for projecting at least one exposed film on the unexposed film with a view to obtaining the special effects.

In accordance with the invention, at least one of the aforesaid objectives is of the automatic-focusing varifocal type and has the characteristics mentioned in the foregoing.

According to another essential feature of the invention, the automatic-focusing varifocal objective which equips the optical system is pivotally mounted on an axis located at the midpoint between the object plane and the image plane and parallel to said planes so as to be capable of taking up two symmetrical positions with respect to said axis by reversal of said objective and so as to ensure that:

when the objective is located between the axis aforesaid and the object, the magnification corresponding to the limits of displacement in translational motion of the first and third groups varies substantially between 1 and 4 and that

when the objective is placed in its second position after reversal about the axis from the previous position, the reduction obtained by translational motion of the first and third groups varies substantially between 1 and 0.25.

In the case of a caption stand, the automaticfocusing varifocal objective provided by the invention makes it possible to obtain magnifications or reductions with a ratio of 1 to 20.

These and other features of the invention will be more apparent upon consideration of the following description and accompanying drawings in which two embodiments of the invention are shown by way of example but not in any limiting sense, and in which:

FIG. **1** is a simplified view in perspective showing a first embodiment of the invention constituted by an optical printer equipped with two variable-focal-length objectives in accordance with the invention;

FIG. **2** is a view in partial elevation along the optical axis of the optical printer of FIG. **1** and showing the assembly of a variable-focal-length objective;

FIG. **3** is a view in side elevation of the variable-focal-length objective of FIG. **2** together with its support;

FIG. **4** is an overhead plan view of the variable-focal-length objective of FIGS. **2** and **3** together with its support;

FIG. **5** is an optical diagram showing the design principle of the objective in accordance with the invention;

FIG. **6** is a diagram showing the elements constituting the different groups of lenses of the variable-focal-length objective in accordance with the invention;

FIG. **7** is an explanatory diagram showing the possibility of reversal of the variable-focal-length objective about an axis which is equidistant from the object and the image, in accordance with an essential feature of the invention;

FIG. **8** is a schematic view in perspective showing a second embodiment of the invention in which the automatic-focusing varifocal objective serves to equip a caption stand.

The optical system shown diagrammatically in FIG. **1** is an optical printer or in other words a device for producing special effects on an exposed film **1** unwound by a camera (not shown), starting from a combination of two exposed films **2**, **3** projected respectively by a main projector **9** and an aerial image projector **6**.

Starting from the end remote from the film-unwinding camera **1**, the device comprises in known manner a lamp **4**, a condenser **5**, the aerial image projector **6** which unwinds the film **3**, a first objective **7**, a con-

denser **8**, the main projector **9** for projecting the second film **2**, and a second objective **11**. All these elements are mounted on a support frame **50** along a general optical axis X—X of the system.

The optical printer shown in FIG. **1** is equipped with two automatic-focusing varifocal objectives **7**, **11** which are intended to permit enlargements or reductions of images which pass in front of the projectors **6**, **9** within predetermined limits while maintaining the image obtained strictly in the plane of the unexposed film **1**.

The objectives **7** and **11** are each rigidly fixed to a lateral shoe **31**, said shoe being disposed vertically and rotatably mounted on a block **32** about a horizontal axis Z—Z which is perpendicular to the optical axis X—X.

The block **32** is in turn slidably mounted in a vertical plane parallel to the axis X—X, on a vertical plate **33**. By way of example, the sliding connection between the plate **33** and the associated block **32** can be provided by an arrangement of the tenon and mortise type forming a dovetail assembly as illustrated in FIG. **1**; this figure shows that the plate **33** is provided with a dovetail tenon **33***a* engaged within a corresponding mortise of the block **32**.

The assembly constituted by the objective **7** (or **11**) together with its support **32**, **33** is in turn mounted on a solepiece **34** which is capable of sliding on a base **35** along an axis X' parallel to the axis Z—Z. Finally, the base **35** is also slidably mounted on a solepiece **36** for displacement along the optical axis X—X. The sliding connections between on the one hand the solepiece **36** and the base **35** and on the other hand between this latter and the plate **34** are obtained by means of "tenon and mortise" assemblies of the dovetail type as in the case of the assembly formed by the plate **33** and the block **32**.

All the displacements along the axis X—X, the axis X', the vertical axis Y of sliding motion of the block **32** can be adjusted by means of micrometer screws **51**, **52**, **53**.

The horizontal axis Z—Z on which the shoe **31** carrying the objective **7**, **11** is pivotally mounted is located at the midpoint between the object plane P (FIG. **5**) and the image plane P' corresponding to the unexposed film **1** and is parallel to these planes. In consequence, and in accordance with an essential feature of the invention, a pivotal movement of the shoe **31** about the axis Z—Z and through a sector of 180 degrees as indicated by the arrows F in FIG. **1** makes it possible to reverse the objective **7** or **11** so as to cause this latter to take up a position **7***a*, **11***a* which is symmetrical with the previous position with respect to the axis Z—Z. It should also be noted that these positions **7***a*, **7** and **11***a*, **11** are also symmetrical in each case with respect to the corresponding vertical axis Y.

In the case of each objective **7**, **11**, the support is provided with two lateral stops **45**, **46** having vertical rods and secured to the base of the block **32** on each side of the shoe **31**. By means of said stops **45**, **46**, the horizontality of the objective **7** or **11** can be suitably adjusted in each of its two positions in which the objective is applied against either of the two rods. The opposite edges **31***a* of the shoe **31** are rounded so as to permit pivotal motion of this latter and of the objective (**7**, **11**) between the stops **45**, **46**.

The possibility of reversal of the objective **7** (or **11**) is shown diagrammatically in FIG. **7**. Thus, in accordance with the invention, the objective is capable of assuming either of the two symmetrical positions with respect to the vertical axis Y—Y after a pivotal displacement about the horizontal axis Z—Z through an angle of 180 degrees. In position **7***a*, the distance D between the objective and the image plane D' is equal to the distance D' between the object plane P and the objective. Correlatively, the distance **D1** between the objective **7** which is placed in the position shown in full outline and the image plane P' is equal to the distance **D2** between the rear face of the objective after reversal at **7***a* and the object plane P. The objective **7**, **11** has a lens formula or "silhouette" which will be described in detail hereinafter and the numerical values are as follows:

D1 = D2 = 355.05 mm
D = D' = 141.5 mm

The objective (**7** or **11**) will now be described with reference to FIGS. **5** and **6**.

The objective **7** in accordance with the invention is constituted by four groups of lenses, viz:

- a first convergent group **10** of four lenses **12** to **15** (shown in detail in FIG. **6**),
- a second divergent group **20** of four lenses **16** to **19**,
- a third convergent group **30** of six lenses **21** to **26**,
- a fourth convergent group **40** of two lenses **27**, **28**,

the first and third groups **10**, **30** being coupled together and movable.

The displacement of these coupled groups **10**, **30** is effected by means of a micrometer knob **47** in a manner known per se, each group **10** and **30** being thus capable of moving over a distance of 43.5 mm. Given that P is the object plane and P' is the plane of the film **1**, a displacement of the movable groups **10**, **30** in the direction of the plane P produces an enlargement of the image in the plane P'. Conversely, a displacement of the groups of lenses **10**, **30** towards the plane P' produces a reduction of the image.

In FIG. **6**, the plane P corresponds to the point A and the point P' corresponds to the point A'.

The formula or "silhouette" of the automaticfocusing varifocal objective in accordance with the invention is given in the following table, in which:

- R is the radius of curvature of the successive faces of the lenses with a precision of 0.002 mm,
- E is the thickness of the lenses in millimeters with a precision of 0.1 mm,
- Nd is the refractive index of the lenses,
- NU (ν) is a complementary characteristic of the lenses.

When the objective has been placed in the position shown in full outline in FIG. **7**, the displacement of the first and third groups of coupled lenses **10, 30** towards the left or in other words towards the object plane P produces an enlargement of the image in the plane P' which can vary between 1 and 4 approximately. After reversal of the objective **7** about the axis Z—Z through an angle of 180 degrees to the position **7***a*, the displacement of the groups of lenses **10, 30** by means of the knob **47** between the limits determined by the characteristics of the objective makes it possible to obtain a reduction of the image in a ratio which varies between 1 and 0.25.

The advantages of the objective and of the optical system equipped with said objective for the production of special effects (optical printer illustrated in FIG. **1** or caption stand) are as follows:

By virtue of the fact that the fixed-focal-length objective of cameras or projectors of optical printers or caption stands is replaced by the variable-focal-length objective in accordance with the invention, cameras or projectors equipped with this variable-focal-length objective can accordingly be allowed to remain stationary. It is in fact solely the focal length of the objective which gives rise to the phenomenon of reduction or enlargement of the desired field by undergoing a variation. This device therefore has an enormous advantage in that it permits complete elimination of play of mechanical parts which could not be suppressed in known systems of the prior art and produced differences in sharpness in the images obtained on the unexposed film. Elimination of mechanical parts and the consequent possibility of moving the cameras or the projectors also simplifies manufacture to a considerable extent and produces a correlative reduction in cost price of the optical system.

The ratio of extreme focal lengths is considerably reduced and permits better correction of aberrations.

Since the variable-focal-length objective in accordance with the invention is incorporated in a pivoting system of the type shown in FIG. **1**, said objective can readily be rotated either in one direction or in the other in order to carry out reductions or enlargements of the image.

In the enlargement or reduction operations, it is not necessary to carry out any correction of diaphragm with the variable-focal-length objective in accordance with the invention. This dispenses with the need for the electromechanical or electronic light-compensating systems which are necessary in conventional systems by reason of the substantial displacements of the film plane and of the objective (increase and decrease as a function of the square of the distance).

The elimination of moving mechanical parts of known devices by installation of at least one variable-focal-length objective in a stationary system simplifies the manufacture of optical printers or caption stands and reduces their overall size to a very appreciable extent.

Finally, if the optical printer or the caption stand is equipped with an additive or subtractive lamphouse, the luminous flux of this latter is not modified during enlargement and reduction operations, which is not the case in a conventional system.

There is shown in a simplified manner in FIG. **8** a caption stand which can be equipped with two variable-focal-length objectives in accordance with the invention.

The system comprises: a first film **43** unwound by a projector **60**, a variable-focal-length objective **42** on a pivoting system of similar design to the system shown in FIG. **1**, a reflecting mirror **41** which reflects the luminous flux towards a condenser device **39** on which a document (not shown) is placed. The supports provided for the elements **39** and **41** are known per se and have therefore not been illustrated. This aerial image and the document aforesaid are re-taken by a variable-focal-length objective **38** mounted on a pivoting system which is similar to the system of FIG. **1**. The resultant image is received by an unpexposed film **37** unwound by a camera **61** secured in such a manner as to be adjustable for height to a vertical upright member **62** which is provided at its base with supporting fins **63**.

The axis A—A of the objective **38** and of the condenser **39** is vertical whereas the axis B—B of the objective **42** and of the projector **50** which unwinds the film **43** is horizontal.

As shown in the figure, the supports provided for the objectives **42** and **38** are similar to those provided for the objectives **7** and **11** and are therefore designated by the same reference numerals. Correlatively, the objective **38** is capable of pivotal displacement about a horizontal axis at right angles to the shoe **31** and to the plane of FIG. **8** as well as to the vertical optical axis A—A in order to take up the position **38***a* shown in dashed outline. Similarly, the objective **42** is capable of pivotal displacement about a vertical axis at right angles to the horizontal optical axis B—B whilst the shoe **31** is capable of pivotal displacement about said vertical axis together with the objective **42**.

The automatic-focusing varifocal objective contemplated by the invention makes it possible in the case of the caption stand of FIG. **8** to obtain enlargements or reductions with a ratio of 1 to 20.

The invention is not limited to the embodiments hereinabove described and can include a large number of alternative forms of construction. Thus it is apparent that, in the case of an optical printer or of a caption stand provided with two objectives, either or both of said objectives may be in accordance with the invention. It is also possible to produce a number of different combinations in which a plurality of objectives are employed either partly or wholly in accordance with the invention. The objectives can be mounted on pivoting systems of any suitable type which is equivalent to the device shown in the drawings.

What is claimed is:

1. A variable-focal-length objective which is intended to equip optical printers and caption stands for the production of special effects on films, wherein said objective is constituted by four groups of lenses, viz:

a first convergent group of four lenses,

a second divergent group of four lenses,

a third convergent group of six lenses,

a fourth convergent group of two lenses,

the first and third groups being coupled together and movable, and wherein said objective has the following lens formula in which:

R is the radius of curvature of the successive faces of the lenses with a precision of 0.002 mm,

E is the thickness of the lenses in millimeters with a precision of 0.1 mm,

Nd is the refractive index of the lenses,

NU (ν) is a complementary characteristic of the lenses.

2. An optical system for the production of special effects on an unexposed film, constituting an optical printer or caption stand and comprising at least one objective associated with means for projecting at least one exposed film on the unexposed film in order to obtain special effects, wherein at least one of the objectives is constituted by four groups of lenses, viz:

a first convergent group of four lenses,

a second divergent group of four lenses,

a third convergent group of six lenses,

a fourth convergent group of two lenses, the first and third groups being coupled together and movable.

3. An optical system according to claim **2**, wherein said variable-focal-length objective is pivotally mounted on an axis located at the midpoint between the object plane and the image plane and parallel to said planes so as to be capable of taking up two symmetrical positions with respect to said axis by reversal of said objective, and wherein:

when the objective is located between the axis aforesaid and the object, the magnification corresponding to the limits of displacement in translational motion of the first and third groups varies substantially between 1 and 4, and

when the objective is placed in its second position after reversal about the axis from the previous position, the reduction obtained by translational motion of the first and third groups varies substantially between 1 and 0.25.

4. An optical system according to claim **3** in which the general optical axis is horizontal, wherein said system comprises means for producing a pivotal displacement of the variable-focal-length objective about a horizontal axis at right angles to the optical axis of the system in order to cause said system to take up successively two symmetrical positions with respect to said axis after reversal through an angle of 180 degrees.

5. An optical system according to claim **4**, wherein the means for producing a pivotal displacement of the objective about the axis aforesaid comprise a vertical shoe mounted on a support block and rotatable about said axis, stops for adjusting the positions of the objective being placed on each side of said shoe.

6. An optical system according to claim **3**, constituted by a caption stand comprising a projector having a horizontal optical axis which is capable of unwinding a first film, a mirror for reflecting the luminous flux to a condenser which is intended to receive a document, an unexposed film unwound by a camera located above the

condenser and carried by a supporting element in such a manner as to ensure that the optical axis of said element and of the camera is vertical, and two variable-focal-length objectives, one objective being mounted between the projector and the reflector for pivotal displacement about a vertical axis at right angles to the horizontal optical axis, the other objective being placed between the condenser and the camera for pivotal displacement about a horizontal axis at right angles to the vertical optical axis.

[57] **ABSTRACT**

Disclosed is a camera including a camera housing and an objective lens having an image axis. The objective lens for the camera is mounted in a tube which is movable between an extended exposure position and a retractive storage position. When the tube is in the extended exposure position, a locking device responsive to operation of the shutter release, increases the biasing force on the objective lens towards its extended position. The locking device is made up of several cams spring biased against two pins radially projecting from the objective tube. The cams are prevented from bearing against the pins by a control linkage which prevention is released during shutter actuation.

CAMERA HAVING AN INDEPENDENTLY FOCUSED RETRACTABLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

The present invention generally concerns a photographic camera and particularly, a miniature camera having a retractable focusable objective lens.

In copending patent application Ser. No. 100,358 entitled "Camera Having an Independently Focused Retractable Objective Lens," filed Dec. 5, 1979, now U.S. Pat. No. 4,280,762, a camera is disclosed which has a relatively small size when the objective lens is retracted. It has good handling, a control means for focusing the camera and viewing through the viewfinder which all facilitate the quick, simple taking of snapshots.

In the above-described camera, the objective tube is spring-biased in its extended position against an adjustable cam which accomplishes the focusing of the camera. Additionally, the same spring force is primarily responsible for extending the objective tube from its retracted position to its extended position. Thus, it is desirable on one hand to have a relatively strong spring force to extend the objective tube and at the same time maintain the objective tube in firm contact with the cam for focusing purposes and on the other hand for ease of focusing and to reduce frictional loads, it is desirable to have a very light biasing of the tube. An additional problem occurs when a relatively light spring is used in that a very small accidental pressure on the side of the objective tube can cause the tube to deflect so that the camera is not focused.

The conflicting interests created by wanting a strong spring on one hand and a weak spring on the other requires a compromise which does not optimally satisfy either of the two requirements.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to provide an improved independently focused retractable objective lens camera, said improvement comprising a mechanism which permits ease of focusing and relatively small forces involved in focusing while at the same time provides precise locking in place of the objective tube in its focused position.

The above and other objects are achieved by providing a camera housing and an objective lens with an image axis, said lens is mounted for movement substantially parallel to the image axis between an extended exposure position and a retracted storage position. The camera includes a means for manually setting the focal range of the camera. A means for variably limiting axial movement of the mount in the extended position in response to the range setting means is provided through means of a ring and cam assembly. A means for variable biasing the mount towards the extended position assures that a minimum bias is provided prior to shutter actuation to facilitate focusing but a high degree of bias is utilized during actual shutter actuation to ensure that the camera is correctly focused.

In a preferred embodiment of the present invention, a locking system is used which, simultaneously with the actuation of the shutter release, engages the objective tube to increase the bais forcing the objective tube against the means limiting axial movement.

BRIEF DESCRIPTION OF THE DRAWING

A more complete appreciation of the invention and the attendant advantages thereof will be more clearly understood by reference to the following drawing, wherein:

The drawing is a front perspective view of an independently focused retractable objective lens system with a shutter-actuated locking means for firmly positioning the objective lens in its extended position.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Referring now to the drawing, a photographic still camera is shown which is one embodiment would use 35 mm roll film. The camera housing **10** indicated in dash-dot lines has an axially displaceable objective tube **11** mounted therein. In the extended position (the position necessary to take a picture with the camera) the objective tube **11** projects from housing **10** and assumes an optically proper arrangement with respect to the film (not shown) which would be located in the camera in its window. When the camera is not in use, the objective tube **11** can be completely retracted inside housing **10** so that the camera provides relatively planar external surfaces facilitating its storage or packaging.

The film transport and shutter reset lever **13** and shutter release **17** (shown in dash-dot lines) are illustrated on the upper side of housing **10**. In order to clarify the presentation of the internal parts of the camera, the conventional knobs for setting aperture size, exposure speed and film speed have been omitted.

In a preferred embodiment, a motorized focusing arrangement **12** is provided with includes an electric setting motor **18** which may be controlled by a known auto-focusing system (again omitted for clarity). A pointer **14** of focusing system **12** is visible in the viewing field **15** of the camera and illustrates on range scale **16**, the distance in viewer **15** which was set by the focusing arrangement **12**.

A focusing ring **19** which is fixed with respect to movement along optical axis **20** is supported concentrically with respect to objective tube **11** and is free to rotate thereabout. The focusing ring **19** includes a cam means **21** which is in contact with projection **22** which is part of the objective tube **11**. Cam means **21** and projection **22** cooperate to form a means for variable limiting axial movement of the objective tube **11** and it can be seen that if focusing ring **19** is revolved about optical axis **20**, the extended position of objective tube **11** will vary slightly in the axial direction.

Cam means **21** and projection **22** are biased into contact with each other when the objective tube **11** extends from housing **10**.

In the specific embodiment shown, cam means **21** and projection **22** are designed as wedge-shaped projections **23** and **24**. Projection **23** is located on the focusing ring **19** on its backside **25** extending towards the inside of the camera housing. Lug **24** is mounted on flange **27** which projects from objective tube **11** and is solidly connected therewith. As will be obvious to one of ordinary skill in the art, a plurality of projections **23** and lugs **24** can exist at different radial positions around the periphery of the focusing ring and flange **27**. Finally, focusing ring **19** includes a segment of a gear crown **26** which meshes with a gear rack **29** of focuser **12**.

The primary bias of objective tube **11** in the axial direction is provided by spring **28** which is prestressed

in its extended position. This spring is of such design that after the objective tube **11** has been moved into the extended position shown, it maintains a small residual force generating a given compression or bias between cam means **21** and projection **22**. This bias is so chosen so as to be lower than the bias necessary to maintain the cam means and the projection in proper contact during film exposure. This lower than adequate bias permits ease of operation of the focusing means **12** especially during auto-focusing.

The extension spring **28** can be either a tension or compression spring and in the present instance is a tension spring acting on double arm rocker assembly **34**. The rocker **34** comprises two arms **30** and **31** which are mutually parallel and rigidly mounted to pivot shaft **32**. A third arm **33** is rigidly mounted to shaft **32** and has extension spring **28** connected thereto. In this manner, the two free ends of arms **30** and **31** are biased in the direction of extension for objective tube **11**.

Objective tube **11** includes pins **37** and **38** mounted on flange **27** which projects radially outward and serve both as extension limit stops and on the other hand move in guideslot **35** to prevent rotation of the objective tube and ensure only axial displacement when the tube is retracted or extended in housing **10**.

In a preferred embodiment, this slotted guide **35** in housing **10** would be present in two locations to handle diametrically opposite pins **37** and **38**, although only one slotted guide **35** is shown for the sake of clarity. At the end of each of the arms **30** and **31** of double rocker **34** is a slot which encloses pins **37** and **38** forming an articulating linkage between rocker **34** and objective tube **11**.

Housing **10** also includes a locking system **36** which is associated with the objective tube **11** and acts only slightly prior to and during image exposure to generate an additional compression between cam means **21** and projection **22** to ensure reliable locating of the objective tube **11** in housing **10** during actual shutter operation. This additional compression must be high enough such that accidental lateral contact of the objective tube **11** by the camera user cannot cause a deflection of the objective tube axis from the optical axis. Ideally, the additional compression for biasing is triggered by the triggering of the exposure process and lasts through closure of the camera shutter.

In a preferred embodiment, locking system **36** is coupled by means of a control linkage **39** to shutter release **17**. The control linkage is so designed that locking system **36** can only engage objective tube **11** essentially simultaneously with the actuation with the shutter release **17**. The locking system **36** in the embodiment shown comprises two spring loaded levers **42** and **43**, which coact with pins **37** and **38** located on the objective tube **11**. The levers pivot about common pivot shaft **44** which is perpendicular to the optic axis **20** and the levers are biased in a direction transverse to the optic axis **20** by compression spring **48**. Each lever includes a cam portion **40** which is essentially an acute angle with respect to the optic axis **20**.

A control bar **41** connected to the shutter release **17**, is displaced upon actuation of the shutter release, and control slider **49** acts upon levers **42** and **43** of the control linkage **39**. The control slider **49** has a tang **50** which rests against control bar **41**, which has a notch **54** into which controlled tang can move when shutter release **17** is displaced a predetermined amount. Control slider **49** in the preferred embodiment is fork-shaped, having tines **51** and **52** which engage levers **42** and **43**. The control bar **41** is longitudinally displaceable against the bias of return spring **53** by means of the operator pressing upon the shutter release **17**. It will be seen that the bias of spring **48** on levers **42** and **43** will force cam **40** to bias the objective tube in its extended position. This bias is additional to the bias in the extended position provided by extension spring **28**. Movement of levers **42** and **43** is prevented by virtue of control linkage **39** bearing against control bar **41**. Thus, spring **48** biases levers **42** and **43** against the forkshaped tines **51** and **52** of control linkage **39** which in turn is then biased against the slide of control bar **41**. However, when shutter release **17** has been depressed to the extent that control linkage **39** can pass into slot **54**, spring **48** causes levers **42** and **43** to move further towards control bar **41**. This further movement permits cam **40** to bear against pins **37** and **38** and thus further bias in a stronger manner, the objective tube towards its extended position. This biasing ensures firm and complete contact between the cam means **21** and projection **22** during the shutter release operation.

A camera shutter release switch **55** is located at the end of travel of control bar **41** and thus the shutter will only be released after the control bar has moved sufficiently in its longitudinal direction to permit control linkage **39** and tang **50** to move into slot **54** thereby locking the objective lens into position for shutter release. An additional camera switch may be mounted so as to be engaged during initial displacement of control bar **41** for the switching on of automatic aperture control or an auto-focus system. It may be advantageous to locate this switch such that it will close a specific time before control bar **41** releases slider **49** such that any auto-focusing will take place prior to the release of the locking system **36** which will then force cam member **21** and projection **22** together locking the objective tube **11** in housing **10**. This locking system then obviates any danger of objective tube misalignment and permits highly accurately focused pictures to be taken. Of course, until shutter release **17** is depressed, cam means **40** will be prevented at least to a large extent from additionally biasing objective tube **11** in its extended position such that under the light biasing pressure of extension spring **28**, the reduced friction between cam means **21** and projection **22** permits easy focusing especially by the auto-focusing system shown.

The camera shown in the drawing is in its picture-taking condition with objective tube **11** projection from housing **10** and biased in this extended position by double rocker **34**. Lug **24** of projection **22** rests upon cam means **21** on the backside of the focusing ring **19**. In this condition, the bias between the projection and cam means is relatively low and thus there are relatively low frictional forces therebetween facilitating ease of rotation of focusing ring **19**. As shown, the locking system **36** is still inactivated and control tang **50** rests against the side of control bar **41**. Thus, the control bar **41** keeps levers **42** and **43** of the locking system biased against the force of compression spring **48** such that cams **40** of the levers do not to a substantial degree anyway, press against pins **37** and **38**.

When the shutter release **17** is depressed, the control bar **41** is displaced longitudinally downward against return force **53**. In a preferred embodiment, the operating sequence permits switch **56** to close whereby an auto-focus system is activated. This auto-focus system in a known manner measures the range to the picture

object and in accordance with any discrepancy between the measured range and the focus of the objective tube **11**, will emit a corresponding control signal to setting motor **18**. This motor drives the gear rack **29** which in turn rotates the focusing ring **19**. The objective tube **11** is displaced in its axial direction by means of cam means **21** bearing on projection **22** until the objective is sharply focused on the film plane. The range set by the auto-focus system is displayed by pointer **14** on the distance scale **16** in the viewer **15** of the camera. During this focusing process, the position of control tang **50** and hence control slider **49** has remained unchanged in view of the design of slot **54** of control bar **41** with an end result that the locking system **36** remains inactive.

As the control bar **41** is further displaced in the longitudinal direction, control tang **50** is permitted to move into slot **54** permitting control slider **49** to move transversely with respect to the optic axis **20** (to the left in the drawing) by a predetermined amount. Compression spring **48**, biasing levers **42** and **43**, permits cams **40** of control levers **41** and **42** to bear against pins **37** and **38** further biasing objective tube **11** in its extension direction. Lugs **24** of projections **22** are strongly pressed against cam means **21** on the backside of focusing ring **19**. Inasmuch as the focusing ring **19** is fixed against axial movement, the objective tube will now be fixed with respect to the housing with a high degree of force in the position previously determined by the auto-focusing system. Thus, the objective tube is now locked in its optically accurate position for taking a picture with respect to the camera housing.

Upon further depressing the shutter release **17**, control bar **41** is displaced until it closes shutter release switch **55** whereupon the shutter is opened and closed in a known manner exposing the photographic film and completing the picture-taking process.

In order to reset the locking system **36** into its inactive position with cams **40** not heavily bearing against pins **37** and **38** such that focusing ring **19** is again rotatable with very light forces, a return lever **57** is provided in the control linkage **39** which is coupled to the shutter reset and/or film advance lever. In a preferred embodiment, a control cam **58** is mounted to the film advance lever **13**, said cam **58** revolving when the lever **13** is advanced in the direction of the arrow shown. Return lever **57** is pivoted about the axis shown and when cam **58** bears against one end of the lever, the other end bears against control tang **50**. When the film advance lever **13** is pivoted (counter-clockwise in the illustrated embodiment) the free end of the lever arm resting against control tang **50** will move towards the optic axis **20**. Control slider **49** is moved so as to lift control tang **50** out of slot **54** permitting control bar **41** under the influence of return spring **53** to move the shutter release **17** to its initial position. When the film advance lever **13** is released, the biasing of lever **57** by cam **58** will be terminated and control tang **50** will again rest against control bar **41** as shown in the drawing. In this position, the objective is no longer locked in position and instead is biased in its extended position primarily by extension spring **28** and thus, the camera assembly is ready for a further sequence of auto-focusing and picture-taking.

Objective tube **11** can be retracted into the camera housing **10** by axially pressing on the objective tube. With pins **37** and **38** sliding in guide slot **35**, arms **30** and **31** of the double rocker **34** pivoted to the rear placing extension spring **28** in further tension. The objective tube **11** completely disappears into housing **10** whereupon the objective tube **11** is locked against the bias of extension spring **28**. Levers **42** and **43** of the locking system **36** further act as retaining levers having at their free end an indexing latch **46** which engage indexing pins **45** and **47** on the objective tube **11**. In a preferred embodiment, pins **45** and **47** can be mounted with one radially projecting outward from the front-end of the objective tube and the other radially projecting from an objective cover **59** which is hinged on the front of the objective tube **11**. When the cover is pushed down into position over the objective tube **11**, pin **47** will extend radially outward with respect to the optical axis **20**. When the objective tube **11** is pressed all the way into the camera with the cover **59** closed, pins **45** and **47** engage latches **46** which retain the objective tube **11** in its retracted position against the bias of extension spring **28**. Additionally, the cover is maintained in its covered position against the bias of an opening spring (not shown).

When it is desired to convert the camera from its storage or shipping condition into a manner for taking pictures, objective tube **11** must be released such that the tube can be extended to its proper position. Actuation knob **60** which is accessible for manual activation on the outside of the camera housing, forces lever **49** in a direction transverse to the optic axis which also displaces levers **42** and **43** against the force of compression spring **48**. This causes latches **46** to disengage the two indexing pins **45** and **47** releasing the objective tube **11** for extension. The extension spring **28** biases the double rocker **34** which moves objective tube **11** into its extended position while at the same time cover **59** is unlatched to move into its extended position.

Although the invention has been described relative to a specific embodiment thereof, it is not so limited and many modifications and variations thereof will be readily apparent to those skilled in the art in light of the above teachings. It is, therefore, to be understood that, within the scope of the appended claims, the invention may be practiced otherwise then as specifically described.

The preferred embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. A camera including a camera housing, an objective lens having an image axis and a shutter release mechanism, said camera further including:

means for setting a focal range of said camera;

means for mounting said objective lens for movement substantially parallel to said image axis, between an extended exposure position and a retracted storage position;

means for variably limiting axial movement of said mounting means in said extended position;

means, responsive to said range setting means, for varying said limiting means; and

means for variably biasing said mounting means towards said extended position, such that said mounting means is less strongly biased toward said extended position during operation of said varying means and more strongly biased toward each extended position during operation of shutter release mechanism.

2. A camera according to claim **1**, wherein said means for variably biasing is operatively connected to and responsive to said shutter release mechanism for more strongly biasing said mounting means towards said ex-

tended position when said shutter release means is activated.

3. The camera of claim 2, wherein said mounting means comprises a tube with said lens mounted therein, said varying means comprises an annulus surrounding said tube and axially fixed with respect to said housing, said limiting means comprising a projection fixed on said tube and in contact with a cam on said annulus when said tube is in said extended exposure position.

4. The camera according to one of claims 1-3, wherein said means for variably biasing includes locking means for biasing said objective tube towards its extended position, and control linkage means for coupling said locking means to said shutter release means such that said locking means biases said objective tube only during actuation of said shutter release means.

5. The camera according to claim 4 wherein said locking means comprises at least one spring loaded lever, and said mounting means includes at least one abutment pin coacting with said locking means.

6. The camera according to claim 5, wherein said spring loaded lever comprises a lever biased by a spring in a direction transverse to the image axis, said lever including a cam means, coacting with said abutment pin, for biasing said mounting means towards said extended exposure position.

7. The camera according to claim 6, wherein said control linkage means comprises a linkage connected to said lever, said shutter release mechanism including a detent, said linkage located between said shutter release mechanism and said lever and preventing movement of said lever toward said shutter release mechanism beyond a predetermined amount, said linkage permitting said lever to move toward said shutter release mechanism beyond said predetermined amount when said shutter release mechanism is at least partially actuated and said linkage extends into said detent.

8. A camera including a camera housing, an objective lens having an image axis and a shutter release mechanism, said camera further including:

means for setting a focal range of said camera;

means for mounting said objective lens for movement between an extended exposure position and a retracted storage position;

means for variably limiting movement of said mounting means in said extended position;

means for varying said limiting means in response to said range setting means; and

means for biasing said mounting means against said limiting means such that said mounting means is less strongly biased against said limiting means during operation of said varying means and more strongly biased against said limiting means during operation of said shutter release mechanism.

[57] **ABSTRACT**

A single lens reflex camera includes a vertical open topped U-shaped bracket mounted in the camera body below the pentaprism, a forwardly located lens mount separably coupled to an objective lens and pairs of links mutually pivoted between their ends connected between the bracket arms and corresponding edges of the lens mount to support the latter in a fixed orientation for linear longitudinal movement along the camera optical axis. A light tight collapsible conduit extends between the camera body and lens mounts and includes telescoping members with relatively slidable side and bottom walls and an accordian top wall. A rack carrying slide arm projects rearwardly from the lens mount and is engaged by a motor driven gear to longitudinally shift the lens mount. The motor is controlled manually or in response to a focus detecting device and the lens mount may be motor advanced and retracted or motor advanced and spring retracted. The lens diaphragm is automatically stopped down by a camera housed mechanism and diaphragm control information is transmitted from the lens mount to the camera body.

INTERCHANGEABLE OBJECTIVE LENS SINGLE-LENS REFLEX CAMERA FOCUSING DEVICE

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to improvements in cameras and it relates particularly to an improved motor focussed, single-lens reflex camera of the interchangeable objective lens type.

In the conventional objective lens exchangeable single-lens reflex cameras, focussing of the objective lens is performed by rotating a focussing ring provided on the objective lens barrel. However, when an automatic focussing device is incorporated in the single-lens reflex camera and a drive device such as an electric motor controlled by the automatic focussing device is used to rotate the focussing ring for focussing an objective lens, it is almost impossible to control the focus of all types of objective lenses, since the distance between the focussing and the camera body varies with the type of objective lens, as does the force required for rotating the focussing ring. Even if, in such type of camera, it is possible to automatically control the focus of all types of objective lenses a complex interlocking mechanism must be provided, thereby posing the problem of an appreciable increase in the size and price of the camera. In an attempt to solve this problem, there has been proposed a device in which an entire objective lens is longitudinally moved along the camera optical axis for controlling focus (U.S. Pat. No. 3,798,660 granted Mar. 19, 1979). With such device, however, the lens mounting member of the camera to which the exchangeable objective lens is mounted, is supported by a ring rotated by a motor within the camera and the rotatable ring itself serves as a guide member therefor, or the lens mounting member is restricted to movement along the optical axis by a guide pin fixed to the camera body. As a result, the length of the available lens shift is greatly limited, posing a further problem. Increasing the length of the available lens shift in such a device requires that the length of a rotatable ring supporting the lens mounting member be increased along the optical axis or that the guide pin be lengthened. However, such increase in size results in a larger camera body, causing much inconvenience. Consequently, the devices heretofore proposed possess the drawback that the length of available lens shift cannot be increased without an increase in the camera size.

Furthermore, with the earlier structures, a lens mounting member on which an exchangeable objective lens is mounted is formed as a cylindrical member, part of which is positioned near the viewer penta prism. In addition, the lens mounting member and its support must be thick and sturdy enough to withstand the weight of an exchangeable objective lens which is coupled to the lens mounting member, thereby necessitating the provision of a large space near the penta prism. Therefore, the earlier structures have the lens mounting member and the supporting member therefore assembled near the camera viewer penta prism, the design freedom of which is greatly impeded in terms of the penta prism arrangement.

SUMMARY OF THE INVENTION

It is a principal object of the present invention to provide improved single lens reflex camera focussing mechanism.

Another object of the present invention is to provide an improved focussing mechanism in an interchangeable objective lens single-lens reflex camera with which focussing is effected by moving the entire objective lens along its optical axis.

Still another object of the present invention is to provide an improved focussing mechanism in which an increase in the length of the available lens shift along the optical axis is achieved without any increase in the size of the camera body.

A further object of the present invention is to provide a focussing mechanism which includes almost none of its component parts near the camera pentaprism thereby permitting freedom of design without interfering with the pentaprism arrangement.

Still a further object of the present invention is to provide a mechanism of the above nature characterized by its reliability, ruggedness, ease and efficiency of operation, minimum space consumption, low cost and great versatility and adaptability.

The above and other objects of the present invention will become apparent from a reading of the following description taken in conjunction with the accompanying drawings which illustrate a preferred embodiment thereof.

A single lens reflux camera in accordance with the present invention comprises a body member having a front aperture and a pentaprism, an apertured mounting member having coupling means for separably engaging an interchangeable objective lens, a pair of laterally spaced longitudinally extendable retractable support members extending between the body member and mounting member and supporting the mounting member for longitudinal movement only at a fixed orientation, an extendable collapsible light tight conduit extending between the mounting and body members in registering with the apertures therein and control motor means in said body member for longitudinally advancing and retracting the mounting member.

In accordance with a preferred form of the improved camera a laterally extending U-shaped bracket is affixed to the body member and includes a bottom cross arm and side arms in opposite sides of the body member front aperture and is open at its top and the mounting member comprises a plate with a bottom and vertical side flanges. Each of the support members comprises a pair of levers or links mutually pivoted intermediate their ends and each lever being pivotally connected at its ends to the bracket side and bottom arms and to a mounting plate flange respectively, one end of each lever being vertically slidably coupled to the bracket side arm or mounting plate flange. The control motor means includes a motor controlled in response to a manual switch or a focus detecting network and coupled to the mounting plate by a motion translator defining rack and gear arrangement.

The improved focussing mechanism permits a wide range of axial movement of the mounting plate coupled objective lens without interfering with the camera components, including the pentaprism, requires no increase in the size of the camera, is reliable, rugged and efficient and is of great versatility and adaptability.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view of a camera embodying the present invention, and illustrated with the objective lens separated;

FIG. **2** is a partially fragmented, perspective view of the camera shown in FIG. **1**, illustrated in a lens mount extended position;

FIG. **3** is a vertical axial longitudinal sectional view of the camera shown in FIG. **1**;

FIG. **4** is a vertical axial longitudinal sectional view of the camera shown in FIG. **2**;

FIG. **5** is a horizontal cross-sectional view of the camera shown in FIG. **1**;

FIG. **6** is a horizontal cross-sectional view of the camera shown in FIG. **2**;

FIG. **7** is an exploded perspective and diagrammatic view of the essential parts of the embodiment of FIG. **1**; and

FIG. **8** is an exploded perspective and diagrammatic view illustrating only the essential parts of another embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawings, particularly FIGS. **1** to **7** thereof which illustrated a preferred embodiment of the present invention, the reference numeral **2** generally designates an objective lens which is equipped with a focussing ring **4**, diaphragm setting ring **6**, a transmission lug **6***a* extending rearwardly from diaphragm setting ring **6** for the transmission of a diaphragm aperture value preset by manually operating diaphragm setting ring **6**, and a diaphragm preset pin **8**.

A camera body **10**, to which objective lens **2** is replaceably mounted, includes a pentaprism portion **10***a*, a film advancing lever **12**, a shutter speed setting dial **14**, a shutter release button **16**, a film speed setting dial **18**, a rewind knob **20** and a cell chamber **22** which also serves as a hand grip. Displayed on the top surface of shutter speed setting dial **14** is a scale of numerals corresponding to shutter speed and a mark "A" for automatic shutter speed control. With a numeral on the scale set to index **14***a*, a shutter mechanism (not shown) operates at a shutter speed corresponding to the set numeral. With mark "A" set to index **14***a*, photography in a diaphragm priority automatic shutter speed control mode is established. Moreover, provided beneath pentaprism portion **10***a* at the front of camera body **10**, is a fixed housing **24**, which is connected through a link assembly to a lens mount **26**, on which objective lens **2** is interchangably mountable, as shown in FIG. **2**. Lens mount **26** is box shaped and open at its rear and top and slidably telescopes into fixed housing **24** and includes rearwardly projecting bottom and side walls at the rear of lens mount **26** which extend along inside the bottom and sides of fixed housing **24**, the inner surfaces thereof overlapping the outer surfaces of lens mount **26**. The top surface of lens mount **26** is connected to fixed housing **24** by means of an accordion wall or collapsible bellows **38**, so that lens mount **26** is joined to fixed housing **24** for external light shielding even when moved along the optical axis. Mounted on the front wall of lens mount **26** are flange ring or annulus **26***a* of lens mount **26**, lens-lock release button **27** which unlocks an objective lens when it is to be removed, and transmission ring **28** with interlocking lug **28***a* which interlocks with transmission lug **26***a* when objective lens **2** is mounted on lens mount **26** to thereby transmit the diaphragm aperture value preset by the objective lens to mechanism in the camera body **10**.

A changeover switch **30** is arranged on the front face of camera body **10** and is manually operable and connected and designed to energize a motor, as hereinafter described, for shifting lens mount **26** along the optical axis when index **30***a* on switch **30** is set to a mark "N" and for retracting lens mount **26** along the optical axis when index **30***a* is set to mark " ". When index **30***a* is set to mark ".", the motor is stopped to cease the movement of lens mount **26**. FIG. **1** shows the condition of lens mount **26** in its fully retracted position along the optical axis.

Disposed within the camera body **10** are a movable mirror **32**, a mirror box **34** and a diaphragm preset ring **36**. Diaphragm preset ring **36** is movable along the optical axis integrally with lens mount **26** so that it is maintained in engagement with diaphragm preset pin **8** of objective lens **2**, when lens mount **26** is shifted to any position within its overall range of shifting along the optical axis. Diaphragm preset ring **36** is rotated clockwise in response to the shutter release operation to permit the rotation of preset pin **8** which is urged to follow diaphragm preset ring **36** and to stop down the diaphragm mechanism.

FIG. **2** shows the condition of lens mount **26** advanced along the optical axis from its fully retracted position as shown in FIG. **1**. Referring to FIG. **2**, the contractable bellows or accordian wall **38** connects fixed housing **24** and lens mount **26** for external light shielding, the bellows being provided only on the top side thereof. The bottom and sides of the bellows or contractable conduit are defined by the fixed housing **24** and lens mount **26** which overlap for external light shielding. Consequently, even when lens mount **26** is shifted along the optical axis, as described later, fixed housing **24** and lens mount **26** are always connected together to shield external light, a light tight expandable chamber being established between housing **24** and lens mount **26**. X-shaped link assemblies **40**, **41** and **42**, as best seen in FIG. **7**, are provided between fixed housing **24** and lens mount **26**, and are longitudinally expandable or extendable along the optical axis, each link assembly moving in a plane parallel to the optical axis. These link assemblies are provided on the bottom and sides of fixed housing **24**, not on the top side thereof, i.e., not near pentaprism portion **10***a* since this would restrict or limit the positioning of the pentaprism, due to the provision of a link assembly on the top side. It is to be noted that although link assemblies provided on the bottom and one side alone are sufficient, their provision along three quadrilateral surfaces, as in the present embodiment, increase the over rigidity and strength of the structure.

With reference to FIGS. **3** and **4** which show the lens mount **26** in its fully retracted and advanced positions respectively, a light transmitting portion is formed in the center of movable mirror **32**, on the rear of which is mounted an auxiliary mirror **32***a* for rotation therewith. With this construction, scene light passing through objective lens **2** is reflected on movable mirror **32** and is directed toward a viewfinder optical system comprising focussing screen **44**, condenser lens **46**, pentaprism **48** and eyepiece **50**. Part of the scene light is transmitted through the center of movable mirror **32** and is reflected by auxiliary mirror **32***a*, and is directed toward a light receiving element **52** arranged at a position optically equivalent to the film surface for the detection of the

focus condition. A light sensing or responsive element **54** for automatic exposure control is arranged at the upper rear face of pentaprism **48**. Also shown in the drawings are shutter mechanism **56**, film **58** and film pressure plate **60**. The focus condition of objective lens **2** is detected by light responsive element **52** for the detection of focussing and is indicated within a viewfinder. As shown in FIG. **7**, the output signal of light responsive element **52** is transmitted as an input to a focus detecting circuit **53**, which detects an in-focus or out-of-focus condition which is displayed by LEDs **55**,**57** and **59** provided inside the viewfinder. When, in the case of the present embodiment, objective lens **2** is focussed closer than an object to be photographed, LED **55** is energized when the lens is focussed at a greater distance than the object, LED **59** is energized and when the object is in proper focus, LED **57** is energized.

A motor **62** is selectively rotated in forward and reverse directions when changeover switch **30** is correspondingly manually operated. Motor **62** which is mounted in the camera body is connected through a pinion and gear **64** to a rack portion **66***a*, a slide or drive arm or lever **66**. Slide arm **66** is restricted to only longitudinal movement parallel to the optical axis by a guide pin **68** carried by mirror box **34** and a guide shaft **70** slidably engaging an elongated longitudinal slot in side arm **66**, as hereinafter described. Formed at the rear of side arm **66** is rack portion **66***a*, and the front end of side arm **66** is connected to the central connecting pivot **42***a* of link assembly **42**. With the above construction, motor **62** is rotated to advance or retract slide arm **66** along the optical axis, whereby link assemblies **42**, **40** and **41** are respectively expanded or contracted, so that lens mount **26** is correspondingly shifted along the optical axis under the guidance of the link assemblies.

As shown in FIGS. **5** and **6** which illustrate lens mount **26** in its fully retracted and advanced positions respectively, a sprocket **72**, a spool **74** and a cell **76** are housed in and proximate grip **22**. Cell **76** is a power supply source for motor **62** to move lens mount **26**. A switch S is electrically transferred by manually operated changeover switch member **30**, and is provided with one movable contact piece a and two fixed contact pieces b and c. When index **30***a* of changeover switch **30** shown in FIGS. **1** and **2** is set to mark " ", contact pieces a and b of switch S are inter-engaged to deliver power from cell **76** to motor **62**, which is thus driven to retract lens mount **26** along the optical axis to the condition shown in FIG. **5**. On the other hand, when index **30***a* is set to mark "N", contact pieces a and c of switch S are inter-engaged, energizing motor **62** to rotate in the reverse direction, whereby lens mount **26** is shifted along the optical axis toward its forwardmost position.

As best seen in FIG. **7**, a fixed mounting frame **78** is secured to mirror box **34** by four inwardly directed pins **78***a* through **78***d*, and is of open topped approximately U-shaped configuration with a lateral bottom cross arm and vertical laterally spaced side arms laterally offset from the pentaprism. Furthermore, provided between fixed frame **78** and mirror box **34** is guide pin **70**, engaging and guiding slide arm **66**. Guide pin **70** also serves as a fastener to secure fixed frame **78** to mirror box **34**. The respective side and bottom arms of fixed frame **78** are connected with the ends of the individual link bars in X-shaped link assemblies **40**, **41** and **42** which are all expandable and contractable in directions parallel to the optical axis. A movable vertical rectangular base plate **80** is provided with a central circular opening and is provided along its side and bottom edges with rearwardly directed flanges **80***a*, **80***b* and **80***c*, to which the other ends of the link bars in the link assemblies are connected, respectively. In other words, the other ends of the link bars or levers of link assembly **40** are rotatably connected to flange **80***a*, those of link assembly **41** to flange **80***b* and those of link assembly **42** to flange **80***c*, respectively. Furthermore, formed on flanges **80***a*, **80***b* and **80***c* are rearwardly projecting tabs **80***d* and **80***e* and a tab **80***f* (not shown), to which lens mount **26** is bonded or secured by screws. Fixed to central connection pivot **42***a* of link assembly **42** is the front end of slide arm **66** which is longitudinally slidable parallel to the optical axis. When motor **62** is energized and driven through control circuit **82** by the manual operation of changeover switch **30**, slide arm **66** is longitudinally moved parallel to the optical axis, whereby link assembly **42** is longitudinally expanded or contracted parallel to the optical axis, and link assemblies **40** and **41** are also expanded or contracted in directions parallel to the optical axis.

Another flange member **26***a* is secured to four fastener pins **84***a* through **84***d* projecting forwardly from movable base plate **80**.

Provided between flange member **26***a* and movable base plate **80** are transmission ring **28**, sliding resistor element **86** described hereinafter, lens mount **26** and diaphragm preset ring **36**. Transmission ring **28** is rotatably supported between flange member **26***a* and lens mount **26**, and is biased counterclockwise by a spring **88**. Interlocking lug **28***a* formed on transmission ring **38** press engages transmission lug **6***a* of objective lens **2**, as shown in FIG. **1**, whereby the angular position thereof is set. In addition, a sliding brush **28***b* is fixed to and projects rearwardly from ring **28**, and is in slidable engagement with sliding resistor element **86** fixed to movable base plate **80**. With the above construction, rotated angular the position of transmission ring **28** is set depending on the rotated angular position of the diaphragm ring of objective lens **2**, and in response thereto, a positional relationship is set between sliding brush **28***b* and sliding resistor **86**, whereby the present aperture value information of the objective lens is transmitted to an exposure control circuit (not shown) in the camera body in the form of a resistance responsive signal.

Diaphragm preset ring **36** includes four circumferentially spaced peripheral slots respectively slidably engaged by pins **84***a* through **84***d*. Accordingly, diaphragm preset ring **36** is rotatable for the length of the peripheral slots, and is biased in a clockwise direction by a spring **90**. Formed on diaphragm preset ring **36** is a rearwardly offset radially inwardly projecting lug **36***a* positioned so that it is engaged by diaphragm preset pin **8** of objective lens **2**, when objective lens **2** shown in FIG. **1** is mounted on lens mount **26**. Furthermore, diaphragm preset ring **36** is provided with arm **36***b* supporting tab **36***a* and extending rearwardly parallel to the optical axis, and a longitudinal slot **36***c* is formed in arm **36***b*. Slidably engaging longitudinal slot **36***c* is a pin **92***a* provided at the end of a diaphragm preset lever **92**, the movement of which is controlled by a well-known diaphragm preset mechanism (not shown) located inside camera body **10**. The lengths of arm **36***b* and slot **36***c* of diaphragm preset ring **36** are set so that follower pin **92***a* of diaphragm preset lever **92** engages slot **36***c* within the overall range of longitudinal movement of lens mount **26**. A stop lever **94** engages diaphragm pre-

set lever **92**, to prevent the rotation thereof and disengages lever **92** in response to the shutter release operation to release the diaphragm preset lever from its stop condition, thereby allowing it to be rotated. With the above construction, the diaphragm of an objective lens is aperture presettable in the overall movable range of lens mount **26** by means of the diaphragm preset mechanism provided inside a camera body. Lens mount **26** is secured to tabs **80***d*, **80***e* and **80***f* of movable base plate **80**.

Considering now the operation of the improved mechanism described above, with the objective lens **2** being mounted on lens mount **26** of camera body **10** and being focussed at infinity, the lens mount **26** is fully retracted along the optical axis as shown in FIGS. **1**, **3** and **5**. Under this condition, the objective lens is in focus when an object is located at infinity, and this condition is indicated in the viewfinder by the illumination of LED **57**. Moreover, under the aforesaid condition, the objective lens is out of focus on an object at a close distance, and this is observed in the viewfinder with the illumination of LED **59**. While looking through the viewfinder, a photographer sets index **30***a* of changeover switch **30** to mark "N". This energizes and drives motor **62** to expand or extend link assemblies **40**, **41** and **42**, whereby lens mount **26** with objective lens **2** mounted thereon is guided and advanced by the link assemblies along the optical axis. While observing the focus condition displayed inside the viewfinder, the photographer sets index **30***a* of changeover switch **30** to mark "." when objective lens **2** is focussed on a desired object, i.e., when LED **57** lights up. This stops motor **62** and any further movement of lens mount **26** whereby their stop and focussed condition is maintained.

When lens mount **26** is at a forward position and the focussing position of objective lens **2** is set at a greater distance than that of the desired object, LED **55** lights up inside the viewfinder, advising the photographer to retract lens mount **26** along the optical axis by setting index **30***a* of changeover switch **30** to mark " ". Thus, the focussing position of objective lens **2** is retracted toward the camera, and when it corresponds to the distance of the desired object, LED **57** momentarily illuminates to indicate the in-focus condition. At this time, the photographer sets index **30***a* of changeover switch **30** to mark "." to stop the movement of objective lens **2**.

With shutter release button **16** then depressed, the diaphragm of objective lens **2** is stopped down to the preset diaphragm aperture value by means of a diaphragm preset mechanism, movable mirror **32** and auxiliary mirror **32***a* are retracted outside the photographic optical path, and thereafter shutter **56** is opened for the time set by shutter speed setting dial **14**. With mark "A" on shutter speed setting dial **14** set to index **14***a*, diaphragm aperture information on objective lens **2** set by sliding resistor **86** and ring **28**, film speed information set by film speed setting dial **18** and the light measurement information output at light responsive element **54** are transmitted as inputs to an automatic exposure control circuit, and the exposure time is controlled by the automatic exposure control circuit.

Thus, in accordance with the embodiment of the present invention described above, focusing of objective lens **2** may be performed without using focusing ring **4**, and focus control changeover switch **30** is arranged near shutter release button **16**, thus allowing focusing and shutter release operations to be accomplished with one hand. In addition, all mechanisms necessary for focusing can be assembled into a camera body, and no focusing interlocking mechanism between the camera body and objective lens is required, resulting in a simple, inexpensive construction. Moreover, according to the present embodiment, the flange back of a camera is changeable by shifting lens mount **26** forward, whereby the closest photographic distance of an objective lens is further shortened by setting the shift of lens mount **26** to an appropriate length to make close-up photography without the use of an extension bellows or close-up ring. In addition, link assemblies **40**, **41** and **42** are simple and compact in construction, yet strong enough to withstand high external forces, thereby assuring the movement and positioning of objective lens **2** along and coaxial with the optical axis. At the same time, the link assemblies require a minimum of applied force for their expansion and contraction and are capable of guidance over great lengths thereby minimizing the required output of the drive device such as a motor, whereby shifting over a longer length is efficiently achieved.

It should be understood that while the mechanism of the present embodiment is constructed such that the drive device is driven in response to a manual operation to control the movement of the objective lens, the present invention is not limited thereto, and the drive device may be automatically controlled by a focus detection device. In this latter case, there are numerous known methods and devices available for focus detection. These include a method utilizing the space frequency of an image formed by an objective lens, that utilizing contrasts, that utilizing a split image, that utilizing the phase difference between the outputs of two light receiving elements disposed symmetrically to the optical axis behind the plane optically equivalent to the film plane by scanning such planes vertically to the optical axis using a grid or the like.

When, moreover, a focus detection method detects a direction in which an objective lens may be moved for focusing a desired object, the rotation direction and speed of motor **62** are controllable based on the output of the focus detection device. With the above construction, changeover switch **30** may be connected and employed as the main switch of the focusing mechanism. Furthermore, when the main switch is constructed and associated such that it is closed upon depression of shutter release button **16**, focusing and photography are initiated by shutter release button **16**, thereby requiring that shutter release button **16** only be depressed by a photographer.

In addition, with the present embodiment, lens mount **26** is shifted forwardly and rearwardly along the optical axis in response to the forward and reverse rotations of motor **62**. However, the improved mechanism may be so construed that link assemblies **40**, **41** and **42** are biased toward their contracted conditions by springs, against whose influence lens mount **26** is shifted forward by the drive device, such as a motor, and lens mount **26** is retracted to its fully retracted position under the action of the springs after its disconnection from the drive devices.

FIG. **8** illustrates another embodiment of the present invention, in which the above construction is achieved. The same reference numbers are used for members corresponding to those in the first embodiments in order to simplify the description. Springs **100**, **101** and **102** are provided between the camera body and the respective

pivoted intersecting point of paired link bars constituting each of the link assemblies **40**, **41** and **42**. These link assemblies are biased by springs **100**, **101** and **102** in the direction of their contraction. In the present embodiment, an automatic focusing mechanism is provided for automatically focusing objective lens **200**. The automatic focusing mechanism includes light receiving element **52**, focus detection circuit **103**, power supply source **104**, start switch **105**, motor control circuit **106** and motor **62** connected as illustrated. Motor control circuit **106** supplies power to rotate motor **62** when start switch **105** is manually closed externally of the camera, and cuts off power when receiving an in-focus signal from focus detection circuit **103** to thereby stop motor **62**. On the other hand, focus detection circuit **103** receives a signal from light receiving element **52** to detect an in-focus or out-of-focus condition of objective lens **200**, and sends an in-focus signal to motor control circuit **106** when objective lens **200** is focused on a desired object. Drive gear **107** drive coupled to motor **62** is connected through a one-way clutch mechanism **108** to gear **64**. Clutch mechanism **108** includes a first clutch gear or member **109** connected to drive gear **107** and second clutch gear or member **110** connected to gear **64**, second clutch gear **110** being axially movable together with gear **64** and biased by a spring (not shown) into engagement with first clutch gear **109**. Clutch mechanism **108** is constructed such that it transmits only the one-way rotation of drive gear **107**, i.e., only the counterclockwise rotation of drive gear **107** under the present embodiment, to gear **64**. A clutch control lever **111** is rotated counterclockwise by an exposure completion signal, e.g., a signal responsive to the completion of travel of the trailing shutter curtain in the case of focal-plane shutter camera, and is reset to the position shown in FIG. **8** in response to the film advance operation.

With the above construction, focusing is enabled by the external manual closing of start switch **105** first to be closed manually and when start switch **105** is closed, drive motor **62** is energized and rotates drive gear **107** counterclockwise, which rotation is transmitted through clutch mechanism to gear **64**, causing rack carrying slide arm **66** engaged therewith to be shifted along the optical axis. As slide arm **66** is shifted forwardly, link assemblies **40**, **41** and **42** are expanded, causing lens mount **26** to be linearly shifted along the optical axis at a fixed vertical orientation. On the other hand, focus detection circuit **103** detects the in-focus or out-of-focus condition by a signal from light receiving element **52** during the shift of objective lens **200**, and generates an in-focus signal when objective lens is focussed on a desired object. With the input of an in-focus signal, motor control circuit **106** interrupts the supply of power to drive motor **62**, which, in turn, stops. Upon the shutter being released when the infocus condition is reached, the film is exposed in the well-known manner, and after exposure with a lapse of a predetermined period of time, clutch control lever **111** is swung counterclockwise by a mechanism (not shown). With clutch control lever **111** swung counterclockwise, gear **64** is retracted to a position out of engagement with rack portion **66***a* of slide arm **66**. In addition, second clutch gear **110** formed integrally with gear **64** is moved to a position where it is disengaged from first clutch gear **109**. With these clutches thus disengaged, the link assemblies are immediately contracted under the action of springs **100**, **101** and **102**, respectively, and lens mount **26** is rapidly shifted to its fully retracted position along the optical axis. With the film advance operation, clutch control lever **111** is rotated clockwise to reset gear **64** and second clutch gear **110** to the positions shown in FIG. **8** in readiness for focusing in the above manner.

It is to be noted that a camera in accordance with the last described embodiment uses an objective lens **200** equipped with an electrical diaphragm mechanism unlike the camera according to the first embodiment. That is, objective lens **200** is provided with a common transparent electrode and ring-shaped transparent electrodes **201***a*$_1$, **201***a*$_2$ . . . **201***an*, each different in diameter and being concentrically arranged to overlap each other. Liquid crystal plate **201** is disposed between lenses **202** and **203**, and pins **204***a*, **204***b*, **204***c* and **204***d* electrically connected to these transparent electrodes, respectively, projected rearwardly from the rear edge of the lenses. On the other hand, movable base plate **80** is provided with contact pieces **205***a*, **205***b*, **205***c* and **205***d* which engage respective pins **204***a*, **204***b* **204***c* and **204***d* when objective lens **200** is mounted on lens mount **26**.

A diaphragm setting dial **206** is rotatably mounted on camera body **10**, and the brush **207** of a slide resistor is connected thereto. A diaphragm control circuit **208** is arranged to actuate a corresponding number of contact pieces **205***a* through **205***d* in response to the adjusted resistance value of the slide resistor. Moreover, the diaphragm control circuit receives an exposure termination signal and a shutter release signal, thereby actuating the preceding contact pieces only when receiving a shutter release signal, and, in contrast, deactuating the contact pieces when receiving an exposure termination signal.

Consequently, when the shutter is released with objective lens **200** mounted on lens mount **26**, a selected plurality of the specified contact pieces **205***a* through **205***d* are turned on in response to preset position of diaphragm setting dial **206**. When an electrical signal applied to the contact pieces is transmitted as an input to objective lens **200** through signal pins **204***a* through **204***d*, the common electrode and the specified ring-shaped electrodes are energized, whereby the transparent electrodes form opaque rings. As a voltage is sequentially applied to the selected successive ring-shaped electrodes **201***a*$_1$ through **201***an*, the round transparent portion in the center of liquid crystal plate **201** gradually decreases in diameter. This is equivalent to the diaphragm being stopped down.

As described above, the camera of the present invention is constructed such that a lens mount on which an exchangeable objective lens is mounted is supported by expandable and contractable link assemblies on a camera body for shifting along the camera optical axis and the link assemblies are expanded and contracted by drive means provided inside the camera body, whereby the entire mount coupled objective lens is moved for focusing. Consequently, all the component parts required for the focusing mechanisms are assembled in the camera body, and as a result, it is possible to eliminate any special interlocking mechanism which interlocks the camera body and an exchangeable objective lens for focusing, thereby achieving a simple and inexpensive construction. In addition, as the objective lens need only be mounted on the lens mount, conventional interchangeable objective lenses may be employed, including objective lenses equipped with no focusing mechanism. Furthermore, the flange back of a camera is changeable by expanding the lens mount, and thus close-up photography is possible without using any

special attachment for close-up photography, such as bellows or a close-up ring. Furthermore, with the mechanism of the present invention, link assemblies are provided to guarantee that the objective lens shifts along and is maintained coaxial with the optical axis. The link assemblies are simple and compact in construction and sufficiently withstand external forces so that the lens mount ensures the accurate shift of the objective lens parallel to the optical axis. In addition, the link assemblies require a minimum of applied force for expansion and contraction and are capable of guidance over a long distance so that great freedom of drive means and other mechanism design is available.

Moreover, when a drive means is arranged for manual control, manual focusing is possible without turning a focusing ring. With the drive means automatically controlled in response to the output of a focus detection device, the earlier focusing operations are unnecessary.

When a diaphragm control mechanism provided inside a camera body is arranged to control the diaphragm of an objective lens within the overall shift range of the lens mount, the diaphragm of the objective lens is controllable based on the information supplied from the camera, although the objective lens is shifted by the drive means to any desired position.

In addition, when the link assemblies are disposed on the three sides other than that of the pentaprism side, the link assemblies are more durable under external forces so that the construction and positioning of the pentaprism and other camera components are not restricted.

While there have been described and illustrated preferred embodiments of the present invention, it is apparent that numerous alterations, additions and omissions may be made without departing from the spirit thereof.

What is claimed is:

1. A single lens reflex camera including a body member and housed in the upper part of said body member, a pentaprism having a downwardly facing bottom face, comprising a lens mount disposed forwardly of said body member, an objective lens separably coupled to said lens mount coaxially with the optical axis of said body member, a pair of laterally spaced extendable contractable extension members extending between said lens mount and body member and supporting said lens mount for longitudinal linear advance and retraction along said optical axis at a fixed orientation of said lens mount, an extendable contractable light tight conduit extending between said body member and lens mount and means located in said body member and coupled to said lens mount for shifting said lens mount along said optical axis.

2. The camera of claim **1** wherein each of said extension members comprises a pair of links swingably pivoted to each other between their respective ends and swingably connected at their inner and other ends to said body member and lens mount respectively.

3. The camera of claim **2** wherein the inner ends of said links of each pair are swingably connected at a fixed point and a vertically movable point respectively on said body member and the opposite outer ends of said links are swingably connected at a vertically movable point and a fixed point respectively on said lens mounts.

4. The camera of claim **3** wherein said link pairs lie in parallel vertical longitudinal planes and including a third contractable extendable pair of swingably connected links lying in a longitudinal horizontal plane below said vertical link pairs and extending between said body member and lens mount.

5. The camera of claim **3** comprising an open topped, laterally extending vertical U-shaped bracket mounted on said body member below said pentaprism and including a bottom cross arm and vertical side arms, the inner ends of said links being connected to said bracket side arms.

6. The camera of claim **3** wherein said conduit comprises a pair of slidably telescoping open topped peripheral walls of substantially U-shaped transverse cross section extending between said body member and lens mount, and a longitudinally contractable extendable accordian wall extending rearwardly from the upper edge of said lens mount to said body member and sealing the upper part of said conduit against light entry.

7. The camera of claim **6** wherein said link pairs are disposed within said conduit.

8. The camera of claim **1** wherein said lens mount shifting means comprises an electric motor located in said body member and means including rotational translational motion translation means coupling said motor to said lens mounts.

9. The camera of claim **8** wherein said motion translation means comprises: a third extendable contractable extension member extending between said lens mount and body member; a slide arm, one end of which is connected to said third extendable contractable extension member, said slide arm extending rearwardly from said extendable contractable extension member and provided with a rack; and a gear driven by said motor and engaging said rack.

10. The camera of claim **8** comprising means including an externally manually operable switch for selectively energizing said motor to rotate in a forward or reverse direction to respectively advance and retract said lens mount.

11. The camera of claim **8** comprising spring means urging said lens mount to a longitudinally retracted position, manually operable means for energizing said motor to advance said lens mount and means for uncoupling said motor from said lens mount to permit the retraction of said lens mount under the influence of said spring.

12. The camera of claim **8** comprising manually operable means for energizing said motor to longitudinally shift said lens mount means for detecting the focus condition of said objective lens on an object and means responsive to said detecting means for de-energizing said motor when said object is in focus.

13. The camera of claim **8** including means for providing a visual signal indicating the condition of focus of said objective lens on a selected object.

14. A focusing device for an exchangeable lens camera which includes a body provided with a finder optical system and a mirror diagonally located within a photographic optical path for reflecting object light upwardly to said finder optical system, comprising:

a lens support member on which an exchangeable lens is mounted;

first and second similar, linearly longitudinally extendable contractable link assemblies extending between and connected to said lens support member and the camera body, said first link assembly lying in a first plane positioned below said mirror and said second link assembly lying in a second plane normal to said first plane;

an extendable and contractable shielding means extending between and secured to said lens support member and the camera body for establishing a light tight chamber between said lens support member and the camera body;

an externally manually operable switch means;

an electric motor actuated in response to the closure of said switch means; and

drive means connected to said electric motor for moving said lens support member.

15. A focusing device as set forth in claim **14**, further comprising a third linearly longitudinally extendable contractable link assembly extending between and connected to said lens support member and the camera body, said third link assembly lying in a plane parallel to said second plane.

16. A focusing device as set forth in claim **14**, wherein said operable switch means is transferable between alternate respective positions for intercepting the current to said motor, for energizing said motor to rotate in a predetermined direction and for energizing said motor to rotate in a reversed direction.

17. A focusing device as set forth in claim **16**, further comprising a light receiving element disposed in a plane optically equivalent to the camera focal plane, a focus detecting circuit for detecting the focus condition of an image projected onto said light receiving element and means for indicating said focus condition in accordance with an output signal from said focus detecting circuit.

18. A focusing device as set forth in claim **14**, further comprising a light receiving element provided in a plane optically equivalent to the camera focal plane, a focus detecting circuit for detecting a focus condition and providing a predetermined output signal when an image projected onto said light receiving element is in focus, and a motor control circuit for actuating said motor in response to the closure of said operable switch means and deactuating said motor in response to said predetermined output signal.

19. A focusing device as set forth in claim **18**, wherein said drive means includes a clutch mechanism having a first condition drive coupling said motor to said link assemblies and a second condition drive uncoupling said motor from said link assemblies, and further comprising means for urging said link assemblies to one extreme position thereof within the focus of the movement of said link assemblies and a control member for displacing said clutch mechanism from its first to second condition in response to the completion of the exposure by the camera.

20. A focusing device as set forth in claim **14**, wherein said exchangeable lens to be mounted on said lens support member includes a diaphragm mechanism and a movable member connected to the diaphragm mechanism and wherein said exchangeable lens camera includes diaphragm control means for stopping down the diaphragm mechanism in said exchangeable lens through said movable member and further comprising extendable contractable interlocking means for interlocking said control means and said movable member, said interlocking means being movable integrally with said lens support member.

[57] **ABSTRACT**

A telephoto objective lens consisting of a positive front lens group and a negative rear lens group which is divided into sub-groups, the rear one being movable for focusing and the front one remaining stationary, thereby the weight of the complete objective is minimized. As the front lens group consists of only one positive and only one negative lens element, since the provision for focusing is made at such lens, this objective lens tends to produce aberrations of which the spherical and comatic aberrations are particularly deteriorated. According to the invention, therefore, the frontmost surface and rearmost surface of the front lens group and the rearmost surfce of the movable subgroup are specified in radius of curvature to achieve good stability of correction of the aberrations throughout the focusing range.

TELE-OBJECTIVE LENS WITH A MOVABLE SUB-GROUP FOR FOCUSING

This is a continuing application of application Ser. No. 870,228, filed Jan. 17, 1978 now abandoned.

BACKGROUND OF THE INVENTION

This invention relates to a tele-objective lens consisting of a front lens group having a positive refractive power and a rear lens group having a negative refractive power.

With the telephoto objective lens, it has been the general practice to move the lens as a whole to effect focusing. In U.S. Pat. No. 4,045,128, however, an inventive type of telephoto objective lens is disclosed wherein the provision for focusing is made at a subgroup thereof. The present invention is related to improvements in the objective system of the type described in U.S. Pat. No. 4,045,128.

The widely accepted design for tele-objective lens developed about 15 years ago was to construct the front lens group from only one positive and only one negative elements. Recently, the general trend is to make use of an additional positive lens element for the purpose of facilitating correction of aberrations.

Because of the relatively large dimensions of the lenses constituting the front lens group to those of lenses rearwardly subsequent thereto, however, increases in the number of lens elements lead to a rapid increase in the production cost, and to a corresponding increase in the weight of the complete objective so that it is inconvenient for a hand-held camera to employ such objective lens, as the so established camera is difficult to manage in performing photography.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a tele-objective lens with the front lens group constructed from only one positive lens element and only one negative lens element, while nevertheless achieving good correction of aberrations.

Another object is to provide a tele-objective lens having a focusing provision made at a part thereof with assurance that it is made possible to maintain a high standard of aberration correction throughout the entire focusing range.

While the present invention is applicable to tele-objective lens system which are movable in whole for focusing purposes, it is described hereinafter particularly with reference to its presently preferred forms in which the rearmost lens group is made movable for focusing. It is, therefore, to be understood that the invention is not limited to the specific embodiment thereof that is illustrated in the accompanying drawing and described hereinafter, but includes all forms thereof that fall within the scope of the appended claims.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an axial sectional view of one embodiment of a tele-objective lens system according to the present invention in two different operative positions for focusing at infinity and close-up.

FIG. **2** is a similar view showing a second embodiment of the invention.

FIG. **3** is a similar view showing a third embodiment of the invention.

FIG. **4** is a similar view showing a fourth embodiment of the invention.

FIGS. **5A** to **5D** are graphic representations of spherical aberration, astigmatism, distortion and lateral chromatic aberration of Example 1 lens system respectively when set at infinity.

FIGS. **6A** to **6D** are graphic representations of the various aberrations of Example 1 lens system when set at close-up.

FIGS. **7A–7D** and **8A–8D** are similar representations of Example 2 lens system when set at infinity and close-up respectively.

FIGS. **9A–9D** and **10A–10D** are similar representations of Example 3 lens system when set at infinity and close-up respectively.

FIGS. **11A–11D** and **12A–12D** are similar representations of Example 4 lens system when set at infinity and close-up respectively.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Four examples of embodiments of a tele-objective lens system according to the present invention are represented in FIGS. **1** to **4**, each of which may conveniently be considered as comprising a front lens group **1** of positive power and a rear lens group of negative power axially spaced apart from each other. The rear lens group is divided into two parts or groups **2** and **3**, of which the rear or third group **3** is movable for focusing purposes, while the front part or second group **2** remaining stationary. As focusing is effected from infinity down to close-ups, the third lens group **3** is moved in a rearward direction from a solid line position to a dashed line position. This constitutes one of the features of the present invention. As has been noted before, the entire system may be moved in whole with reference to the film plane to effect focusing. In this case, it is recommended that the third lens group **3** is stationary to occupy the solid line position at which the system is otherwise set for infinitely distant object.

According to the present invention, the first lens group **1** consists of two lenses, one of which is of positive power and another one which is of negative power. The second lens group **2** consists of a substantially single lens of negative power in the form of a meniscus lens rearwardly concave. This lens may be constructed from plano-convex and plano-concave lens elements to form an achromatic doublet. Though such aberrational correction is considered as unnecessary from the appropriate residual aberrations of the entire system, the employment of such doublet will be amendable to low cost production techniques. The third lens group **3** is overall of a negative refractive power and consists of two lenses one of which is of positive power and another one which is of negative power.

In FIGS. **1**, **3** and **4**, as the positive and negative lenses in the first group **1**, use is made of a double convex lens and a forwardly concave lens respectively arranged in the order named from the front to create an air lens therebetween, while, in FIG. **2**, such arrangement is reversed comprising a forwardly convex negative meniscus lens and a forwardly convex positive lens axially spaced from each other to create an air lens. The rearmost surface of the first group **1** is configured to a radius of curvature extremely near the infinite one. In FIGS. **1**, **2** and **3**, the third group **3** is constructed in the form of a doublet of the positive and negative lenses arranged in this order for the first two objectives and of

the negative and positive ones arranged in this order for the last, while in FIG. 4, the positive and negative lenses are arranged in this order from the front to create an air space therebetween.

In a preferred embodiment with the above mentioned basic construction and arrangement of the lens elements, the objective of the invention fulfills at least one of the following requirements:

$$-0.01<F/(F_{1p}\cdot V_{1p})+F/(F_{1n}\cdot V_{1n})<0.01 \quad (1)$$

$$0.85<(R'_1+R_1)/(R'_1-R_1)<1.1 \quad (2)$$

$$-3.5F<F_A<-1.5F \quad (3)$$

$$0.07F<R'_2<0.1F \quad (4)$$

$$0.7F<|F_3|<1.3F \quad (5)$$

$$-0.015<F/(F_{3p}\cdot V_{3p})+F/(F_{3n}\cdot V_{3n})<0.015 \quad (6)$$

$$0.15F<R'_3<0.35F \quad (7)$$

wherein F is the focal length of the entire system when focused for infinitely distant object; F_1 is the focal length of the first group; F_{1p} is the focal length of the positive lens in the first group; F_{1n} is the focal length of the negative lens in the first group; V_{1p} is the Abbe number of the positive lens in the first group; V_{1n} is the Abbe number of the negative lens in the first group; R_1 is the radius of curvature of the first surface (r_1) of the first group; R'_1 is the radius of curvature of the rearmost surface (r_4) of the first group; F_A is the focal length of the air lens (r_2, r_3) in the first group; R'_2 is the radius of curvature of the rearmost surface (r_6) of the second group; R'_3 is the radius of curvature of the rearmost surface (r_9 or r_{10}) of the third group; R_3 is the focal length of the third group; F_{3p} is the focal length of the positive lens in the third group; F_{3n} is the focal length of the negative lens in the third group; V_{3p} is the Abbe number of the positive lens in the third group; and V_{3n} is the Abbe number of the negative lens in the third group.

Whilst the tele-objective lens adapted to be bodily movable for focusing enables the residual aberrations generally to be maintained substantially stable through the entire focusing range, that type of tele-objective lens which makes the focusing provision at a part thereof gives rise to the high possibility of producing a great variation of aberrations and particularly spherical aberration ascribable to the fosusing member itself, as focusing is performed, thereby the balance in aberration correction of the entire system is lost so that high grade imaging performance can not be preserved throughout the entire focusing range.

In order to eliminate such variation of the various aberrations with focusing, the following two prerequisites must be satisfied simultaneously.

(1) The spherical aberration and coma of the focusing lens group are made minimized in terms of aberration coefficients, and the proper balance between the both aberration coefficients is established, and

(2) the entire system is well corrected for the various aberrations.

In this connection, it should further be explained that, in a two-group tele-objective lens system made movable in whole for focusing, the spherical aberration of the front group tends to be under-corrected, and, therefore, is required to be balanced out by the suitable design of the rear group to achieve a high standard of aberration correction through the entire system. If accommodation for change of object position is provided by imparting an independent movement to the rear group of the objective lens, the residual spherical aberration will be varied to a correspondingly large extent, as the height of incidence of image forming rays of light at the rear group is changed.

According to the formulated features of the invention, the second lens group is designed under condition (4) to provide an appropriate amount of aberration which contributes to the high standard of aberration correction of the entire system, while permitting the spherical aberration and coma of the focusing or third group to be limited to minimum and to be balanced out with each other. The design features of the first group are set forth at (1), (2) and (3), and those of the third group at (5), (6) and (7) each of which will be explained below.

Conditions (1) and (6) gives assistance in the stabilization of longitudinal chromatic aberration throughout the focusing range. As the objective of the invention is adapted to operate with a semi-angular field of view not exceeding 4 degrees, when these conditions are established, it is possible to limit the lateral chromatic aberration also to an acceptable level.

Conditions (2) and (3) are concerned with the configuration of the first group which constitutes the most important ones of the design features of the entire system particularly when the system is question is of the type described, and which affects the state of aberration connection of the entire system to a large proportion. What is generally called "shape factor" in the art of single lenses corresponds to condition (2). When any one of the upper and lower limits of this condition is exceeded, under-corrected spherical aberration will be resulted. Condition (3) determines a value of refractive power of the air lens defined by the positive and negative lenses. This air lens affects spherical aberration, comatic aberration, field of curvature and others. With regard to the spherical aberration, when the upper limit is exceeded, it will be over-corrected, while when the lower limit is exceeded, it will become under-corrected or increated in the ring band form.

Condition (4) inparts to the second group, or the negative meniscus lens that amounts of spherical aberration and coma which are over-corrected as seen in itself. This is so set forth by taking into account the fact that, if the third group movable for focusing is designed under condition (7) to have the rearmost surface of rearward concavity with limitation of spherical aberration and coma to minimum, the complete system with such third group produces under-corrected spherical aberration and coma.

Condition (5) controls the range of movement of the third group for focusing adjustments. When the upper limit is exceeded, the range of movement is so largely extended that mechanical interference due to the practical photographic lens structure can not be avoided. When the lower limit is violated, it is made difficult to correct the aberrations to satisfactory level.

Condition (7) is, as mentioned above, concerned with the configuration of the third group. When the upper limit is violated, the spherical aberration becomes under-corrected as the object distance is decreased. When the lower limit is violated, the spherical aberration becomes over-corrected with decrease in the object distance.

Four specific examples of preferred embodiments of the tele-objective lens system of the invention may be

constructed in accordance with the numerical data given below for the radii of curvature, r, the lens thicknesses and axial separations, d, along with the corresponding indices of refraction, nd, for the spectral D line of sodium and the Abbe numbers for the various lens elements. The minus values of the radii, r, indicate surfaces concave toward the front. The variable separation, d_6, with focusing is taken at the value shown when the objective is set forth infinitely distant object.

What is claimed is:

1. A tele-objective lens, with a movable sub-group for focusing, comprising:

a positive lens group, consisting of one positive lens and one negative lens spaced from each other, and the curvature of the frontmost lens surface thereof being stronger than that of the rearmost lens surface, and

a negative lens group, being located axially in the image side of said positive lens group and consisting of a stationary meniscus lens and a movable sub-group for focusing;

said stationary meniscus lens facing with its concave surface toward said movable sub-group, and said movable sub-group including positive and negative lenses; and wherein, when the focal length of the whole system is F and the focal length of said movable sub-group is F_3, said tele-objective lens satisfies the condition of $0.7F < |F_3| < 1.3F$.

2. A tele-objective lens according to claim **1**, wherein said positive lens group consists of a double convex lens and a forwardly concave negative lens arranged in this order from the front.

3. A tele-objective lens according to claim **1**, wherein said positive lens group consists of a forwardly convex negative meniscus lens and a forwardly convex positive lens arranged in this order from the front.

4. The tele-objective lens of claim **1**, wherein the lens elements have the following values:

	F = 100.0 r	FNo. 1:5.6 d	2ω = 8° nd	vd
1	33.5058	2.949	1.58913	61.1
2	−36.2942	1.912		
3	−33.4085	1.424	1.6727	32.1
4	−671.5298	23.725		
5	8.9708	1.356	1.58913	61.1
6	8.1227	2.749		
7	41.4383	0.712	1.69895	30.1
8	1156.5338	0.542	1.713	53.9
9	25.6539			

and wherein F is a focal length, 2ω is a view angle, r is a radius of the lens surface, d is an axial length or air gap of a lens, nd represents the refractive index of the lens medium and vd represents Abbe number of the lens medium.

5. The tele-objective lens of claim **1**, wherein the lens elements have the following values:

	F = 100.0 r	FNo. 1:5.6 d	2ω = 8° nd	vd
1	30.1688	1.424	1.69895	30.1
2	17.7817	0.946		
3	18.4847	2.902	1.58913	61.1
4	−6059.6105	25.502		
5	10.4502	1.356	1.58913	61.1
6	9.3380	2.729		
7	31.6054	1.210	1.69895	30.1
8	110.6620	0.542	1.713	53.9
9	19.9742			

and wherein F is a focal length, 2ω is a view angle, r is a radius of the lens surface, d is an axial length or air gap of a lens, nd represents the refractive index of the lens medium and vd represents Abbe number of the lens medium.

6. The tele-objective lens of claim **1**, wherein the lens elements have the following values:

	F = 100.0	FNo. 1:5.6	2ω = 8°	
	r	d	nd	vd
1	32.8478	3.214	1.58913	61.1
2	−35.5624	1.075		
3	−32.2451	1.424	1.6727	32.1
4	−622.9698	25.403		
5	9.5414	1.356	1.58913	61.1
6	8.6190	2.749		
7	32.9044	0.542	1.713	53.9
8	15.3051	0.685	1.80518	25.4
9	17.9393			

and wherein F is a focal length, 2ω is a view angle, r is a radius of the lens surface, d is an axial length or air gap of a lens, nd represents the refractive index of the lens medium and vd represents Abbe number of the lens medium.

7. The tele-objective lens of claim **1**, wherein the lens elements have the following values:

	F = 100.0	FNo. 1:5.6	2ω = 8°	
	r	d	nd	vd
1	33.7136	3.108	1.58913	61.1
2	−37.1715	1.054		
3	−33.8288	1.424	1.6727	32.1
4	−773.2559	1.675		
5	9.5251	1.356	1.58913	61.1
6	8.6254	2.749		
7	34.5403	0.695	1.69893	25.4
8	179.4034	0.088		
9	176.2224	0.542	1.713	53.9
10	22.7308			

and wherein F is a focal length, 2ω is a view angle, r is a radius of the lens surface, d is an axial length or air gap of a lens, nd represents the refractive index of the lens medium and vd represents Abbe number of the lens medium.

[57] **ABSTRACT**

A mechanical mounting system for a zoom objective having provision for close-up operation includes an actuator serving to perform both focusing and zooming operations as it is turned and axially moved respectively. When the actuator is axially moved to the wide angle position and when it is turned to the lower limit of the focusing range, a drive connection between the actuator and a camming cylinder for the zoom and close-up control is established even in the transverse direction. Upon transverse movement of the actuator beyond the focusing range, the camming cylinder is turned to axially move the variator forwardly while the compensator remains stationary in the wide angle position thereby effecting a close-up operation.

FIG.21

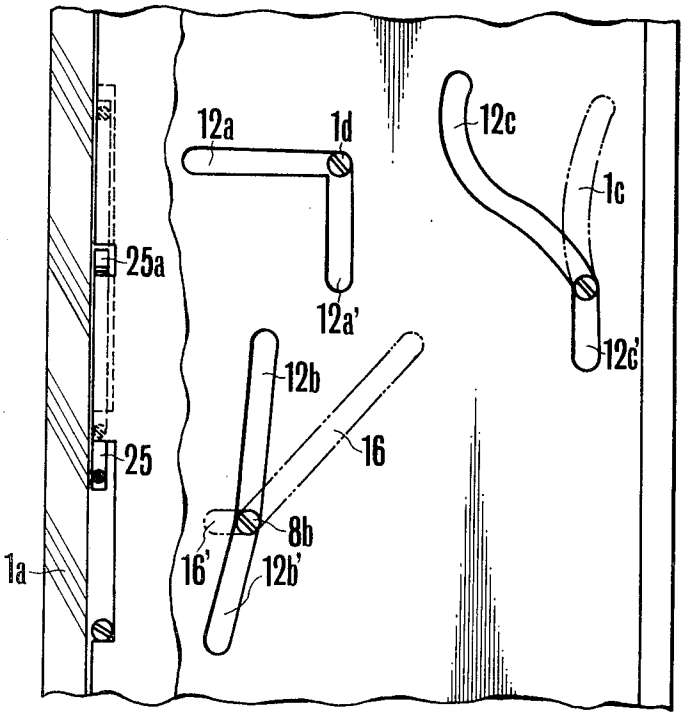

FIG.22

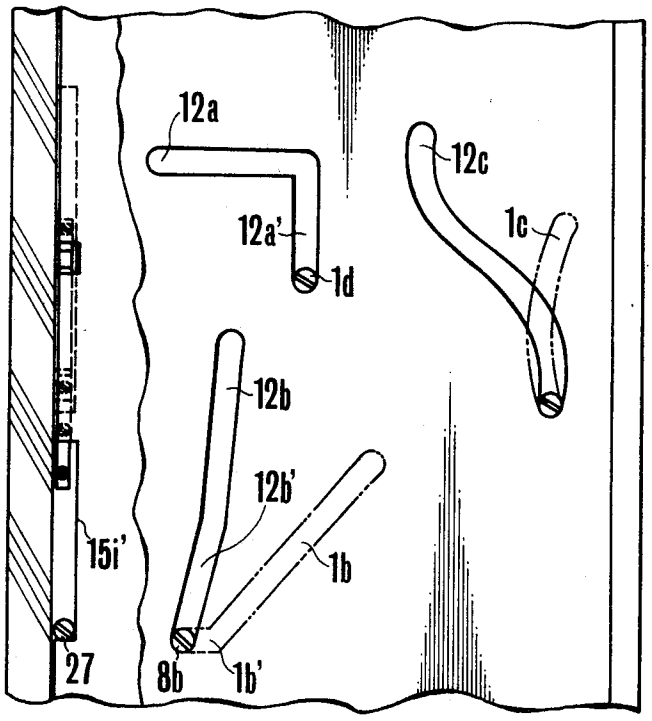

MECHANICAL MOUNTING SYSTEM FOR ZOOM OBJECTIVE

The present invention relates generally to photographic lens devices and more particularly to zoom lens assemblies wherein provision is made for a close-up mechanism therein.

In the prior art, a wide variety of mechanical mounting systems for zoom lenses having close-up capability have been proposed. An example of such a system is disclosed in U.S. Pat. No. 4,097,124 wherein in the mounting for the zoom lens focusing and close-up operation are performed by a common actuator **13** of the zoom control which is rotated about the optical axis of the lens assembly or moved axially, respectively. When it is desired to select operation in the close-up range, the operator must however rotate a mode ring **18** so that engagement of a pin **30** in a slot is changed from a zoom control slot Z1 to a macro-control slot M1. That is, in the mechanical mounting system of this prior art reference, the zooming operation and the close-up operation are entirely independent of each other and their exists no consecutive relationship therebetween. Of course, it will be apparent that the type of zoom lens assembly described in this reference is meritorious in that accidental changeover of the optical system to the close-up range when zooming is being performed may be prevented.

In this context it should be considered that the usefulness of a zoom lens may be enhanced if the action of focusing a lens assembly upon an object to be photographed may be followed by a series of actuations of the shutter release mechanism with different magnifications of an image of the object as desired. Furthermore, the manageability and convenience of the lens assembly will be improved also when focusing operation, zooming operation and close-up operation may be performed consecutively relative to each other by a single actuating member.

Since, in conventional zooming systems, the total axial movement of the actuator member must be equal to that of the variator, the longitudinal length of the mounting unit must be considerably increased thereby sacrificing ease of handling and portability of the device.

A further more serious problem will be encountered when total axial movement of the variator is increased since it is difficult to hold the variator truly normal to the tubular body of the lens assembly during its entire excursion. Thus, the fitting accuracy of the movable lens cell in the tubular body of the assembly must be increased. This tends to lead to requirements for supplying high-precision mechanical parts and for employing much more delicate assembly techniques.

With regard to the zoom control mechanism, it has been common practice in the prior art, as disclosed for example in U.S. Pat. No. 4,097,924, that the variator and the compensator are fixedly carried by respective movable sleeves which are arranged in a superimposed relationship relative to each other. It is therefore of great importance that the dimensions of the sleeves be limited to very close tolerances and the assembly procedure particularly with regard to the fitting adjustment must be so fine that there can be no looseness or play between the sleeve and the tubular body of the assembly while insuring smooth operation of the control mechanism.

This will contribute to an increase in the production costs of the system.

In view of the foregoing, the present invention is directed toward provision of a mechanical mounting system for a zoom objective having three ranges of zooming, focusing and close-up operation selectively rendered by only one actuator sleeve without requiring recourse to selector means.

A further aim of the invention is to provide a mounting system for a zoom objective having a close-up mechanism operating with a common actuator for zooming and for focusing in such a manner that the three operations may be formed consecutively.

A further goal of the invention is the provision of a zoom lens assembly characterized by high accuracy while limiting to a minimum deviation of the points of positioning of each individual moving part from prescribed ideal positions as the magnification varying lens holder and the image shift compensating lens holder are moved along a common optical axis. A further aim of the invention is to provide a novel zoom control mechanism having a shorter total axial movement of the actuator than that of the variator and to provide a zoom objective having improved manageability and portability.

SUMMARY OF THE INVENTION

In accordance with the present invention, a zoom lens assembly is provided wherein a single actuator ring is arranged in the mechanical mounting system to effect zooming operation upon axial movement thereof and upon rotative movement thereof about the optical axis to effect close-up operation whereby the transition from the axial to the rotative phase of movement may be caused to occur only after passage of the wide-angle end. In the assembly of the invention, means are provided for preventing accidental selection of the close-up range which would otherwise occur when the actuator nears the wide angle end of movement thereof. Utilization of such means makes it possible to eliminate the drawback that the sharp focus condition will be broken after the close-up range is selected.

In order to achieve high accuracy of zoom control, there is provided in accordance with another feature of the invention a novel and improved differentiating mechanism for the variator and the compensator mounting members which is also adapted for suitable use in axial movement of the variator independently of the compensator which remains stationery in the wide angle position when a close-up operation is being performed.

The most characteristic feature of the invention resides in the fact that in order to enable an operator to perform zooming and close-up operations consecutively, i.e. without having to remove his hand from the actuator member, an intermediate member is provided causing axial movement of the actuator to effect zooming operation and causing rotative movement thereof about the optical axis to effect close-up operation with a detent mechanism being provided for bringing and taking this intermediate member into and out of drive connection with the actuator member.

The various features of novelty which characterize the invention are pointed out with particularity in the claims annexed to and forming a part of this disclosure. For a better understanding of the invention, its operating advantages and specific objects attained by its use, reference should be had to the accompanying drawings

and descriptive matter in which there are illustrated and described preferred embodiments of the invention.

DESCRIPTION OF THE DRAWINGS

In the drawings:

FIG. **1** is an axial sectional view of one embodiment of a lens assembly in accordance with the present invention;

FIG. **2** is a prospective view of a variator mounting member of the assembly of FIG. **1**;

FIG. **3** is a perspective view of a compensator mounting member of the assembly of FIG. **1**;

FIG. **4** is a perspective view of a tubular body of the assembly of FIG. **1** having provided thereon guide means and pin means operating as an engaging device;

FIG. **5** is a perspective view of a cam sleeve or intermediate member of the assembly arranged between the tubular body shown in FIG. **4** and an operational member of the lens assembly of FIG. **1** and provided with longitudinal guide means for axial movement of the operational member, with transverse guide means and with variator guides for the zooming and close-up regions, respectively;

FIGS. **6–8** are developed representations of the tubular body and the cam sleeve with the engaging means of the variator and compensator holders assuming the telephoto, wide angle and close-up positions relative to the guide slots, respectively;

FIGS. **9** and **10** are partial sectional views of a detent mechanism for a drive connection between the operational member and the cam sleeve shown in the idle and the active positions, respectively;

FIGS. **11–14** show an example of an improvement in the lens assembly of FIGS. **1–10** with a mechanism for assuring occurrence of a transition from the zooming to the close-up position past the wide angle end, with FIG. **11** being a schematic diagram showing the normal and erroneous paths of movement of the engaging means of the tubular body in the contiguous guide slot means;

FIG. **12** being a perspective view of the main parts of the changeover mechanism, and FIGS. **13** and **14** being sectional views of the mechanism shown in two operative positions;

FIG. **15** is a longitudinal sectional view of a lens assembly provided with the changeover mechanism of FIGS. **11–14**;

FIG. **16** is a longitudinal sectional view of a lens assembly comprising another embodiment of the invention including a detent mechanism between the actuator member and the cam sleeve in the close-up position;

FIG. **17** is a perspective view of the tubular body of the embodiment of FIG. **16**;

FIG. **18** is a perspective view of the cam sleeve having a spring member fixedly mounted at the end thereof;

FIG. **19** is a perspective view of a contiguous sleeve having a cut-out therein; and

FIGS. **20–22** are developed representations showing the main parts for purposes of depicting the detent mechanism of this embodiment.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawings, wherein similar parts are identified with like reference numerals throughout the various figures thereof, the present invention is shown in various embodiments by application thereof to interchangeable lens mounting systems for single lens reflex cameras.

The lens mounting assembly of the invention includes a tubular body **1** and an adapter **2** which is fixedly mounted at the rear end of the tubular body by means of screw fasteners **2***a*. The adapter **2** is equipped with coupling means to enable attachment of the lens assembly to a camera body (not shown).

A relay lens group **L1** is held within the tubular body. A screw fastener **2***c* is provided for fixing a cell member **2***b* containing the first lens group **L1** to the tubular body **1**. At the other end of the tubular body **1** there is shown a front barrel member **6** coupled in unison with a cell **4** containing a second lens group **L2** which is movable for effecting the focusing of the lens assembly. The cell **4** and the tubular body **1** are in threaded engagement with each other by means of helicoid portions **1***a* and **6***a*. A relay sleeve **2***d* has thereon a distance scale and is fixedly mounted on the tubular body **1** by a screw **2***e*.

Lens holder members **8** and **10**, shown in FIGS. **2** and **3**, respectively, containing a magnification varying lens group **L3** and an image shift compensating lens group **L4**, respectively, are movably fitted in the inner diameter of the tubular body **1**. The holder **8** of the third lens group **L3** is formed with four longitudinally elongated arms **8***a* which are slideably fitted in respective recesses **10***a* of the holder **10** of the fourth lens group **L4**.

Guide pins **8***b* and **10***c* arranged, respectively, on the holders **8** and **10** are engaged in respective slots **1***b* and **1***c* provided through the wall of the tubular body **1**, as shown in FIG. **4**, to control movement of the variator **L3** and the compensator **L4**.

Movably fitted on the outer diameter of the tubular body **1** is a cam sleeve **12**, shown in FIG. **5**, having a first cam slot **12***a* with a longitudinal orientation and a second cam slot **12***a'* having a transverse orientation. Third and fourth cam slots **12***b* and **12***b'* are also provided in the sleeve **12**. In the first cam slot **12***a* there is engaged the guide pin **1***d* mounted on the tubular body **1**. In the other cam slot **12***b* there is engaged the guide pin **8***b* which extends radially from the lens holder **8** through the cam slot **1***b* of the tubular body **1** (see FIG. **1**).

An actuating member **14** is fitted on the outer diameter of the lens barrel and it is provided with a longitudinal groove **14***a* into which the pin **6***b* of the front barrel member **6** enters. Axial movement of the actuator **14** leaves the second lens group **L3** stationery in its position. On the other hand, rotative movement about the optical axis causes axial movement of the front barrel **6** through the helicoid connection **1***a*, **6***a*.

An interlocking sleeve **15** is inserted into a space between the actuator **14** and the cam sleeve **12** and is fixedly secured to the actuator **14** by a fastener screw **14***b*. The interlocking sleeve **15** has an inner integral flange formed in a front end portion **15***a* thereof and arranged between an outward flange **12***c* of the cam sleeve **12** and a ring **16** which is fixedly fitted on the sleeve **12** so that the interlocking sleeve **15** is rotatable relative to the cam sleeve **12** while being restrained from axial movement.

As best seen in FIGS. **9** and **10**, a pin **17** and a spring **18** are arranged to constitute a locking means together with a detent hole **15***b* for simultaneous rotation of the actuator **14**, the interlocking sleeve **15** and the cam sleeve **12** in predetermined positions (the close-up positions). The pin **17** is movably fitted in a hole provided in the wall of a flange at the front end of the cam sleeve **12** and it is pressed by the spring **18** against the radial shoulder of the interlocking sleeve **15**, the arrangement

being such that when the actuator **14** is turned beyond the normal focusing range toward the close-up operating range, the pin **17** will enter the detent hole **15***b* and thereby a drive connection will be established between the actuator ring **14** and the cam member **12**.

In the operation of the embodiment of the mounting mechanism for the zoom objective of the present invention depicted in FIGS. **1–8**, when the actuator member **14** is moved axially, since the interlocking sleeve **15** is clamped between the ring member **16** and the radial flange of the cam member **12**, the actuator **14**, the interlocking sleeve **15** and the cam member **12** will be moved axially as a unit. The total axial movement of the actuating member will be defined by the longitudinal length of the path of possible relative movement of the pin **1***d* on the tubular body **1** in the first cam slot **12***a* of the cam member **12**.

As the actuator member **14** is axially moved from the telephoto position shown in FIG. **6** to the wide angle position of FIG. **7**, with the cam sleeve **12** being simultaneously axially moved and guided by the pin and slot connection **1***d*, **12***a*, the third lens group or variator L3 is axially and rotatably moved toward the front of the assembly by the pin **8***b* extending through both slots **1***b* and **12***b* in the tubular body **1** and the cam sleeve **12**, respectively. At the same time, the rotative component of motion of the variator lens cell **8** is transmitted through the elongated arms/fitted slots connection **8***a*, **10***a* of FIGS. **2** and **3** to the compensator lens cell **10** whereby the latter is caused to move axially toward the front of the assembly guided by the pin **10***c* engaging in the slot **1***c*.

It should be noted that in this embodiment, the lens holding members **8** and **10** are axially elongated in order to slideably engage with each other over the entire zooming range. Also, the armed portions **8***a* and the slotted portions **10***a* are maintained in overall surface contact with each other with the lens holding members **8** and **10** fitted in the common inner diameter of the tubular body **1**. Therefore, it is possible to hold the variator and the comparator in a truly normal position relative to the common optical axis during the entire range of movement thereof. It is also possible to avoid the existence of play between the lens holders and the tubular body while still permitting a smooth axial movement of the individual lens holders **8** and **10**. Furthermore, the motion of the member **8** may be transmitted to the member **10** with a relatively small amount of force.

When the actuating member **14** is rotated about the optical axis, motion of the actuating member **14** is transmitted through the pin/axial slot connection **6***b*, **14***a* in order to turn the front barrel **6** while simultaneously causing the barrel **6** to move axially by virtue of the helicoid coupling **6***a*, **1***a* thus moving the second group L2 in order to effect focusing to accommodate differing object positions.

It is noted that when in the focusing mode of operation, the third and the fourth lens groups L3 and L4 will remain stationary since, although the interlocking sleeve **15** is clamped by the cam member **12** and the restraining member **16**, it is rotatable so as not to transmit the driving torque of the actuating member **14** to the cam sleeve **12** and the lens holders **8** and **10**.

It is further noted that in this embodiment it is necessary to provide stopper means arranged between the interlocking sleeve **15** and the cam member **12** to enable focusing to be performed at any zooming station. This will be more fully explained hereinafter in connection with a further embodiment of the invention.

Since the linearly advancing operation of the actuator member **14** contributes only to movement of the cam sleeve **12** cooperative with the one cam follower pin **8***b* on the variator holder **8**, and since the pin **8***d* always occupies the intersection of the lead slot **1***b* and the second cam slot **12***b*, of which the latter is inclined with respect to the optical axis, the variator holder **8** will move axially at a faster rate than that of the actuator **14**. As a result, the total axial movement of the actuating member **14** may be made shorter than that of the variator holder **8**. The relationship between the amounts of movement of the actuator **14** and the lens holder **8** may be termed an accelerating relationship.

As a result of this accelerating function, it is possible to employ an increased range of variation of image magnification for an equivalent amount of movement of the actuator **14**. That is, the actuator may be shortened in the longitudinal direction to effect a zooming function equivalent to that provided by conventional devices.

In order to operate the lens assembly of the invention for close-up photography, the operator may first move the actuator **14** forwardly from the telephoto position to the wide angle position where the pin **1***d* on the tubular body **1** lies in the rear end of the longitudinal slot **12***a* and is aligned to the transverse slot **12***a'* to permit rotative movement of the cam sleeve **12**. As the actuating member **14** assumes an intermediate focusing position where the detent hole **15***b* is out of alignment with the pin **17**, when the actuating member **14** is turned to the lower limit of the normal focusing range, the interlocking sleeve **15** will be drivingly connected to the cam sleeve **12** by the pin **17** engaging in the detent hole, as shown in FIG. **10**, and thus there will be completed the selection of the close-up range.

As the actuator member **14** is further rotated, the third lens group L3 is moved forwardly without the accompanyment of any rotative movement because of the guidance of the pin **8***b* by the axial slot **1***b'*. Therefore, the fourth lens group L4 is maintained stationery in the same position when in the wide angle setting during close-up operation.

Thereafter, when the actuating member **14** and the interlocking sleeve **15** are to be returned from the close-up range to the zooming range, the actuating member **14** is turned in the direction opposite to that indicated by the arrow B to move the detent hole **15***b* away from the pin **17** as the hemispheric head of the pin **17** is slideably moved on the tapered surface **15***c* against the force of the spring **18** so that the interlocking sleeve **15** is then disconnected from the cam sleeve. The pin **1***d* returns from the solid-line position to the dashed-line position shown in FIG. **8** and thus the zooming range is rendered operative.

It will be seen from the foregoing that the present invention provides for the fixed sleeve **1** having the cammed portions **1***b* and **1***c* controlling movement of the optical lenses L3, L4 which contributes to change of the image magnification and image shift compensation. Only one operating member in the form of an outer sleeve on the fixed sleeve **1** is sufficient to effect zooming, focusing and close-up operation selectively. For this purpose, the camming member **12** is arranged to cooperate with the operating member **14** and it is formed with cammed portions **12***a'*, **12***b* and **12***b'* controlling the transition to and the adjustment of the close-

up range. Furthermore, there is provided interlocking means **15***c*, **17** and **18** for placing the operating member into and out of drive connection with the cam member **12**. When it is desired to shift the operating member **14** from one range to another, the interlocking means is rendered either effective or ineffective in order to make it possible for zooming, focusing and close-up adjustments to be consecutively performed.

With this construction and arrangement, the features of the present invention may be embodied in a fixed sleeve **1**, a cam sleeve **12**, operating member **14** and lenses L2, L3 and L4 alone. Thus, a relatively simple structure may be provided for the mounting mechanism.

The present invention has been described in connection with the embodiment of FIGS. **1–8** as applied to a four-component zoom objective with a focusing lens, variator, compensator and relay lens. However, it should be understood that the invention is applicable to a three-component zoom objective with the exclusion of the relay lens. Further, the invention is described in the form of an interchangeable lens assembly as an example of an embodiment thereof but it should be understood that it is applicable to a built-in zoom lens assembly for photographic instruments.

FIGS. **11–15** show an example of improvements in the first embodiment previously described herein. Since in the embodiment of FIGS. **1–10**, the direction of movement of the actuator is changed through a right angle as a transition occurs between the zooming and the close-up ranges, and since the pin **1***d* engaging in the slots **12***a*, **12***a*′ is round in cross-sectional configuration, a looseness or play is produced when the pin **1***d* enters the corner of the slots **12***a* and **12***a*′ as shown in FIG. **11**. Because of this there exists a rather high possibility that there will occur abnormal transition particularly when the zooming range is exchanged for the close-up range.

FIG. **11** shows two extreme paths of movement of the pin **1***d* as it is guided by the slots **12***a* and **12***a*′, one of which is indicated by perpendicularly crossed lines X and Y and considered to be normal, and the other of which is indicated by the curved line Z. In the latter connection it should be explained that the actuator **14** may change its movement from the axial direction to the transverse direction when it reaches a point at a distance equal one-half of the width of the slot **12***a*′ ahead of the wide angle position. In other words, the actuator **14** while having already entered the close-up range may be further moved axially forwardly to effect the balance of the zooming function. This gives rise to a problem in that as zooming is being performed in the close-up range it becomes difficult to perform a focusing adjustment for close-ups.

FIGS. **12–14** show an example of a mechanism to overcome this drawback. In FIG. **12**, the same reference numerals are utilized to denote similar parts as those depicted in FIGS. **1–10**. As is also shown in FIG. **15**, the tubular body **1** is provided with sensing means **20**, **21**, **22** at the forward part thereof. The sensing means is arranged in axial alignment with the front ends of the overlapped cam sleeve **12** and interlocking sleeve **15** so that the position of the actuator **14** in the axial direction may be sensed. The sensing means comprises the ring member **20** fixedly mounted on the tubular body **1** and having a hole or groove in which a flanged pin **21** is movably fitted with a spring **22** urging the pin **21** to project outwardly of the ring **20** toward the cam and interlocking sleeves **12** and **15**.

The cam sleeve **12** is provided with a cut-out **12***f* formed in a front end portion thereof and arranged in alignment with the projected portion of the pin **21** of the sensing means. The front end surface **15***e* of the interlocking sleeve **15** is also configured with a slope **15***f* radially aligned with the cut-out **12***f* intervening between axially differentiated stages **15***g***1** and **15***g***2**.

With the mechanism described, as the actuator **14** is moved forwardly when it reaches the wide angle position the projected portion of the pin **21** will be pushed into the hole or groove by the action of the tapered surface **15***f* of the interlocking sleeve **15**. Assuming a situation before the actuator **14** has been moved forwardly through the full range to the wide angle position, i.e. after having been stopped at a position within a range of distances of from a to b as shown in FIG. **11**, if the actuator is turned about the optical axis then the projected portion of the pin **21** engages the cut-out **12***f* to hinder further movement of the actuator **14**. That is, as shown in FIG. **13**, although the center of the pin **1***d* lies at a point O_3 in the range of a to b in FIG. **11** in order to permit transverse movement of the actuator **14**, the pin **21** will be allowed to enter the cut-out **12***f* so that the actuator **14** cannot be fully turned. Then when the actuator **14** is turned in a reverse direction and followed with actual movement to the wide angle end, the pin **21** is pushed by the tapered surface **15***f* of the interlocking sleeve **15** against the force of the spring **22** thereby being disengaged from the cut-out **12***f* to permit the full range of close-up operation.

FIGS. **16–22** show another embodiment of the change-over mechanism for selection of the zooming and close-up ranges. In this embodiment, the variator and the compensator holders are of different construction from that shown in FIGS. **2** and **3**.

The intermediate or cam member **12** is not only provided with the guide slots **12***a*, **12***a*′, **12***b*, **12***b*′ but it is also provided with a new guide slot **12***c* into which a pin **10***c* on the compensator holder **10** will extend through the guide slot **1***c* of the tubular body **1**. The guide slot **12***c* is arranged contiguously to a transverse guide slot **12***c*′.

On the other hand, the variator and compensator holders are modified so that the arms and the open slots are not in surface contact with each other. That is, the armed portions **8***a* although lying in the respective cut-outs **10**′ formed in the portions of the compensator holder **10** are arranged so as not to constitute the motion transmitting intermediary as the cut-outs **10**′ are over-slotted. With this construction, axial movement of the compensator is controlled by the pin **10***c* engaging in the guide slots **12***c* and **1***c*. The two methods of axially moving the compensator holder **10**, **10**′ each have advantages and disadvantages and the selection of either one of the methods may be optional depending upon the type of mechanical mounting involved.

Referring now to the axial sectional view of FIG. **15**, it is noted that the operating means (the actuator **14** and the inner sleeve **15** contiguous thereto) and the cam sleeve **12** are maintained in threaded relationship with a short pitch. The device includes a diaphragm unit **22** carried by the fixed support member **26**, a diaphragm presetting ring **23** and a signal transmitting member **24**, these parts constituting a mechanism of known construction in the art whose detailed explanation is therefore omitted. In FIGS. **16–22**, a spring member **25**, an interconnecting plate **26** and a cut-out **15***h* of the cam sleeve **15** constitute an interlocking mechanism for the

operating means and the cam member when in the close-up range. The spring member **25** is affixed to the cam member **12** at one end, i.e. the front side thereof, by means of screws and the interconnecting plate **26** is affixed to the tubular body **1** also at one end, i.e. the object side, by means of screws.

The free end of the spring member **25** is formed with an outwardly folded portion **25***a* which has a spring property so that when the axial movement of the actuating member **14** (**15**) to the wide angle position is followed by rotative movement about the optical axis, the actuating member **14** and the cam member **12** will be connected to each other and will be simultaneously rotated about the optical axis in order to effect close-up operation guided by the pin **1***d* on the tubular body **1** engaging in the transverse slot **12***a*′ of the cam sleeve **12**.

With reference to FIGS. **20–22**, this connecting operation is explained with greater detail and FIG. **20** is a developed view of the tubular body **1** and the cam member **12** with the actuating member **14** in the telephoto position showing an arrangement of the various parts constituting the interlocking mechanism. In this state, the free end **25***a* of the spring member **25** is seated in the cut-out **15***h* formed in an end portion of the cam member **15**.

FIG. **21** is a developed view showing the changed positions of the various parts when the actuating member is axially moved from the telephoto to the wide angle position. In the zooming range between the positions shown in FIGS. **21** and **22**, only the longitudinal slot **12***a* of the cam member **12** is operative with pin **1***d* so that while the free end **25***a* of the spring **25** is engaged in the cut-out **15***h*, the cam member **12**, the intermediate sleeve **15** and the actuator member **14** are moved as a unit. During focusing, the actuator member **14** and the intermediate sleeve **15** are axially moved relative to the cam member **12**. However, since the pitch of the screw threads is made very fine, the influence of this movement upon the optical system will be negligible. It should be noted that the pin **27** shown in FIG. **16** is a stopper means between the cam member **12** and the actuating member **14** or the intermediate sleeve **15** during focusing. This pin **27** is fixedly mounted to the cam member **12** and positioned so as to engage in the hole **15***i* formed in the front end portion of the intermediate sleeve **15**.

Therefore, during focusing, the pin **27** shown in FIG. **20** is movable from one end of the hole **15***i* to the other. Within this range, the actuating member **14** and the intermediate sleeve **15** are moved freely relative to the cam sleeve. With this angle of rotation, the focusing lens L2 is caused to axially move through a distance corresponding to the pitch of the helicoids **6***a* and **1***a* between the front barrel **6** and the tubular body **1**.

When the actuating member **14** is next turned about the optical axis from the wide angle position, the member **14** and the intermediate sleeve **15** abut with the stopper pin **27** against the end of the opening **15***i*. Upon further rotation of the actuating member **14** about the optical axis, the pin **1***d* moves along the transverse guide slot **12***a*′ and the spring member **25** will ride upon the upper part of the interconnecting plate **26** (see FIG. **22**).

The rotative movement of the actuating member **14** and the intermediate member **15** about the optical axis is also transmitted by the spring member **25** to the cam member so that they turn as a unit about the optical axis. By rotation of the cam member **12** due to this connecting function, the pin **8***b* on the variator holder **8** is moved along the cross point of the guides **12***b*′ and **1***b*′ and the lens holder **8** moves in the axial direction toward the front of the lens assembly with variation of the spacing between the variator and the compensator thus effecting close-up operation.

To return from the close-up positions to the zooming positions, the actuating member **14** is turned in the reverse direction until the pin **1***d* reaches the changeover point of the guides **12***a* and **12***a*′ shown in FIG. **21** where the spring member **25** is disengaged from the interconnecting plate **26**. By axially moving the actuating member **14**, the cam sleeve **12** is restricted from rotative movement about the optical axis and only the axial movement is effective to achieve zooming.

It will be seen from the foregoing that the zoom lens assembly of the invention is capable of consecutively performing zooming operation followed by close-up operation and that therefore it is superior in its manageability with a mechanism for connecting and separating the actuating means and the intermediate member when in the transit to the close-up range being simple in structure and capable of meeting the demands of the market for a low price and high quality product.

Furthermore, the magnification varying lens holding member **8** and the image shift compensating lens holding member **10**, **10**′ can be accelerated in axial movement by engagement of the pins **8***b* and **8***c* in the guide slots **1***b*, **12***b*, **1***c*, **12***c* with the advantage that the longitudinal length of the lens assembly may be shortened to a considerable degree.

While specific embodiments of the invention have been shown and described in detail to illustrate the application of the inventive principles, it will be understood that the invention may be embodied otherwise without departing from such principles.

What is claimed is:

1. A zoom lens assembly having a single operational member adapted to selectively perform zooming operation and close-up operation comprising:

(a) first and second lens mounting members for holding first and second lens groups movable for zooming operation with variation of image magnification while image shift is compensated for respectively;

(b) a cylindrical member in which said first and said second lens mounting members are fitted and which has first and second guide means for guiding said first and said second lens mounting member, with third guide means being formed contiguous to said first guide means for guiding said first lens mounting member to close-up range;

(c) an intermediate member fitted between said operational member and said cylindrical member having contiguous first and second guide means formed therein to guide said operational member either axially or transversely, said first or said second guide means being penetrated by engaging means on said cylindrical member, and having third and fourth guide means cooperative with said first guide means of said cylindrical member to control movement of said first lens mounting member;

(d) interlocking means for said operational member and said first lens mounting member, and engaging means on said first lens mounting member extending through said first guide means of said cylindrical member to engage said third or said fourth guide means of said intermediate member so that as

said operational member is actuated, said first lens mounting member is moved;

(e) drive connection means between said first lens mounting member and said second lens mounting member, one of said two lens mounting members being provided with axially elongated armed portions, the other of said lens mounting members having engaging portions for engagement with said armed portions so that motion of said first lens mounting member is transmitted to said second lens mounting member; and

(f) interlocking means for close-up operation arranged upon changeover of said operational member from the zooming range to the close-up range to interlock said intermediate member and said operational member with each other in transverse directions.

2. A zoom lens assembly according to claim **1**, wherein said interlocking means comprises an engaging pin provided in an opposite position to said operational member and said intermediate member, and a detent portion for engagement with said engaging pin, said operational member when changed over to close-up range being interlocked with said intermediate member.

3. A zoom lens assembly according to claim **1**, wherein said third guide means of said cylindrical member is provided in axially parallel relationship therewith so that when said operational member is actuated for close-up operation, the spacing between said first and said second lens groups is varied as the first lens group is axially moved while the second lens group remains stationary at a zooming position.

4. A zoom lens assembly according to claim **1**, further including means for changing over to said second guide means only when said engaging means of said cylindrical member has come to a predetermined position of said first guide means of said intermediate means.

5. A zoom lens assembly according to claim **4**, including sensing means comprising:

(a) a pin positioned to face at both of said operational member and said intermediate member and urged to move in an axial direction while being supported by said cylindrical member;

(b) a recess formed in a portion of said intermediate member to engage said pin, said recess engaging said pin when said engaging means of said cylindrical member is out of a predetermined position of said first guide means of said intermediate member, said operational member being thereby incapable of performing closeup operation; and

(c) means for releasing said pin from the engagement with said recess, said means operating to take said pin out of the engagement with the recess when said operational member is changed from zooming range to close-up range.

6. A zoom lens assembly having a single operational member capable upon rotation thereof about an optical axis of said lens assembly to effect focusing of said assembly and upon axial movement thereof to effect zooming operation of said assembly, comprising:

(a) an elongated cylindrical member having first and second guide means for controlling axial movement of first and second movable lens groups contributing to a change of image magnification and to image shift compensation during zooming operation;

(b) first and second lens mounting members for containing said first movable lens group and said second movable lens group, said lens mounting members being individually fitted in the inner diameter of said cylindrical member;

(c) means for controlling the movement of said first lens mounting member by the axial movement of said single operational member, said means including a pin member radially extending from said first lens mounting member and engaging in said first guide means so that it is controlled by said first guide means;

(d) means for controlling the movement of said second lens mounting member by said first lens mounting member, said controlling means comprising arms axially extending from one of said two lens mounting members to engage respective cutouts formed in the other of said lens mounting members in surface-contacting relation, said first lens mounting member being adapted to be axially moved while turned about said optical axis to impart rotative motion to said second lens mounting member;

(e) an intermediate member arranged between said cylindrical member and said operational member, said intermediate member being provided with axially elongated first guide means and second guide means inclined with respect to said optical axis, with engagement means extending radially from said cylindrical member passing through said first guide means of said intermediate member and with engagement means extending radially from said first lens mounting member passing through said second guide means of said intermediate member after having passed through said first guide means of said cylindrical member so that said first lens mounting member is accelerated in axial movement of the combined action of both guide means of said intermediate and said cylindrical members; and

(f) means for controlling movement of said second lens mounting member comprising engagement means extending radially from said second lens mounting member and said second guide means of said cylindrical member, with said engagement means engaging in said second guide means to control movement of said second lens mounting member.

7. A zoom lens assembly having a single operational member adapted to selectively perform zooming operation and closeup operation including

(a) first and second lens mounting members for holding first and second lens groups movable for zooming operation with variation of image magnification while the image shift is compensated respectively;

(b) a cylindrical member in which said first and said second lens mounting members are fitted;

(c) a third lens mounting member for holding a third lens movable for focusing; and

(d) first guide means responsive to said operational member for axially moving said third lens mounting member to effect focusing, said zoom lens assembly comprising:

(A) an intermediate member fitted in a space between said cylindrical member and said operational member; said intermediate member having second guide means for guiding said single operational member responsive to zooming operation and closeup operation, and third and fourth guide means for guiding said first and second

lens mounting members responsive to zooming operation and closeup operation;

(B) interlocking means for interlocking said operational member and said intermediate member, said interlocking means being interlocked when said operational member is operated beyond the normal focusing range toward the closeup operating range;

(C) fifth guide means for changing the distance between said first and second lens mounting members in response to closeup operation of said operational member, said fifth guide means being formed continuously with at least one of said third and fourth guide means, at least one of said lens groups being shifted to the closeup direction when said interlocking means is made effective and said intermediate member is guided in proportional relationship with said fifth guide means.

8. A zoom lens assembly according to claim **7** or **1**, wherein said interlocking means comprises:

(a) a spring member affixed to said intermediate member; and

(b) an interconnecting plate affixed to said cylindrical member, and arranged so that the movement of said operational member to one terminal end of the zooming range is followed by a rotative movement thereof, said spring member riding thereon to interlock said intermediate member and said operational member.

[57] **ABSTRACT**

The adjustable objective holder for optical projectors has a focussing support formed as a single piece defining two pairs of juxtaposed walls forming a parallelogram. The walls of one pair are rigid whereas the walls in the other pair are flexible. One rigid wall is fixedly mounted to the apparatus and supports for rotation a control shaft. The opposite rigid wall has on its inner surface a control groove which engages an eccentric formed on the end of the control shaft so that during the rotation of the eccentric the flexible walls are uniformly swung and due to the parallel linkage the movable rigid wall together with the objective performs a linear movement at right angles to the transparency.

ADJUSTABLE OBJECTIVE HOLDER

BACKGROUND OF THE INVENTION

This invention relates in general to optical devices and in particular to an adjustable objective holder in such devices like microfiche readers, overhead projectors and the like in which the objective has to be displaceable at right angles to a film carrier in order to adjust a sharp focus.

The objective holders or optical devices of the aforedescribed type are generally known in the art. The construction of such holders, however, has to meet various contradicting requirements which are frequently difficult to meet. For instance to achieve a uniformly sharp projected image it is necessary that the objective be exactly displaceable at right angles to the film. Also, for the sake of a good quality of the projected image the objective holder is to be designed without any play. Inasmuch as optical devices in many cases are subject to vibrations, the objective holder has to be designed such as to prevent any unintentional displacement of the objective which would require a repeated manual readjustment of the sharp focus. In the case of microfiche readers it is frequently also desired that the objective be changeable in a simple and fast manner for another one. Furthermore, since optical apparatuses are mostly mass produced, it is of importance that in order to achieve a low price the objective holder be also inexpensive in manufacture.

Prior art optical devices only partially meet the above-mentioned requirements. For example, a conventional objective holder employs a tubular piece having an inner thread in which the objective which is provided with an outer thread is screwed. The focussing is made exactly as in a photographic camera by turning the objective in the tubular piece.

Such a known objective holder, however, requires high manufacturing tolerances and is therefore expensive to manufacture. For instance, in microfiche film readers in many cases only a small marginal area of the objective is used for the transmission of the light beam. Furthermore, the objectives used in such mass produced optical devices have not for economic reasons the same optical quality over their entire lens surface. It may happen, therefore, that in an objective which is focussed by turning, the projected light beam passes through such an area of the objective surface in which the optical quality is relatively poor.

Also known is an objective holder which axially displaces the objective lens in order to adjust the sharp focus. This arrangement has the advantage that in the case of an assymetric transmission of the light beam it is possible during the installation of the objective into the holder to select such a position or range on the objective surface which ensures the best quality of the projection. This selected range or position is not changed during the axial displacement of the objective. Conventionally, the objective holders of this kind are assembled of two sleeves of which the inner sleeve supports the objective and is provided with a groove cooperating with an excenter so that by operating the excenter by means of an adjustment shaft the inner sleeve is axially displaced. This known construction also requires an extremely high manufacturing accuracy and therefore is also expensive. Any play between the two sleeves produces optical deterioration because due to the one-sided

engagement of the excenter the inner sleeve has a tendency to tilt relative to the outer sleeve.

SUMMARY OF THE INVENTION

It is, therefore, a general object of the present invention to overcome the aforementioned disadvantages.

More particularly, it is an object of the invention to provide an improved objective holder of the aforedescribed type which enables an exact focus adjustment by a nonrotational displacement move.

Another object of this invention is to provide such an objective holder which is compact in structure and unsensitive to vibrations.

Still another object of this invention is to provide such an improved objective holder which is inexpensive to manufacture.

In keeping with these objects and others which will become apparent hereafter, one feature of the invention resides in the provision of a focussing support having two pairs of juxtaposed walls forming a parallelogram; one pair of the walls being rigid and the other pair being flexible, the outer surface of one of the rigid walls including means for mounting an objective thereon and the inner surface of this one rigid wall being formed with a control groove or bore extending transversely relative to the outer surface, the other rigid wall supporting for rotation a control shaft having an eccentric end portion, the eccentric portion engaging the control bore to swing the pair of flexible walls and thus to displace the one rigid wall during the rotation of the shaft, and means for fixedly mounting the other rigid wall in the optical device.

The advantageous features of this invention result from the application of the principle of a parallel linkage such as used for example in drafting machines, in a mounting support or holder for an objective. Two parallel pairs of walls are lined together into a parallelogram to provide parallel motion of the objective supporting wall at right angles to the film carrier. When this focussing parallel linkage support is die cast as of a suitable synthetic material the manufacture is relatively simple without requiring highly accurate machining and consequently the resulting one-piece objective support of this invention enables the production of high-quality optical devices at reduced costs.

Due to the fact that the objective is displaced by means of an excenter which engages a control groove or bore in the rigid supporting wall of the focussing support, it is possible to rotate the control knob on the shaft of the excenter in both opposite directions without encountering any limit stop. The objective itself during the continuous rotation of the control eccentric performs only a straight reciprocating movement. As a consequence, the optical apparatus equipped with the objective holder of this invention is safeguarded against operational errors and cannot be damaged by improper turning of the focus control knob.

It is also of advantage that to adjust the focus of the objective only minute frictional forces are present since the objective holder operates without any guiding grooves. In spite of this easy control, there is no danger of a self-induced midadjustment of the objective inasmuch as the frictional forces in the bearing of the control shaft are sufficient to hold the objective in any of its adjusted positions. Furthermore, since the objective is held in the desired position without the use of any guiding surfaces, it cannot become jammed by thermal effects on such surfaces when the optical apparatus radi-

ates heat during its operation. By virtue of the fact that the objective performs a straight axial displacement only without any rotational movement to attain its sharp focussing position, it is possible prior to its installation into an optical apparatus which employes assymetrical light beams, to select such a range of the objective surface which exhibits the best optical quality.

As an additional advantage of the objective holder of this invention should be mentioned also the fact that it is insensitive to vibrational effects and requires negligible setting work or expenditures during its installation in the optical apparatus. The construction of the focussing support has a low mass and by virtue of the fact that the whole focussing support can be manufactured exclusively of a suitable plastic material, it has a negligible weight and is therefore suitable particularly for portable optical devices.

In a preferred embodiment of this invention the control shaft is supported for rotation in a bearing sleeve formed in a projection extending from the inner surface of the fixed rigid wall of the support and terminating close to the control groove for the eccentric in the opposite rigid wall carrying the objective. This arrangement has the advantage that the swinging movement of the flexible walls of the support has only a negligible influence on the position of the eccentric. Accordingly, it is only the rotary movement of the eccentric which changes the sharp focus adjustment and not the pendulum-like movement of the flexible walls.

A particularly inexpensive manufacture of the objective holder of this invention will result when, according to another feature of this invention, the entire focussing support is manufactured as a single piece by injection molding of a suitable plastic material. It is also possible to employ in this injection molding process a complementary form having a configuration which eliminates any movable part of the casting die thus further reducing the manufacturing cost and ensuring a long working life.

According to still another feature of this invention, the rigid wall of the focussing support which carries the objective is shaped with a dove-tail guiding groove engaging a correspondingly shaped mounting plate of the objective. In this manner, the objective can be easily exchanged and mounted on the focussing support.

It is also advantageous when an arresting member is provided between the dove-tailed guiding surfaces of the objective in its mounting position. This arresting member determines automatically the working position of the objective and of its supporting plate relative to the dovetailed guide.

According to still another feature of this invention the whole focusing support is made of a material which is elastically deformable. Due to this elastic deformability the distance between the objective and the film carrier in any focussing position is maintained stable inasmuch as the walls exert a small bias against the eccentric and against the control shaft. In this manner any play in the objective holder of this invention is completely eliminated.

The novel features which are considered as characteristic for the invention are set forth in particular in the appended claims. The invention itself, however, both as to its construction and its method of operation, together with additional objects and advantages thereof, will be best understood from the following description of specific embodiments when read in connection with the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** is a sectional top view of a portion of a film reader including the objective holder of this invention;

FIG. **2** is a top view of the adjustable focussing support in the holder of this invention;

FIG. **3** is a side view of the support of FIG. **2**; and

FIG. **4** is another side view of the support of FIG. **2**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring firstly to FIG. **1** there is illustrated a housing **1** of a microfiche film reader having its front wall provided with a screen **4** of a ground glass plate upon which the projected picture is displayed. A control knob **2** on a control shaft **3** for sharp focussing projects beside the screen **4**.

A lateral wall of the housing **1** a portion of which is also illustrated in the drawing, is provided with means for guiding a film frame or casing **5** enclosing a transparent microfiche to be read. By means of nonillustrated levers the film casing is movable in two axial directions. An objective **6** mounted on a focussing support **7**, serves for the projection of the light beam passing through the transparent microfiche. The focussing support **7** includes a mounting base **8** which is fastened to a metal sheet **9** secured to the housing **1** of the optical apparatus.

For the sake of clarity it should be also mentioned that the projection is effected by a light beam transmitted from non-illustrated lamp and reflected by a reflecting mirror **10** through a light condenser **11** which directs a uniform light beam through the transparent image and through the objective **6**. Behind the objective **6** the light is again reflected by a reversing mirror **25** to another nonillustrated mirror from which the projected image is reflected on the screen **4**.

The essential part of the objective holder of this invention is the aforementioned focussing support **7** which is illustrated also in detail in FIGS. **2** to **4**. As seen from FIG. **2**, the focussing support **7** has two pairs of juxtaposed walls **14**, **14'** and **15**, **15'** forming together a parallelogram. Walls **14** and **14'** have a relatively large thickness whereas the other pair of walls **15** and **15'** are reduced in thickness and are therefore flexible. The edge of one rigid wall **14** is integral with a mounting base **18** forming therewith a substantially right angle. This base plate **8** as seen particularly from FIG. **4** is provided with two indentations or recesses **16** and **17** for receiving fastening screws by means of which the whole objective holder is secured to the housing of the microfiche reader. The outer surface of the opposite rigid wall **14'** is formed with a dove-tailed guide **18** for receiving the correspondingly shaped supporting plate **12** of the objective. An arresting member **19** is formed in the wall **14'** to arrest the objective plate **12** in its working position. The inner surface of the rigid wall **14'** is formed with an inwardly projecting block **20** including a control groove **21** extending parallel to the flexible walls **15** and **15'**.

Also, the inner surface of the rigid wall **14** is shaped with an inwardly directed block **22** extending in close proximity to the control groove **21** and defining a through bore **23** directed against the control groove **21** and serving as a bearing sleeve for control shaft **3**. The free end of the shaft **3** projects through the front wall of housing **1** and supports the control knob **2**.

Referring back to FIG. **1**, the inner end of shaft **3** has the form of an eccentric **24** which engages the control

groove **21**. By rotating the control knob **2** and thus the shaft **3**, the periphery of eccentric **24** displaces the block **20** and thus causes a swinging movement of the flexible walls **15** and **15'** and a corresponding movement of the rigid wall **14'** which is displaced parallel to the opposite rigid wall **14**. Due to the fact that flexible walls **15** and **15'** are integrally linked to the stationary rigid walls **14** and **14'**, the latter performs a rectilinear parallel movement which changes the distance of the objective **6** from the film casing **5**. The rigid walls as well as the effective flexible walls **15** and **15'** have the same lengths linked together at right angles. As a consequence, the resulting parallelogram ensures that the wall **14'** is axially displaced at a constant angle relative to the film in the casing.

As mentioned above, the whole focussing support **7** is produced as a single piece preferably by injection molding of a suitable plastic material.

It will be understood that each of the elements described above, or two or more together, may also find a useful application in other types of constructions differing from the types described above.

While the invention has been illustrated and described as embodied in a specific example of the objective holder, it is not intended to be limited to the details shown, since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features that, from the standpoint of prior art, fairly constitute essential characteristics of the generic or specific aspects of this invention.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims:

1. An adjustable objective holder for use in a projecting device, comprising: a focussing support having two pairs of juxtaposed walls forming a parallelogram; one pair of said walls being rigid and the other pair of said walls being flexible; the outer surface of one of said rigid walls including means for mounting an objective thereon and the inner surface of said one rigid wall being formed with a control groove; the other rigid wall supporting for rotation a control shaft having an eccentric end portion, said eccentric portion engaging said control groove to swing said pair of flexible walls and thus to displace along a straight line said one rigid wall during the rotation of said shaft; and means for fixedly mounting said other rigid wall in said device.

2. The objective holder as defined in claim **1** wherein the inner surface of said other rigid wall is formed with a bearing block defining a through bore directed toward the control groove, at least a portion of said through bore forming the bearing sleeve for said control shaft and said bearing sleeve being located in close proximity to said control groove.

3. The objective holder as defined in claim **1** wherein said focussing support is made as a single piece of a plastic material shaped by an injection molding process.

4. The objective holder as defined in claim **1** wherein said mounting means on said outer surface of said one of said rigid walls is a dovetail guide for engaging a correspondingly shaped carrier plate for said objective.

5. The objective holder as defined in claim **4** wherein said dovetail guide includes an arresting member for locking the carrier plate for said objective in a fixed mounting position.

6. The objective holder as defined in claim **1** wherein said focussing support is made of an elastically deformable material for exerting a bias on said eccentric in any position of the latter.

7. The objective holder as defined in claim **1** wherein said means for fixedly mounting includes a mounting base integral with an edge portion of said other rigid wall.

[57] **ABSTRACT**

An optical conversion attachment assembly for objective camera lenses is provided to convert a lens into a monocular optical device. A camera exchangeable lens can be detachably mounted on the barrel of an optical attachment having an erecting prism and an ocular system to vary the diopter power. The optical attachment further provides a device for automatically contacting and holding the diaphragm of the camera exchange lens at a maximum aperture opening.

OPTICAL CONVERSION ASSEMBLY FOR OBJECTIVE CAMERA LENSES

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an optical conversion assembly to convert exchangeable objective lenses of a camera into a monocular optical device such as a telescope, a microscope or a viewer.

2. Description of the Prior Art

The interchangeable lenses that are utilized on high quality still cameras such as 35 mm cameras and movie cameras have developed to a state wherein they have excellent resolving powers from the vicinity of the optical axis of the field of view to the outer circumference. These lenses are frequently coated to prevent reflection losses across a broad wavelength spectrum. The lenses provide highly accurate color reproduction with a minimum of reflection between the lens surfaces and minimum internal reflection in the lens barrel to eliminate any optical flare and ghost images. In many cases, the commercial cost of these wide angle, telephoto, and zoom lenses far exceeds the cost of the camera bodies.

Frequently, both amateur and professional photographers carry a number of exchangeable lenses with their camera to be prepared for various types of shots requiring the different lenses. These lenses can represent a substantial investment and to date have generally found no other substantial application other than being mounted on the camera. There is thus a need in the prior art to permit alternative utilization of these interchangeable lenses outside of the camera photography field.

Cited of general interest for its disclosure of a prism system in a telescope in U.S. Pat. No. 4,030,808.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide an optical attachment which is capable of converting exchangeable objective lenses of cameras into a useful monocular optical device, such as a telescope, a microscope or a viewer.

The optical attachment of the present invention includes a barrel housing having at one end a lens mounting means capable of interfacing with appropriate mounting means on a camera exchangeable lens such as a bayonet mounting arrangement. Means are provided on the optical attachment for automatically contacting and holding the diaphragm of the camera exchangeable lens in a maximum aperture opening. An ocular system is provided including movable lens to permit diopter power adjustment. Mounted within the barrel housing is a prism erecting system for rotating the transmitted image both about a vertical and horizontal axis to provide an erect viewing image.

The foregoing and other objects, features and advantages of the present invention will become more readily apparent from the following description of illustrated embodiments thereof taken in reference with respect to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** discloses an exploded perspective view of the combination of a camera objective lens and the optical conversation assembly of the present invention, and

FIG. **2** discloses a partially schematic cross-sectional view of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical art to make and use the invention and sets forth the best mode contemplated by the inventors of carrying out their invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide an optical conversion assembly capable of being removably mounted on various camera objective lenses to permit their secondary use as a monocular optical device in a relatively economical manner.

The description will now be given of the preferred embodiment of the present invention according to the drawing.

Referring to FIG. **1**, an objective camera exchangeable lens **4** has a camera mounting means **6** which is well known per se, such as a known bayonet flange **6***a* used by the Minolta Camera Co. The exchangeable lens **4** is capable of being mounted on a camera body (not shown) by means of the camera mounting means **6**. Exchangeable lens **4** carries a diaphragm interlocking pin **4***c* which is biased in the direction of arrow (a) so as to stop down an internal diaphragm mechanism to a predetermined aperture size which can be preset by an external diaphragm setting ring member **4***d*. Diaphragm interlocking pin **4***c*, when forcibly moved in a direction opposite to that of arrow (a), increases the aperture size of the diaphragm mechanism, irrespective of the set position of diaphragm setting member **4***d*. Therefore, the diaphragm mechanism is maintained in its fully opened condition as long as diaphragm interlocking pin **4***c* is maintained at an extreme position in the direction opposite to that of arrow (a).

Provided at the front end of an optical conversion attachment assembly **5** is lens mounting means **8**, which is capable of direct coupling to the camera mounting means **6** of exchangeable lens **4**. The lens mounting means **8** firmly secures exchangeable lens **4** to optical assembly **5** to form a monocular optical device, such as a telescope or a microscope. The construction of lens mounting means **8** is identical to the known lens mounting means provided on a camera body for securing an exchangeable lens and includes spaced flange retainer members of a complementary shape and configuration.

When lens mounting means **8** of optical attachment **5** is coupled to camera mounting means **6** of exchangeable lens **4**, the optical attachment **5** is rotated in the direction of arrow (b), the exchangeable lens **4** and optical attachment **5** are firmly connected in place and can then be locked by a locking means (not shown) so that both may not be disconnected from each other. Provided in the vicinity of lens mounting means **8** of optical attachment **5** is a tongue member **9**, which automatically engages diaphragm interlocking pin **4***c* of exchangeable lens **4** when optical attachment **5** and exchangeable lens **4** are coupled to each other in the abovementioned manner so as to move diaphragm interlocking pin **4***c* in the direction opposite to that of arrow (a) and hold the aperture opening to a maximum nonadjustable position.

Referring now to FIG. **2**, internal cylinder **26** is formed integrally with external cylinder **10** and includes two prisms **28** and **30** that comprise a prism erecting system. These prisms are mounted with a slight gap

between their opposing surfaces, B1 and B2. The prisms **28** and **30** can be Schmidt or Pechan prisms having a light incident surface A and a light exiting surface D, both of which cross the optical axis l_1 at a substantially right angle (90°). Light incident on prism **28** from light incident surface A is reflected onto opposing surface B_1, then reflected on side surface C and transmitted through opposing surface B_1. The light is then incident upon surface B_2 of prism **30**. After being reflected on light exiting surface D and reflected on roof surface E, the light is reflected on opposing surface B_2 and is transmitted rearward through the light exiting surface D as a result of this prism system. The top and bottom of an image are inverted through these five reflections of light and the left and right of the image is also inverted by roof surface E of prism **30**. That is to say, the image passing through prisms **28** and **30** is inverted vertically and horizontally.

Semicircular cylindrical prism support member **34** is formed integrally with an ocular cylinder **32** which is located inside internal cylinder **26** of external cylinder **10** to support prisms **28** and **30**. In more detail, prisms **28** and **30** are fixed by a leaf spring (not shown) inside the prism support member **34** and they are further pressed against the front end of ocular cylinder **32** by holder **36** which is fixed on the tip of prism support member **34** so that they may not move along the optical axis, l. Holder **36** has a circular opening **36***a*, which is adjacent the rear surface of a lens system of exchangeable lens **4**. Ocular cylinder **32** is screw fastened through threads **32***a* at its front end to external cylinder **10**. Provided inside ocular cylinder **32** is a sliding internal cylinder **38**, which is slidable along the optical axis. Mounted inside sliding internal cylinder **38** are a lens **40**, cemented doublet **44** and lens **48** which are arranged in that order from the front at predetermined intervals set by spacers **42** and **46** to comprise the ocular system. Furthermore, ocular holding ring **50** is screwed through thread **38***a* to the front end of sliding internal cylinder **38**. Lens **40**, cemented doublet **44** and lens **48** making up the ocular system are fixed by ocular holding ring **50** as it presses against flange **38***c* formed at the other opening end of sliding internal cylinder **38**. Pin **52**, carried by sliding internal cylinder **38**, is fitted into cam groove **54***a* formed on the internal surface of diopter adjusting ring **54**. Pin **52** further extends through groove **32***b* formed on ocular cylinder **32** and extending elongated along the optical axis.

Diopter adjusting ring **54** is rotatably engaged with the circumference of ocular cylinder **32** and is restricted in axial movement by fixed ring **56** screwed to the rear end of ocular cylinder **32**. When diopter adjusting ring **54** is rotated, pin **52**, carried by sliding internal cylinder **38**, is forced by cam groove **54***a* and guided by groove **32***b* to shift along the optical axis. As a result, the sliding internal cylinder **38** and the ocular system consisting of lens **40**, cemented doublet **44** and lens **48** are moved, as a whole, along the optical axis for dioptric adjustment. Formed circumferentially on fixed ring **56** is an annular groove **56***b* which is fitted with a rubber ocular hood **58**.

Provided on the circumference of external cylinder **10** is an index **60** for use in mounting an exchangeable lens and a lock release button **62** for removing the exchangeable lens.

With the above construction, optical attachment **5** and exchangeable lens **4** can be matched so that the indices **60** and **4***e* may coincide with each other, and optical attachment **5** is rotated in the direction of arrow b to be firmly coupled with an exchangeable lens **4**. During this connection, the diaphragm interlocking pin **4***c* of exchangeable lens **4** is moved by tongue member **9** in the direction opposite to that of arrow (a), whereby the diaphragm mechanism of exchangeable lens **4** is maintained in its fully opened condition. Then, diopter adjustment is performed by rotating diopter adjusting ring **54**. While observing through the ocular section at the rear, distance setting ring **4***b* of exchangeable lens **4** is rotated, whereby the real image of an object erected vertically and horizontally appears at the rear of light projecting surface D of prism **30**. Looking at an object through the ocular, an enlarged image erected vertically and horizontally appears.

For example, when mounting an exchangeable lens of focal length 50 mm for use as a standard lens for 35 mm single lens reflex cameras, it is possible to provide an ocular system such as a telescope with 5X to 10X magnification. Furthermore, by mounting zoom lenses of focal length 100 mm to 200 mm on the optical attachment it is possible to provide telescopes with a higher magnification. Thus, even when different exchangeable lenses are used, the distance is constant from the mounting surface to the focal plane of various types of exchangeable lenses capable of mounting on a single type of camera. Real images transmitted through the exchangeable lenses are always in focus at the same position and can be observed by the same ocular. Therefore, the optical attachment can be used for a variety of exchangeable lenses and produces sharp images at all times with any type of exchangeable lenses.

Furthermore, when an intermediate ring or bellows is provided between an exchangeable lens and the optical attachment for closeups, the optical attachment can be used as a microscope of 20X to 100X magnification. Such a microscope, contrary to conventional ones, has a wide field of view and is capable of producing an erect image.

The use of the above described optical attachment makes it possible to observe the magnification and image formation of exchangeable lenses without using a camera. In this case, images are visible without being affected by a focal plane or the like of a camera, making it possible to easily see the difference of angle of views of exchangeable lenses and also to use the optical attachment as a viewer for comparing exchangeable lenses at camera shops. It should be understood that when the optical attachment is used in the above manner, a field-of-view frame corresponding to a field of an object to be photographed is provided in the vicinity of the focal plane of an exchangeable lens so as to obtain a clearer picture angle of the exchangeable lens. The prism erecting system of the above optical attachment is not limited only to the so-called Schmidt type, but may be of any prism systems, including the Porro, Abbe, Springer and Hensoldt type in which a light incident surface and a light projecting surface are substantially normal to the optical axis of a mounted exchangeable lens. In addition, the magnification of an ocular system is not limited to that mentioned above.

A strap mounted means and a tripod mounting means may be provided on the circumferences of the external cylinder **10** and ocular cylinder **32** to facilitate carrying and use.

The above optical attachment is not limited in application to exchangeable lenses for use in single lens reflex cameras. Any exchangeable lens for lens exchangeable cameras, regardless of whether it is a still or movie

camera, may be provided with an appropriate optical attachment having lens mounting means, a prism erecting system and a predetermined ocular section.

The optical attachment in accordance with the present invention comprises a lens mounting means for mounting an exchangeable lens, a prism erecting system having a light incident surface and a light projecting surface which are substantially on the optical axis of the exchangeable lens mounted on the lens mounting means. The prism system inverts the top, bottom, left and right of a real image through the exchangeable lens, and an ocular is provided at the rear of the prism erecting system. When used, the optical attachment is capable of converting an exchangeable lens for a camera such as an objective lens into a telescope, whereby a high performance telescope can be provided. Such a telesco pe is free to have varying magnifications by changing exchangeable lenses. With an intermediate or bellows for closeups provided between the optical attachment and an exchangeable lens, the optical attachment can further be used as a microscope. The microscope thus obtained is wide in field of view to produce high performance with erect images. In addition, such a telescope or a microscope may be used by looking at any desired object to be observed, resulting in great convenience of use. Yet, the optical attachment is compact, lightweight and very convenient to carry.

It is to be further understood that various modifications of the generic concepts of this invention are possible without departing from its spirit and accordingly the scope of the present invention should be determined solely from the following claims.

What is claimed is:

1. An optical attachment adapted for use with an objective camera exchangeable lens which includes a diaphragm interlocking member movable between a first position to maximize an aperture size of a diaphragm mechanism and a second position to minimize the aperture size, said diaphragm interlocking member being biased toward said second position, the optical attachment capable of providing a view of an object without the necessity of a camera body comprising:

lens mounting means on which said camera exchangeable lens can be detachably mounted, said lens mounting means having an axis capable of alignment with an optical axis of a camera exchangeable lens when mounted thereon;

a prism erecting system for rotating an image about vertical and horizontal axes, said prism erecting system provided on said axis and including a light entrance surface perpendicular to said axis and a light emitting surface in parallel with said light entrance surface;

retaining means for retaining said diaphragm interlocking member in its first position when said camera exchangeable lens is operatively connected, and

an occular system provided in the light path of the light emitted from said light emitting surface.

2. An optical attachment as set forth in claim 1 further comprising a dioptric adjusting assembly including means holding at least a part of said ocular system for axial movement thereof and externally accessible means interconnected to said part of ocular system for moving the same.

3. An optical attachment as set forth in claim 1 wherein said lens mounting means includes a plurality of flange retainer members of a complementary shape and configuration to lockingly interface with a bayonet flange.

4. An optical attachment as set forth in claim 1 wherein said prism erecting system is configured to position both the light entrance surface and the light emitting surface on a longitudinal axis substantially coincident with the optical axis.

5. An optical attachment as set forth in claim 1 wherein the ocular system includes a lens assembly capable of substantial magnification of the object image of the objective camera lens without substantial increase in the image aberrations to provide a telescope effect.

6. An optical attachment adapted for use with a camera exchangeable lens comprising:

lens mounting means on which said camera exchangeable lens can be detachably mounted, said lens mounting means having an axis capable of alignment with an optical axis of said camera exchangeable lens when mounted thereon and means for automatically contacting and holding a diaphragm of the camera exchangeable lens to a non-adjustable maximum aperture opening;

an ocular system having an optical axis in parallel with said axis of lens mounting means; and

a prism erecting system for inverting an image both in horizontal and vertical directions, said prism erecting system being provided between said lens mounting means and said ocular system and having an optical axis connected to said axis of lens mounting means and said optical axis of ocular system.

7. A combination of a camera objective exchangeable lens and an optical attachment device for use as a monocular optical device comprising:

a camera exchangeable lens with a diaphragm detachably mountable on a camera for use as an objective, said camera exchangeable lens having an optical axis and a diaphragm interlocking member movable between a first position to maximize an aperture size of a diaphragm mechanism and a second position to minimize the aperture size, said diaphragm interlocking member being biased toward said second position; and an optical attachment detachably mounted on said camera exchangeable lens, said optical attachment including an ocular system having an optical axis in parallel with said optical axis of said camera exchangeable lens and a prism erecting system for inverting an image both in horizontal and vertical directions, said prism erecting system being provided between said camera exchangeable lens and said ocular system and having an optical axis connected to said axis of both of said camera exchangeable lens and ocular system, said optical attachment includes retaining means for retaining said diaphragm interlocking member in its first position.

8. The device as set forth in claim 7, wherein said optical attachment further includes a dioptric adjusting device including means holding at least a part of said ocular system for axial movement thereof and externally accessible means interconnected to said part of ocular system for moving the same.

[57] **ABSTRACT**

A telephoto objective comprising a stationary convergent front lens group and a rear lens group which includes a lens member axially movable for focusing behind a front lens member which remains stationary during focusing, and an operating mechanism therefor. In order to achieve excellent stability of the various aberrations and particularly spherical aberration throughout the focusing range, compensation for the residual aberrations introduced by the front lens group is concentrated in the stationary front member of the rear lens group, while the movable rear member is configured to provide minimized variation of aberrations by constructing these two members as being divergent with their front surfaces convex to the object. In this particular arrangement, the movable member is moved toward the image plane as the objective is focused from the position for an object at infinity to the position for a close object.

TELEPHOTO OBJECTIVE

Matter enclosed in heavy brackets [ ] appears in the original patent but forms no part of this reissue specification; matter printed in italics indicates the additions made by reissue.

BACKGROUND OF THE INVENTION

This invention relates to optical objectives for photographic devices, and more particularly to a telephoto objective comprising a stationary front lens group and a rear lens group which includes a member axially movable to focus while still maintaining improved stabilization of the aberrations throughout the focusing range.

In general, the focusing of an optical objective is effected by axially moving the objective bodily with reference to the image plane. But this may be otherwise achieved by axial movement of a part of the objective, for example, either the front, or the rear lens group thereof with reference to the other part which remains stationary during focusing. In telephoto objectives, if made bodily movable for focusing purposes, the amount of movement of the objective throughout the focusing range tends to increase, and this in turn calls for increases in the weight and bulk of the objective and the driving torque of its focusing mechanism as well as in the production cost thereof, thus it being made more difficult to keep the weight and bulk of the complete objective including its mechanical mounting and focusing mechanism within easily manageable proportion.

With a telephoto objective having the provision for focusing made at a rear part of the lens system, it is possible to minimize the movement of the focusing part and to employ a focusing mechanism of small size and weaker driving torque, because the focusing part comprises only a fraction of the weight and bulk of the complete objective, thereby giving an advantage of facilitating high-speed focus adjustment of the objective. Another advantage deriving from the selection of the rear lens group of the objective for employment as the movable part for focusing purposes is that the front lens group which is of a relatively large weight and bulk may be supported in fixedly secured relation with a camera body to minimize the probability of producing a jiggle or oscillation of the image at the focal plane by small accidental motions of the objective and camera assembly which is otherwise encountered particularly when the objective is telephoto in nature. However, this system has a disadvantage that variation of the aberration particularly variation of the spherical aberration due to the movement of the lens is large, and the image forming ability is low. Further, in order for an objective to embody an advantageously small overall length, a convergent lens group is usually selected for employment as the front part thereof in combination with a divergent rear lens group having design parameters determined so as to cancell out the residual spherical aberration introduced by the front lens group in a focusing position for an object at infinity. However, as the objective is focused from this position to a position for a close object, the axial separation between the front and rear lens groups is increased with decrease in the hight of incidence of an axial ray upon the rear lens group, so that occurrence of the positive spherical aberration is less, while varying the value of the spherical aberration to a remarkable extent. In this respect, it is well known that this arrangement is disadvantageous

for stabilization of the image aberrations throughout the focusing range.

SUMMARY OF THE INVENTION

The present invention has for a general object to provide the above-mentioned advantages in the case of a telephoto objective having the provision for focusing made at the rear part thereof, while still proving improved stabilization of the aberrations throughout the focusing range.

A concomitant object of the invention is to provide a focusing mechanism for use with an telephoto objective of the character described which assists in high-speed focus adjustment thereof.

In order to avoid the above defect in the focusing system by the movement of rear lens group, it is necessary to lessen the occurrence of the aberration particularly the spherical aberration in the rear lens group, but if the aberration is lessened in this way the spherical aberration of the whole lens system is remarkably undercorrection.

The telephoto objective of the invention is characterized in comprising a convergent front lens group and a rear lens group which includes a lens member axially movable to effect focusing in front of, or behind a lens member which remains stationary during focusing. This particular arrangement gives rise to the possibility of cancelling out the residual aberrations introduced by the convergent front lens group by suitable design of the stationary lens member of the rear lens group and gives high standard of stabilization of the various aberrations and particularly spherical aberration throughout the focusing range provided that the movable member is designed to give a good standard of stabilization of the aberrations throughout the focusing range.

Further, a good compromise has been achieved between the requirements of providing a large range of focusing adjustments with relatively small axial translations of the movable member of the rear lens group and of providing a distribution of powers between the stationary and movable parts of the objective which effects achievement of a high standard of aberration correction.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a diagrammatic view of an example of a telephoto objective according to an embodiment of the invention in two focusing positions.

FIG. **2** is a similar view of another example of the embodiment of the invention.

FIGS. **3a–3c** is a graphic representation of aberration achieved in the example of FIG. **1** when focused for an infinite object distance.

FIGS. **4a–4c** is a similar representation when focused for an object distance of 1,000 millimeters.

FIGS. **5a–5c** is a graphic representation of aberration achieved in the example of FIG. **2** when focused for an infinite object distance.

FIGS. **6a–6c** is a similar representation when focused for an object distance of 1,000 millimeters.

FIG. **7** is an axial sectional view of a barrel type mechanical mounting with a focusing mechanism adapted for use with the objective of the invention.

FIG. **8** is a similar view with a modification of the focusing mechanism.

FIG. 9 is a fragmentary sectional view of a focus-preselecting device in the focusing mechanism of FIGS. 7 or 8.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIGS. 1 and 2, there are shown two specific examples of a preferred embodiment of the invention as comprising a front lens group A which has a positive, power and remains stationary during focusing, and a rear lens group which has a negative power and is divided into two parts B and C, the rear part C being made axially movable to effect focusing to suit differing object distances, while the front part B remains stationary during focusing. The stationary part B consists of a negative meniscus singlet lens member in the instance of FIG. 1, or of a negative meniscus doublet lens member in the instance of FIG. 2, with the first refracting surface counting from the front convex to the front, and with the rearmost surface having a radius of curvature which is smallest among all of the surfaces of member B. The movable rear part C is constructed from a negative meniscus doublet lens member with the first surface convex to the front, and with the rearmost surface having a radius of curvature which is smallest among all the surfaces of member C. The absolute focal length of member B is larger than that of member C. A diaphragm D which is stationary is located behind movable member C at a distance to permit the entire range of focusing movement thereof.

As the objective of FIGS. 1 or 2 is focused from the position C marked in solid line for an object at infinity to the position C' marked in broken line for a close object, movable member C progressively approaches the focal plane FP through the space of a distance Δx as defined by the following formula

$$\Delta x = \frac{-2}{B\left(1+\sqrt{1-\frac{4A}{B^2}}\right)}$$

wherein

$$A = \frac{1}{F}\,\frac{1}{Fc}\left(\frac{S}{Ff}+1\right)$$

$$B = \frac{1}{Ff}\left(\frac{S_1}{Ff}+1\right)-\frac{1}{F}\left(\frac{S_1-O_1}{F}+1\right)$$

where

S_1 is the object distance as measuring from the vertex of the first refracting surface of the objective;

F is the focal length of the complete objective when focused for an infinitely distance object;

Ff is the focal length of the combined group A and member B;

Fc is the focal length of the movable member C; O_1 is the distance from the vertex of the first refractings surface to the primary principal point of the complete object; and

Δx when measured in a direction to the focal plane takes a plus sign.

In order to facilitate the solution of aberrational problems, it is preferred to specify the characteristics of the members B and C by the following relationships:

$$0.4F<|FC|<0.9F;Fc<0 \quad (1)$$

$$0.15F<Rc<0.25F \quad (2)$$

$$0.05<F(Fcv\cdot Vcv)+f/(Fcc\cdot Vcc)<0.05 \quad (3)$$

$$0.05F<Rb<0.15F \quad (4)$$

wherein

Rc is the radius of curvature of the rearmost surface of the member C;

Rb is the radius of curvature of the rearmost surface of the member B;

Fcv is the focal length of the positive lens element of the member C;

Vcv is the Abbe's number value for the material of the positive lens element of the member C

Fcc is the focal length of the negative lens element of the member C;

Vcc is the Abbe's number value for the material of the negative lens element of the member C.

Condition (1) assists toward achievement of a good compromise between the requirements of providing a large range of focusing adjustment with relatively small axial movement of the movable member C and of providing excellent stabilization of the aberrations throughout the focusing range. When the power of member C is otherwise increased, it is made rapidly more difficult to achieve the desired high standard of aberration correction although the axial translation of member C may be decreased to obtain an equivalent focusing effect. Conversely, the use of a lens member having a power smaller than that corresponding to the upper limit of condition (1) as the focusing member requires a focusing mechanism of increased size due to the increased axial translations of the focusing member.

Condition (2) assists in minimizing the residual aberrations and particularly spherical aberration introduced by the focusing member C to provide a good standard of stabilization of the aberrations throughout the focusing range.

Condition (3) assists in the stabilization with focusing of chromatic aberrations.

The use of a lens member having the parameters within the ranges specified above as the focusing member C results in somewhat under-corrections of the spherical aberration, coma and astigmatism of the complete objective. In order to preserve a good state of correction of the image aberrations, the stationary lens member B of the rear lens group must be designed according to condition (4) to provide correspondingly over-corrected values of the above-identified aberrations.

The specific examples of a telephoto objective of the invention as illustrated in FIGS. 1 and 2 may be constructed in accordance with the numerical data given in Tables 1 and 3 below respectively, in which R_1, R_2 . . . designate the radii of curvature of the individual surfaces of the objective counting from the front, the positive sign indicating that the surface is convex to the front and the negative sign that it is concave thereto, d_1, d_2 . . . designate the axial separations between successive refracting surfaces of the objective, N_1, N_2 . . . designate the refractive indices for the spectral d line of sodium of the materials from which the various lens elements of the objective are made, and V_1, V_2 . . . designate the Abbe numbers of the materials.

It will be appreciated from the foregoing description that, with a telephoto objective consisting of a convergent front lens group and a divergent rear lens group, the present invention provides a two part rear lens group, only one part of which is axially movable for focussing purposes, thereby giving rise to the possibility of achieving a high standard of aberration stabilization throughout the range of focussing movement. Therefore, by comparison with a conventional telephoto objective which is made bodily movable for focussing, or which has a front lens group movable for focussing, the objective of the invention is improved with respect to the focussing manupulation owing to the decreased weight and bulk of the complete objective, which will in turn reduce the probability of producing an oscilation of the image at the focal plane when it is used in association with a hand-held camera. On the other hand, by comparison with a conventional telephoto objective having a rear lens group which made bodily movable for focussing, the objective of the invention is remarkably improved with respect to the imaging performance owing to the stationary part of the rear lens group which is designed to provide improved stabilization of the various aberrations throughout the focussing range. It is to be noted that the present invention is not limited to use in the construction of three-component telephoto objective described and is useful to facilitate the design of the focussing member for any telephoto lens including additional lens components of almost zero powers located in front of, or behind the front part B, or behind the rear part C of the rear lens group, and that further assistance in achieving a higher standard of correction of the image aberrations can be obtained if an additional component which remains stationary during focussing is employed for arrangement between the front and rear lens groups.

Referring now to FIG. 7, there is shown a lens mount with a cam-operated focussing mechanism adapted for use with the telephoto objective of the character described, where L_1 and L_2 designate the front and rear lens groups of the objective respectively, and L_{21} and L_{22} designate the stationary front and movable rear parts of the rear lens groups L_2 respectively. This lens mount is connected to a single lens reflex camera, not shown, by an adapter **2** whose rear end constitutes a bayonet coupling engaging the camera housing. Rigidly connected to adapter **2** is a barrel **1** at one end thereof, the opposite end portion of which has a guide barrel **3** fixedly secured thereto and provided with a longitudinally elongated guiding slot **3a**. Mounted within guide barrel **3** is a slidable sleeve **4** carrying the movable lens member L_{22}. The sleeve **4** can be moved longitudinally but can not be rotated with reference to barrel **3**, as it is

prevented from rotating by a pin **6** outwardly radially extending from the slidable sleeve **4** and provided with a roller rotatable thereabout in the guiding slot **3a**. The roller **7** projects beyond the guiding slot **3a** and engages with a herical camming groove **5a** formed in the inner surface of a focus adjusting sleeve **5** which is rotatably mounted on guide barrel **3**. The parts, **3a**, **5**, **5a**, **6** and **7** constitutes the above mentioned camo perated focusing mechanism. Rigidly coupled to guide barrel **3** is a tubular extension **8** carrying the front lens group L_1 and the front part L_{21} of the rear lens group L_2 mounted therein in fixed relation to each other and to the extension **8**. The lens mount has a diaphgram device **10** mounted therein at a location behind the movable lens member L_{22}. The diaphragm device **10** is provided with a control lever **9**, and a presetting lever **11** cooperating with a diaphgram adjusting ring **12** rotatably mounted on barrel **1**. The control lever **9** serves to adjust the diaphragm device **10** to a preselected setting in response to an actuation of a camera release member. The presetting lever **11** serves to adjust the position of a diaphragm blade-operating cam member **13** in accordance with the preselected diaphragm value by the ring **12**, and also to transmit the diaphragm information to a diaphragm control mechanism not shown in the camera housing in response to a rotation of ring **12**. A filter being mounted in a filter holder **14** which is detachably mounted behind the diaphragm device **10** in the barrel **1**. The lens mount is further provided with a support member **15** having a nut formed therein for engagement with a bolt of a tripod not shown.

The operation of the focussing mechanism of FIG. **7** in connection with the diaphragm device **10** which constitutes a part of the exposure control apparatus of the camera. In order to make an exposure in the diaphragm preselection automatic exposure range, the operator turns the ring **12** to select a desired diaphragm value, thereby the position of the cam member **13** is adjusted through the presetting lever **11**. At the same time, the diaphragm information is introduced to the exposure control apparatus in the camera through the presetting lever **11**. On the other hand, when the camera is switched to the shutter preselection automatic exposure range, the position of the cam member **13** is adjusted in accordance with a computed diaphragm value through the presetting lever **11**.

In focussing the objective, the operator turns the rotary sleeve **5**, thereby the roller **7** is driven for movement along the guiding slot **3a** through the roller **7** and camming groove **5a** connection, causing axial translation of the slidable sleeve **4** with the lens member L_2 therein. What object the objective has been focussed for is recognizable either by the angular position of sleever **5**, or by looking through the viewfinder in which an image of the corresponding object is formed in sharpest focus. Next, the operator may depress the shutter release button not shown, thereby the diaphragm device **10** is first operated to the preselected setting through the control lever **9**, and thereafter the shutter mechanism is actuated to initiate an exposure.

The filter holder **14** is removably attached to the lens barrel so that various filters may be interchanged. When the filter is not used, it is desirable to use a transparent plate to adjust the optical path length.

FIG. **8** shows a modification of the focussing mechanism of FIG. **7** with employment of a longitudinally slidable focus-adjusting sleeve **51** in place of the rotary sleeve **5** of FIG. **7**. The sleeve **51** is fixedly connected to a slidable sleeve **52** carrying the movable lens member L_{22} through a pin **54** extending through a longitudinally elongated guiding slot **53b** provided in the guide barrel **53** corresponding to the guide barrel **3** of FIG. **7**. In order to define the range of possible focussing movements of the lens member L_{22}, there is provided a longitudinal groove **53a** formed in the outer surface of guide barrel **53** for engagement with a pin **55** internally radially extending from the focus adjusting sleeve **51**. In focussing the objective, the operator moves the external sleeve **51** to effect axial translation of the lens member L_{22}, as the internal sleeve **52** is guided through the pin **54** and guiding slot **53b** connection.

FIG. **9** shows a focussing position preselecting device particularly adapted for association with the focussing mechanism of FIG. **7**. The device comprises a pair of radially grooves recesses **101a** formed at the ends of a focus adjusting sleeve **101** corresponding to the sleeve **5** of FIG. **7** in longitudinal alignment with each other, a pair of click stop balls **103** which are biased by respective springs **104** in the opposite directions to each other for normal engagement with the respective recesses **101a**, and a pair of focus presetting rings **102** rotatably mounted on the guide barrel corresponding to the part **3** of FIG. **7**. The rings **102** each has a hole longitudinally bored therein for the mounting of ball **103** and spring **104**, and are provided with respective fasteners having knobs **105**. In operating the device, the rings **102** are turned as a unit to place the reaction points thereof in registry with a graduation representing a desired object distance for which the objective is to be focussed, and then are secured in position fixed to the guide barrel by means of the operated knobs **105**. With this arrangement, when the focus adjusting sleeve **101** is turned to a position where the recesses **101a** engage with balls **103**, the desired focussing effect is automatically obtained.

It will be appreciated form FIGS. **7**, **8** and **9** that the present invention provides a focussing mechanism of simple construction which may be incorporated in the lens mount for the telephoto objective of the character described at a location close to the center of the physical length of the complete objective including the lens mount and, in some cases, of the center of gravity of the objective and camera assembly. Such a central location of the focussing mechanism permits easy management procedures for high speed smooth focus adjustments of the objective, while holding the assembly by hand, and accordingly faciliates to prevent the production of an oscillation of the image at the film plane which would be otherwise introduced by the small accidental motions of the assembly owing to the difficult manupulation thereof and the necessity of large driving torque in operation of focussing mechanism. Furthermore, the constructions of the telephoto objective of the character described and the focussing mechanism therefor are advantageous for the provision of focussing down to a shorter object distance.

What is claimed is:

1. A telephoto objective of high speed adjustable focus comprising a front lens group which has a positive refracting power and remains stationary during focussing, and a rear lens group which is divided into two parts, of which one part is axially movable to effect focussing to suit differing object distances, wherein said movable part of said rear lens being located behind the other part which is stationary during focussing and wherein the characteristics of the various lens elements of said front and rear lens groups and their spatial rela-

tionships to each other are substantially of the proportions indicated by the numerical data in the following table, in which R designates the radii of curvature of the refracting surfaces identified by the corresponding subscript numerals and numbered from the front to the rear of the objective, the positive sign indicating that the surface is convex to the front and the negative sign that it is concave thereto, D designates the axial separations between successive refracting surfaces of the objective being numbered from the front to the rear; N designates the refractive indices for the spectral D line of sodium of the materials of the elements being numbered from the front to the rear; and ν designates the Abbe numbers of the materials:

Distance between surface R_1 and the focal plane: 80.01				
R_1 =	68.8306	d_1 = 3.625	N_1 = 1.48749	ν_1 = 70.1

Object distance from the focal plane	Focal length of the complete objective	Variable axial air separation (d_{10})
Infinity	100.00	2.250
−1,000	93.73	10.208

3. A telephoto objective of high speed adjustable focus comprising:

a front lens group which has a positive refracting power and remains stationary during focussing; and

a rear lens group having a negative refracting power and composed of a stationary sub-group and at least one movable sub-group, said movable sub-group having a negative refracting power, a frontmost surface of which has a convex face toward the object, said movable sub-group being moved on the optical axis toward an image so as to cause the telephoto object to focus an object at a near distance from its focussing on an object at a far distance.

4. A telephoto objective according to claim 3, in which said stationary sub-group is arranged nearer the object than said movable sub-group.

5. A telephoto objective according to claim 3, in which said stationary sub-group has a negative refractory power and its frontmost surface is convex toward the object.

6. A telephoto objective according to claim 5, in which said stationary sub-group is a negative meniscus lens.

7. A telephoto objective according to claim 5, in which said stationary sub-group comprises a positive meniscus lens and a negative meniscus lens arranged in the written order.

8. A telephoto objective according to claim 3, wherein the absolute focal length of said stationary sub-group is larger than that of said movable sub-group.

9. A telephoto objective according to claim 8, in which said stationary sub-group comprises a positive meniscus lens and a negative meniscus lens arranged in the written order.

10. A telephoto objective according to claim 3, in which said front lens group comprises a positive lens, a negative lens and a positive lens.

11. A telephoto objective according to claim 10, in which said positive lenses is a biconvex lens, and said negative lens, is a negative meniscus lens having its concave face toward the object.

12. A telephoto objective of high speed adjustable focus comprising:

a primary lens group which comprises at least three lenses, has a positive refracting power and is stationary at a constant distance from the focal plane;

a middle lens group which is on the image side axially apart from said primary lens group and has a negative refracting power and front lens-surface of which group faces toward the object; and

a rearmost lens group which is first behind said middle lens group and has a negative refracting power, and comprises at least one positive lens and at least one negative lens, said rearmost lens group moving axially to the image side when refocussing is done from an object far from the object to an object near the object.

13. A telephoto objective according to claim 12, in which said primary lens group comprises a biconvex lens, a negative lens having the concave face toward the object and a positive lens arranged in the written order from the object side.

14. A telephoto objective according to claim 12, in which said middle lens group comprises a negative meniscus lens.

15. A telephoto objective according to claim 12, in which said rearmost lens group comprises a positive

meniscus lens and a negative lens arranged in the written order from the object side.

16. A telephoto objective of high speed adjustable focus comprising a front lens group which has a positive refracting power and remains stationary during focussing, and a rear lens group which is positioned on the image side axially apart from said front lens group and has a negative refracting power, said rear lens group being divided into two parts of which one part is axially movable to effect focussing to suit differing object distance, and the other part has a negative refracting power and stationary during focussing.

17. A telephoto objective according to claim **16**, wherein said movable part of said rear lens group is located behind the other part which is stationary during focussing.

18. A telephoto objective according to claim **16**, wherein said movable part of said rear lens group is located behind the other part which is stationary during focussing and composed of a plurality of lenses.

19. A telephoto objective according to claim **18**, wherein said movable lens part of said rear lens group has a rearmost surface concave to the rear, and said rearmost surface has a radius of curvature which is smallest among all the surfaces of said movable part.

20. A telephoto objective according to claim **16**, wherein said stationary part of said rear lens group has a frontmost surface convex to the front.

21. A telephoto objective according to claim **20**, wherein said stationary part has a rearmost surface concave to the rear, and said rearmost surface has a radius of curvature which is smallest among all the surfaces of the stationary part.

22. A telephoto objective according to claim **16**, wherein the movable part of said rear lens group has a negative refracting power, and the absolute focal length of the stationary part of said rear lens group is larger than that of said movable part, wherein said movable part is moved on the optical axis toward the image so as to cause the objective to focus an object at near distance from its focusing on an object at infinite distance.

23. A telephoto objective of high speed adjustable focus comprising: a front lens group which has a positive power and remains stationary during focusing, and a rear lens group which is positioned on the image side of said front lens group and has a negative power, said rear lens group consisting of at least one stationary sub-group and a movable sub-group, said movable sub-group having a negative power and being axially movable to focus, wherein the absolute focal length of said stationary sub-group is larger than that of said movable sub-group.

24. A telephoto objective according to claim 23, wherein the diameter of each component lens of said front lens group is larger than that of the rear lens.

25. A telephoto objective according to claim 23, wherein the movable sub-group includes a positive lens for compensating as spherical aberration of said movable sub-group and a negative lens.

[57] **ABSTRACT**

An improved tesser type objective lens system having a rear aperture stop with a relatively wide field angle of about 60° and an F-number of about F 2.8 is provided. The thickness of the second negative lens in the lens system is increased relative to the total axial distance of the lens system which permits the reduction of the Petzval sum while maintaining a balance correction of spherical aberration and coma.

TESSER TYPE OBJECTIVE LENS SYSTEM HAVING A REAR APERTURE STOP

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a tesser type lens system having an aperture stop located at the rear of the lens system and more particularly to a lens system of this type having a relatively wide field angle of about 60° and an F-number of about F. 2.8.

2. Description of the Prior Art

The prior art is quite familiar with various forms of tesser type lens systems having a rear aperture stop. These photographic objectives are frequently used in compact cameras, for example, to facilitate the incorporation of a shutter mechanism into the camera body. Numerous examples of prior art literature exist disclosing a tesser type lens system having an aperture stop located at the rear of the lens system so that the aperture stop can be controlled by a relatively simple mechanism. The prior art has recognized that it is difficult to effectively correct astigmatism and field curvature in the zonal area of the image if the field angle is desired to be increased to 60°.

Although numerous examples of prior art references indicate that this is a close art, there is still room for improvement in correcting abberations such as astigmatism, field curvature and coma in the zonal to marginal areas of the image.

Examples of relevant prior art can be found in U.S. Pat. No. 3,615,126 and U.S. Pat. No. 3,895,857. Additional tesser type objective lens systems having rear aperture stops are disclosed in Japanese Utility Model Publication No. 42-22354, Japanese Patent Publications Nos. 50-3163 and 51-10092 and Japanese Patent Application Laid-Open to Public Inspection No. 49-38620.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide an improved tesser type lens system having a rear aperture stop wherein aberrations associated with a field angle of approximately 60° can be favorably corrected.

The tesser type objective lens system includes from image to object side a first positive meniscus lens, a second negative lens, and a third positive doublet consisting of a positive element and a negative element cemented to the positive element on its image side. Finally an aperture stop is located at the image side of the doublet. This lens system fulfills the following conditions:

(1)	0.3	<	$D_3/(D_1 + D_2 + D_3)$	<0.45
(2)	0.05F	<	D_3	<0.08F
(3)	0.03F	<	D_4	<0.045F
(4)	−2.4F	<	R_3	<−1.6F
(5)	0.25F	<	R_6	<0.33F
(6)	0.13	<	N_4-N_3	<0.22
(7)	$(N_1 + N_4)/2 > 1.75$			

wherein:

F represents the focal length of the entire lens system;

D_i represents the i-th axial distance from the object side;

R_i represents the radius of curvature of the i-th surface from the object side; and

N_i represents the refractive index of the i-th glass material from the object side with respect to the ray of d-line.

The features of the present invention, which are believed to be novel, are set forth with particularity in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may be best understood by reference to the following description, taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** represents a cross sectional view of a first embodiment of the present invention;

FIGS. **2***a*, **2***b*, **2***c* and **2***e* represent graphic plots of various aberrations of the first embodiment;

FIG. **3** represents a cross sectional view of a second embodiment of the present invention;

FIGS. **4***a*, **4***b*, **4***c*, **4***d* and **4***e* represent graphic plots of various aberrations of the second embodiment;

FIG. **5** represents a cross sectional view of a third embodiment of the present invention; and

FIGS. **6***a*, **6***b*, **6***c*, **6***d* and **6***e* represent graphic plots of various aberrations of the third embodiment.

BRIEF DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical art to make and use the invention and sets forth the best mode contemplated by the inventor for carrying out his invention. Various modifications however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide an improved tesser type objective lens system having a rear aperture stop with favorable corrections of various higher order aberrations.

The derivation of the formulae and the relation set forth herein can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromise balance of acceptable aberrations in a relatively easily manufactured and economical lens system for utilization, for example, with a camera.

Various examples of the present invention will hereinafter be described with reference to tabulated physical and optical characteristics in various Tables. The parameters of the lens elements of the present invention are listed in separate embodiments corresponding to the Figures which are illustrated diagrammatically. As usual, in conventional lens diagrams, the light is assumed to travel from left to right. The lenses are disclosed as assembled into three separate optical units. Both in the diagrams and in the Tables the radii of curvature of the lenses are indicated by R, with a subscript corresponding to the consecutive number of the lens element surfaces from object to image side.

In the Tables, a negative sign indicates the radii on centers of curvature lying on the object side of their vertices. In both the Figures and the Tables, the axial spacings are disclosed as, D, along the optical axis and include both the axial spacings between the lens elements and thickness of the lens elements.

All linear dimensions are given in absolute values and are given with reference to an equivalent focal length of unity. The Tables also provide with respect to each example, the intended relative aperture and the total field of view 2ω. Finally, the refractive index is designated, N, while the Abbe Number is designated ν.

FIGS. 1, 3 and 5 utilize lens elements of basically the same configuration with only the dimensions varying between each embodiment. Accordingly different reference numbers are not necessary and a diagram of each embodiment is conveniently located adjacent the aberration graphs for convenient reference to the lens designer.

With reference to FIGS. 1, 3 and 5 and in accordance with the present invention, a tesser type objective lens system having a rear aperture stop, S, comprises a first positive meniscus lens I convex to the object side; a second negative lens II located at the image side of the first positive meniscus lens I, and a third positive doublet III located at the image side of the second negative lens II. The third positive doublet consists of a positive element and a negative element cemented to the positive element by an intermediate cementing surface, R_6, convex to the object side. The aperture stop S is located at the image side of the third doublet III. The lens system of the present invention fulfills the following conditions:

(1)	0.3 <	$D_3/(D_1 + D_2 + D_3)$	<0.45
(2)	0.05F <	D_3	<0.08F
(3)	0.03F <	D_4	<0.045F
(4)	−2.4F <	R_3	<−1.6F
(5)	0.25F <	R_6	<0.33F
(6)	0.13 <	N_4-N_3	<0.22
(7)	$(N_1 + N_4)/2 > 1.75$		

wherein:

F represents the focal length of the entire lens system;

D_i represents the i-th axial distance from the object side;

R_i represents the radius of curvature of the i-th surface from the object side; and

N_i represents the refractive index of the i-th glass material from the object side with respect to the ray of d-line.

The following is an explanation of the purpose of the above seven parameters of the present invention. As noted in the description of the prior art, there has existed a general difficulty in effectively correcting astigmatism and field curvature in a tesser type lens system having a rear aperture. This problem existed because in a conventional design the Petzval sum could not be successfully reduced while at the same time maintaining a proper balance correction of spherical aberration and coma. In other words, the conventional design technique for reducing a Petzval sum by increasing the index of refraction for the positive lens elements in the lens system while reducing the index of refraction of the negative lens elements in the lens system would inevitably deteriorate the corrections of the spherical aberration and coma.

The present invention has adopted a novel design technique for reducing the Petzval sum while maintaining the corrections of spherical aberration and coma so that both astigmatism and field curvature as well as the spherical aberration and coma are correctly balanced.

In accordance with the present invention, this correction is achieved by increasing the thickness D_3 of the second negative lens II relative to the total axial distance, D1+D2+D3, to a greater degree than that suggested in a conventional tesser type lens design. By means of this relatively increased thickness of D3, the front surface R3 of the second negative lens II is located closer to the front surface R1 of the whole lens system. This allows the second negative lens II to utilize glass material of a relatively low refractive index to successfully reduce the Petzval sum, while the corrections of spherical aberration and coma can still be balanced. Conditions (1) and (2) relate to this particular design technique. In those cases wherein the lower limit of condition (1) or (2) is violated it will be difficult to desirably reduce the Petzval sum.

If the upper limit of these conditions are violated the chromatic aberration with respect to a shorter wavelength of light will be overcorrected in the zonal to marginal area of the image. Additionally if the upper limit of condition (2) is violated the lens design will fail to meet the criterion of a compact lens system which is necessary in commercially acceptable lenses. As a supplement to conditions (1) and (2), condition (7) is also utilized for reducing the Petzval sum, by requiring the refractive indices for the positive lens elements to be relatively high.

Conditions (3) through (6) are designed to insure the appropriate balance correction of coma in the zonial to marginal area of the image. By adherence to these conditions, it is possible to increase the absolute value of the radius of curvature R_3 of the front surface of the second negative lens II in accordance with the increase of its lens thickness D3. It is also possible to give the cemented surface R6 a suitably great refractive power by means of reducing the radius of curvature R6 and increasing the difference between the refractive indices N3 and N4 at both sides of the surface R6. Additionally, the airspace D4 between the second negative lens II and the third doublet III will be reduced. It has been found difficult to correct coma if any one of the following limits are violated, the upper limit of condition (3); both the upper and lower limits of condition (4); the upper limit of condition (5) and the lower limit of condition (6). The lower limit of condition (3) further defines a limit of a practical lens arrangement. Finally, it should be noted that an excessively large refractive power to the cementing surface R6 will result in causing an under correction of the meridonial field curvature if the lower limit of condition (5) or upper limit of condition (6) is violated.

Tables 1 through 3 show respectively 3 embodiments of the present invention. FIG. 1 corresponds to Table 1 while FIG. 2*a* discloses spherical aberration, FIG. 2*b* discloses astigmatism, FIG. 2*c* discloses distortion, and FIG. 2*d* discloses lateral aberration for a field angle of 30° while FIG. 2*e* discloses lateral aberration for a field angle of 19°. FIG. 3 corresponds to Table 2 with the aberrations being set forth in FIGS. 4*a* through 4*e*. FIG. 5 corresponds to Table 3 with the aberrations being set forth in FIGS. 6*a* through 6*e*.

It is to be further understood that various modifications of the generic concepts of this invention are possible without departing from its spirit and accordingly the scope of the present invention should be determined solely from the following claims.

What is claimed is:

1. An improved tesser type objective lens system having a rear aperture stop comprising:

a first positive meniscus lens convex to the object side;

a second negative lens located at the image side of the first positive meniscus lens;

a third positive doublet located at the image side of the second negative lens, the third positive doublet consisting of a positive element and a negative element cemented to the positive element by an intermediate cemented surface convex to the object side; and

an aperture stop located at the image side of the third doublet, wherein the lens system fulfills the following conditions:

0.3	<	$D_3/(D_1 + D_2 + D_3)$	<	0.45
0.05F	<	D_3	<	0.08F
0.03F	<	D_4	<	0.045F
−2.4F	<	R_3	<	−1.6F
0.25F	<	R_6	<	0.33F
0.13	<	N_4-N_3	<	0.22
		$(N_1 + N_4)/2 > 1.75$		

wherein:

F represents the focal length of the whole lens system;

D_i represents the i-th axial distance from the object side;

R_i represents the radius of curvature of the i-th surface from the object side; and

N_i represents the refractive index of the i-th glass material from the object side with respect to the ray of d-line.

2. An improved tesser lens system comprising the following design parameters:

F = 100 1 : 2.8 2ω = 60°

	Radius of Curvature		Axial Distance		Refractive Index		Abbe Number
R_1	34.04	D_1	8.0	N_1	1.7885	ν_1	45.7
R_2	100.9	D_2	2.5

R_7	−81.78	S (Aperture Stop)					

5. An improved tesser type objective lens system having a field angle of about 60° and a rear aperture stop comprising:

a first positive meniscus lens convex to the object side;

a second negative lens located at the image side of the first positive meniscus lens;

a third positive doublet located at the image side of the second negative lens, the third positive doublet consisting of a positive element and a negative element cemented to the positive element by an intermediate cemented surface convex to the object side; and

an aperture stop located at the image side of the third doublet, wherein the lens system fulfills the following conditions:

0.3	<	$D_3/(D_1 + D_2 + D_3)$	<	0.45
0.05F	<	D_3	<	0.08F
−2.4F	<	R_3	<	−1.6F
0.25F	<	R_6	<	0.33F
0.13	<	N_4-N_3	<	0.22

wherein:

F represents the focal length of the whole lens system;

D_i represents the i-th axial distance from the object side;

R_i represents the radius of curvature of the i-th surface from the object side; and

N_i represents the refractive index of the i-th glass material from the object side with respect to the ray of d-line.

6. The invention of claim 5 wherein the index of refraction of the second negative lens is approximately 1.7 or less.

7. An improved tesser type objective lens system having a field angle of approximately 60° and a rear aperture stop comprising from object to image side:

a first positive meniscus lens convex to the object side;

a relatively thick second negative lens with an index of refraction of approximately 1.7 or less, located at the image side of the first positive meniscus lens;

a third positive doublet located at the image side of the second negative lens, the third positive doublet consisting of a positive element and a negative element with an intermediate surface convex to the object side; and

an aperture stop located at the image side of the third doublet, wherein the lens system fulfills the following conditions to permit a reduction in the Petzval Sum below a conventional tesser value while still maintaining a balanced correction of spherical aberration, coma, astigmatism, and field curvature:

$$0.3 < \frac{D_3}{D_1 + D_2 + D_3} < 0.45$$

$$0.055F \leqq D_3 < 0.08F$$

wherein:

D_i represents the i-th axial distance of both air spaces and lens thicknesses and F represents the focal length of the entire lens system.

[57] **ABSTRACT**

Disclosed is a camera including a camera housing and an objective lens having an image axis. The objective lens for the camera is mounted in a tube which is movable between an extended exposure position and a retracted storage position. When the tube is in the extended exposure position, an annulus around the tube cooperates with a projection on the tube to set the precise extended position necessary to provide a sharply focused image on the camera film.

FIG. 2

CAMERA HAVING AN INDEPENDENTLY FOCUSED RETRACTABLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

The invention generally concerns a photographic camera and particularly a miniature camera having a focusable objective lens.

In cameras of this type, the range setting device is arranged directly on the objective tube in the form of a rotating ring. This setting ring carries a range scale whereby the range number desired must be made to coincide with a marking stationarily arranged on the objective tube, in order to set the range desired. To set the range, the user of the camera is thus always forced to remove the camera from his eye and to set the range on the objective tube. This is extremely disadvantageous, because the observation of the object must be interrupted, when it is desired for example to continuously adjust the range to a moving object. Such a camera is poorly adapted for use in taking snapshots, because its handling is rather cumbersome. The modern requirements of a snapshot camera demamd as a minimum that an indication of range be provided in the viewfinder so that the necessary distance may be set and verified in the viewfinder without taking the camera from the eye, thus interrupting the observation of the object. The indication of a range set on the objective of the camera in a range indicating device in the viewfinder is, technically, extremely involved in a camera with an objective tube which slides in and out and thus is highly subject to problems, and as a result such a device has not been provided.

Another disadvantage of this known camera consists of the fact that the handling of the camera during the setting of the range is not of optimum ease. The diameter of the objective in such cameras having an objective tube capable of sliding in and out is mostly very small so that on the one hand the range scale is arranged in a highly crowded manner, which renders it difficult to read and on the other, the relatively small range setting annulus offers no easy grip that would facilitate handling.

SUMMARY OF THE INVENTION

It is thus an object of the present invention to provide a camera with an objective tube capable of sliding in and out, wherein the handling of the camera with respect to range setting is substantially improved. It is a further object of the present invention to provide an indication of the range selected in the viewfinder by simple means. It is a still further object to provide a camera which is simple in design and provides savings in production costs, while at the same time being sturdy and not susceptible to defects. An additional object is to provide a camera in which the accurate optical alignment of the objective lens in its exposure position is possible.

The above and other objects are achieved by providing a camera including a camera housing and an objective lens having an image axis. Additionally, means for manually setting the range of the camera and means for mounting the objective lens for movement, substantially parallel to the image axis, between an extended exposure position and the retracted storage position are provided. Furthermore, means for variably limiting axial movement of the mounting means in the extended position and means, responsive to the range setting means,

for varying the limiting means are also provided. Thus, the mounting means is movable between a retracted position and an extended position and whose extended position is adjusted by said limiting means which in concert with said varying means and in response to the range setting means, adjusts the axial position of the objective lens to ensure a properly focused image.

Further embodiments of the present invention comprise an indicator and a viewfinder reflecting the position of the range setting means and thus the focal distance of the objective lens. Additional embodiments include means for biasing the lens mounting means towards its extended exposure position in combination with means locking the mounting means in a retracted storage position. A further embodiment includes releasing means permitting said lens mounting means under the influence of the biasing means to move to its extended exposure position.

BRIEF DESCRIPTION OF THE DRAWINGS

A more complete appreciation of the invention and the attendant advantages thereof will be more clearly understood by reference to the following drawings wherein:

FIG. **1** is a front perspective view of one embodiment of the present invention with the lens tube in the storage position; and

FIG. **2** is a front perspective view of the embodiment of FIG. **1**, but in its extended exposure position.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

The range setting device arranged on the housing of the camera, according to the present invention, facilitates the setting of the range by the user of the camera because this range setting device may be designed independently of the diameter of the objective tube and arranged in an economically favorable manner on the camera housing. Beyond this, a device indicating the range in the viewfinder may be effectuated very simply in association with the range setting device arranged in the housing of the camera. Such a design is of the utmost simplicity. The range setting device arranged in the camera housing is particularly advantageous if a flash unit is additionally integrated with the housing. In such a case the range setter may also be able to perform simultaneous adjusting functions for the flash unit.

As a result of the measures taken in accordance with the invention, in spite of the removal of the range setting device from the objective tube and its arrangement on the housing of the camera, the transmission of the setting of the range from the range setting device to the objective is very simple from a design standpoint, sturdy and has low susceptibility to failure. Further, a significant optical advantage is achieved. By means of the present invention, complete adjustment of the objective lens takes place during the setting of the range and not, as in the case of the prior art camera, only during setting of the front lens. This substantially improves the imaging quality of the objective.

The measures taken in keeping with the invention make it further possible to set the range on a camera not ready for exposure, i.e. with the objective tube retracted into the camera housing. This is of particular advantage for cameras wherein the retracted objective tube is additionally covered in front. Such a capability represents a significant step to improve the camera in

the direction of a "rapid shot camera." The range may be set while the camera is still closed. The touch of a button is then sufficient to make the objective tube emerge. The exposure can then be triggered without wasting valuable time on the setting or resetting of the camera. In one embodiment, wedge-like projection on the setting annulus cooperates with at least one projection on the objective tube to effect transmission between the range setting device and the objective tube, that is overall simple in design, inexpensive to manufacture and sturdy.

In a further embodiment a slideout spring is prestressed in the retracted state of the objective tube such that the camera may be made ready for exposure very rapidly. The touch of a button on the corresponding locking element is sufficient to cause the objective tube to slide into its exposure position and to be frictionally arrested. All this may take place without a need for the user of the camera to remove his eye from the viewfinder and thus to interrupt his observation of the object. The preparation time of the camera for the actual performance of an exposure is thus extremely short.

A further embodiment includes a means for locking the objective tube in the camera housing that is simple and reliable and which, simultaneously, may be entrusted with additional functions.

In a further most advantageous embodiment, the satisfactory frictional stopping of the extended objective tube is obtained in its position of exposure, specifically in each of the different axial positions of the objective tube corresponding to the range setting. The objective tube and thus the objective is held securely in its optically correct position and cannot be deflected from this position by the accidental application of lateral pressure on the objective tube by the user of the camera.

In an additional embodiment a spring element secures a locking lever in place when the objective tube is retracted into the camera housing, and it effects the frictional arrest of the objective tube by means of the inclined edges of the locking lever, in the exposure position of the objective tube.

In a further embodiment, the locking of one of the two locking levers with a pin on the objective tube and the other locking lever with a pawl on the front cover which is hingedly mounted on the objective tube, permits the covering of the objective lens when the tube is in its retracted position. This front or objective cover automatically snaps into its open position, uncovering the objective, when the lock of the objective tube is released and the latter slides into its ready position under the pressure of the spring. Because the objective cover is arranged on the front side of the objective tube above the opening of the objective and, in the open position, stands out essentially at a right angle from the front side of the objective tube, the cover additionally performs the function of a sunshade. When converting the camera from its exposure ready position into its transport state, it is merely necessary to deflect the objective cover to the front side of the objective tube and to push the objective tube further into the camera housing by exerting additional pressure on the cover. When the objective tube arrives in its locking position, the locking levers automatically engage the objective tube and the cover and hold both, so that the objective tube is completely inserted in the camera housing and the objective protectively covered.

Referring now to the drawings wherein like reference characters designate like parts throughout the several views, FIGS. **1** and **2** illustrate a miniature camera designed for 35 mm film. It has a housing **10** indicated in the drawing by a dash-and-dot line and an objective tube **11** arranged in an axially displaceable manner. In the position ready for exposure of the camera, wherein photographic exposures may be effected, as in FIG. **2**, the objective tube **11** protrudes from the housing **10** and assumes its optically correct coordination with respect to the film placed in the window of the camera. When not in use, the objective tube may be inserted completely in the housing **10** as in FIG. **1**, so that the camera displays exclusively flat limiting surfaces without protruding parts that would interfere with the suitability for packing of the camera. In this so-called transport state of the camera, the latter is particularly compact and convenient and may be carried comfortably by the user.

In addition to the usual control knobs for the setting of the diaphragm and/or the exposure time and film sensitivity, the camera also has a range setting device **12**, arranged on the housing **10**. The range setting device **12** is designed in the form of a sliding key **13**, mounted transversely to the optical axis **20** in a longitudinally displaceable manner. A pointer **14** is rigidly connected with the range setting device. The pointer **14** serves to visually indicate the range set by means of the range setting device **12**. For this purpose, a distance scale **16** is arranged in the viewfinder **15** and the pointer **14** has a marker **17** correlated with the range scale **16** and following the displacement of the range setting device **12** while sliding along the range scale **16**.

The range setting device **12** is coupled with a setting annulus **19** by means of a pin and slot **18**. The setting annulus **19** is mounted in the housing **10** stationarily in the axial direction but rotatably around the optical axis **20** of the camera. On the setting annulus **19** and on the objective tube **11**, the adjusting elements **21** and **22**, respectively, are fixably mounted on their support, but in coordination with and displaceable relative to each other. The adjusting elements **21** and **22** rest in frictional contact against each other in the exposure position of the objective tube **11** (FIG. **2**) and determine the axial position of the objective tube **11** as a function of the rotating position of the setting annulus. The adjusting elements **21** and **22** are provided herein in the form of wedge-like protrusions **23** and noses **24**. The protrusions **23** are mounted on the setting annulus **19**, specifically on the rear side **25** of said annulus facing the inside of the housing, and have an axial depth increasing in the circumferential direction of the annulus **19**. The noses **24** coordinated with these protrusions **23** protrude from the circumference of the objective tube **11**, preferably at the rear end **26** of the tube or close to it.

The noses **24** are arranged on a flange **27** stationarily joined with the objective tube **11** and protruding over the objective tube **11**, and are radially aligned. The protrusions **23** and the noses **24** are distributed in a regular manner around the circumference of the setting annulus **19** and the flange **27**, respectively. In the exposure position of the objective tube **11**, depending on the rotational position of the setting annulus **19**, the noses **24** may contact the protrusions **23** at locations where they have different axial depths. As the result, the axial position of the objective tube **11** with respect to the image window can be changed. The actuation of the range setting device **12** thus alters the overall axial position of the objective tube **11** and therefore that of the objective lens held in the tube. With a suitable layout of the range

setting device 12 and the axial depth of wedge like protrusion 23, when a certain range is set by means of the sliding key 13 the objective tube 11 is positioned axially by means of the rotation of setting annulus 19. The range indicated by the pointer 14 in the viewfinder 15 is the distance necessary for the objective lens to reproduce sharply on film the object image of the camera.

The objective tube 11 is outwardly biased in the axial direction by an inwardly pulling spring 28, which is prestressed at least in the retracted state of the objective tube 11. In the present case, the spring 28 is provided in the form of a tension spring 29, engaging a lever arm 30 of a dual arm lever 31. The dual arm lever 31 is rotatable around the longitudinal axis of rotating axle 32 which is rotatably mounted in the housing 10 and engages with its other lever arm 33 the objective tube 11, specifically the flange 27. The lever arm 33 is here designed as a rocker arm, possessing two rocker arms 35 and 36, torsionally connected with the rotating axle 32. The tension spring 29 engages the lever arm 30 which is again torsionally connected with the rotating axle 32 and biases the rocker arm 34 in the outward direction of the objective tube.

The objective tube 11 carries on its flange 27, radially protruding and diametrically arranged pilot pins 37 and 38. The two pilot pins 37, 38 enter the guide slots 39 extending along the optical axis 20 (as seen in FIG. 2 where only the upper guide slot 39 is shown). By means of the pilot pins 37 and 38 and the guide slots 39, the objective tube 11 is guided satisfactorily in the axial direction. The two rocker arms 35 and 36 of the rocker 34, each have a slit 40 and 41, respectively, at their free ends, whereby they embrace the two pilot pins 37 and 38. This provides a hinged connection between the rocker 34 and the objective 11 so that the rocking motion of the rocker 34 is translated into an axial displacement of the objective tube 11.

In the housing 10 of the camera, a locking lever 42 is pivotably arranged about a rotation axle 43. An identical locking lever, again rotatable around the axle 43, is found on the underside of the objective tube 11, diametrically opposed to the upper locking lever 42. For reasons of clarity of the drawing, the lower locking lever is not shown. It is, however, identical with the upper locking lever 42 so that any reference to said upper locking lever 42 is equally valid for the lower locking lever. The locking lever 42 and the objective tube 11 both carry mutually coordinated and interlocking arresting elements 44 and 45, respectively, which engage each other in the retracted state of the objective tube 11, thus locking the objective tube in place in its retracted position with spring 28 under stress.

The arresting element 44 on the locking lever 42 is designed as arresting pawl 46 and the arresting element 45 on the objective tube 11 as a plunger pin 47. The plunger pin 47 is arranged on the front end of the objective tube 11. The locking lever 42 is prestressed by means of a spring element 49, provided in the form of a helical compression spring 48 so as to support the arresting action of the arresting elements 44 and 45. The locking lever 42 is coupled with manually actuated release element 50 carrying a slide knob 51, which protrudes form the front side of the camera housing 10 and may be displaced manually, in a direction transverse to the optical axis 20. Upon the displacement of the slide knob 51, the locking lever 42 is rotated against the force of the helical compression spring 48 and the arresting elements 44 and 45 are disengaged. The objective tube 11 is released. Under the effect of the spring 28 the rocker arm 34 urges the objective tube 11 into its exposure position.

The locking lever 42 has a bevelled edge 52 inclined at an acute angle to the optical axis 20. In the exposure position of the objective tube 11, i.e. with the objective tube 11 protruding from the housing 10, this bevelled edge 52 is resting in frictional contact against the pilot pin 37 and urges the objective tube 11 in the outward direction. Correspondingly, the lower locking lever is in frictional contact by means of a similar bevelled edge with the pilot pin 38. The frictional contact joining the bevelled edges 52 and the pilot pins 37 and 38, respectively, is effected by the helical compression spring 48. This application pressure of the helical compression spring may be dimensioned exactly and is nearly always constant, because the position of the locking lever 42 and thus the compression of the helical spring 48 is unchanging in almost all possible positions of the objective tube 11 along the optical axis 20.

On the front side of the objective tube 11 an objective lens cover 53 is pivotally mounted. The mounting point 54 of the cover 53 is located above the lens opening 55 of the objective tube 11. On its side opposite to the mounting point 54, the objective cover 53 carries an arresting projection 56 (FIG. 2). When the objective cover 53 is pressed onto the orifice 55 of the objective tube 11 (the position of FIG. 1), the arresting projection 56 is embraced by the pawl of the lower locking lever in the manner described hereinabove for the upper locking lever 47 and the plunger pin 47 on the upper side of the objective tube 11. When the objective cover 53 is in place on the objective tube 11 and the tube 11 retracted, the latter is held in position on the one hand by the engagement of the upper locking lever 42 with the plunger pin 47 and on the other hand by the engagement of the lower locking lever 42 with the arresting projection 56 of the objective cover, whereby the objective cover 53 is also held simultaneously in its position covering the objective lens.

The objective cover 53 is prestressed by means of a spring, not shown, so that, upon release, it automatically assumes the position shown in FIG. 2, thus essentially protruding at right angles from the front side of the objective tube 11. The objective cover 53 therey automatically uncovers the objective lens and simultaneously assumes a position wherein it acts as a sunshade.

In the transport state of the camera, i.e. when not in use (as in FIG. 1), the objective tube 11 is completely retracted into the housing 10 of the camera. The objective cover 53 is fixed onto the front side of the objective tube 11 and covers the lens opening 55 thereof and thus the objective lens in a protective manner. In this position, the objective tube 11 and the objective cover 53 is held in position by the two locking levers; of these, only the upper locking cover 42 is visible in the figures. The latter embraces with its pawl 46 the plunger pin 47 on the objective tube 11, while the lower locking lever with its similarly designed pawl grips the arresting protrusion 56 of the objective cover 53. The helical compression spring 48 maintains the secure locking of the objective tube 11 and the objective cover 53. In this position, the spring 28 is under stress.

The displacement of the sliding knob 51 of the release element 50 in the direction of the arrow A, pulls the two locking levers 42 in the direction of the arrow A. The upper locking lever pawl 46 and the plunger pin 47, and

the lower locking lever pawl and the arresting protrusion **56** are disengaged. The spring **28** urges the objective tube **11** by means of the rocker **34** out of the housing, until the protrusions **24** come to rest against the wedge-like protrusions **23**. Depending on the rotational position of the setting annulus **19**, corresponding to the range setting by means of the range setting device **12**, the objective tube **11** emerges, more or less, from the housing **10**. Simultaneously with the release of the lock between the arresting protrusion **56** and the lower locking lever, the objective cover **53** opens and assumes its position shown in FIG. **2**. Upon the release of the sliding knob **51**, the release element **50** and the upper and lower locking levers **42** return to the position shown in FIG. **2**. The upper locking lever **42** with its bevelled edge **52** thereby comes to rest against the pilot pin **37** and the lower locking lever correspondingly with its bevelled edge against the pilot pin **38**. The extended objective tube **11** is thus satisfactorily arrested and secured in its position of exposure.

In the example of embodiment described hereinabove, the objective cover **53** is designed so that it may be removed without difficulty from the objective tube **11**. This is achieved in the simplest manner by the suitable design of the mounting **54**. This makes it possible to mount further attachments in place of the objective cover **53** on the objective, particularly optical attachments. Thereby, for example, rapid changes between two focal lengths of the objective may be effected. During transportation, i.e., with the objective tube **11** retracted, such an adapter objective is securely fastened to the camera.

Although the invention has been described relative to a specific embodiment thereof, it is not so limited and many modifications and variations thereof will be readily apparent to those skilled in the art in light of the above teachings. It is, therefore, to be understood that, within the scope of the appended claims, the invention may be practiced otherwise than as specifically described.

The embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. A camera including a camera housing and an objective lens having an image axis:

means for manually setting the focal range of said camera;

means for mounting said objective lens for movement substantially parallel to said image axis, between an extended exposure position and retracted storage position;

means for variably limiting axial movement of said mounting means in said extended position;

means, responsive to said range setting means, for varying said limiting means; and

means for releasably locking said mounting means in said storage position, said locking means comprising at least one locking lever pivotally mounted at one end with an arresting pawl on the other end and a plunger pin mounted on said mounting means such that in said storage position said pawl releasably engages said plunger pin preventing extention of said mounting means, said locking means further including means for releasing said plunger pin from engagement with said pawl, said releasing means comprising a release element internal to said camera housing, and connected to said locking means; and a manually actuated knob, external to said housing, for operating said release lever removing said locking means pawl from engagement with said plunger pin,

said camera further comprising an objective lens cover, pivotally mounted on said mounting means for movement between an open position and a closed position, said cover including an arresting projection, wherein said locking means comprises two locking levers disposed in diametrically opposing positions with respect to said mounting means, said one end of each of said levers pivotally mounted on a common pivoting axle and said arresting pawl of one of said locking levers releasably engages said plunger pin and said arresting pawl of the other of said locking levers releasably engages said arresting projection only when said cover is in said closed position and said mounting means is in said storage position.

2. The camera according to claim **1**, said camera including means for biasing said cover towards said open position, said cover in said open position being essentially parallel with said axis.

3. The camera according to claim **1**, said camera further including a viewfinder with a range scale and a pointer connected to said range setting means and extending into said viewfinder for indicating on said range scale the focal distance of said objective lens.

[57] **ABSTRACT**

The present invention relates to an objective for still cameras and motion picture cameras into which the critical focusing values of the two boundary points of a selected depth of field range are fed without being examined, whereupon the lenses and the diaphragm are adjusted automatically for a sharp reproduction of the respective range.

FIG. 2

DEPTH OF FIELD OBJECTIVE

This is a continuation, of application Ser. No. 656,607, filed Feb. 12, 1976, now abandoned.

BACKGROUND OF THE INVENTION

For a more accurate depth of field photography, the user of the camera normally relies on the depth of field scale. The operation involves the following six steps, one after the other: (a) Focusing one boundary point of the desired depth of field range. (b) Reading and memorizing the selected distance. (c) Focusing the other boundary point. (d) Reading and memorizing this second selected distance. (e) Rotating the focusing ring until the two memorized distances face the same stop numbers of the depth of field scale. (f) Adjusting the diaphragm in accordance with these stop numbers.

My Swiss Pat. No. 517,314 discloses a camera embodying a device which automatically performs the aforediscussed series of manipulations. No satisfactory construction of an objective which can carry out such manipulations is known as yet. However, the automatic exposure time device which is disclosed on page 3, lines 6 and 7 of the Swiss Patent has been incorporated in the meantime in at least 16 modern cameras. Moreover, there are many additional proposals relating to automated focusing aids. When photographing, only the selection of depth of field would still require manual adjustment including the four steps b, d, e and f during which the camera is not trained upon the subject or scene. Therefore, there exists a need for an objective which is capable of carrying out these manipulations in an automatic way.

OBJECTS AND SUMMARY OF THE INVENTION

An object of the present invention is to provide an objective of the type indicated hereinbefore, namely, an objective wherein the depth of field is automatically adjusted upon transmission of information pertaining to the two boundary points. Thus, instead of the aforesaid complex operations, the photographer is required to carry out only the two steps of determining the boundaries of the depth of field range. In other words, the photographer is still free to select the object even if focusing itself is automated.

Another object of the invention is to provide the objective with a device which can select the same depth of field position as is accomplished by the aforementioned six steps. This involves the movement of the lens mount to an intermediate position between the positions corresponding to the two focused boundary points and a corresponding adjustment of the diaphragm. During the step e, the lens system is shifted away from the position of focusing upon the second boundary point and, when the two distances denoting the selected boundary points face the same f/stop numbers of the depth of field scale, the lens system reaches precisely a position midway between the two boundary focus positions, as considered in the direction of the optical axis. Consequently, the step e involves moving the lens system exactly by half the distance it had to be advanced from focusing of the farthest boundary point to that of the nearest boundary point, or vice versa.

A further object of the invention is to provide a method and a device which automatically accomplish the aforediscussed forward and rearward movements of the lens system within an objective regardless of whether the information pertaining to the two boundary points is supplied manually (e.g., by depressing suitable keys) or automatically.

During the step f, that diaphragm aperture size is selected which is indicated by the two distances focused out on the depth of field scale. This aperture size has a specific relationship to the total focusing difference. When the stray circle diameter is based upon a specific millimeter fraction, the maximum focusing difference is defined by the distance which is indicated by the depth of field scale as converted torque between the pairs of the greatest f/stop numbers. Smaller f/stop numbers are associated with the correspondingly smaller focusing differences.

The present invention embraces all methods and devices which adjust the diaphragm automatically in accordance with the focusing differences within an objective in response to feeding of information by means of a key or in response to automatic feeding.

The shifting of the lens mount to a position midway between the positions assumed during focusing upon the two boundary points is derived from the movement which the objective had to carry out between the said positions. According to the invention, adjustment of the diaphragm is derived from the movement of the lens system.

BRIEF DESCRIPTION OF THE DRAWING

FIG. **1** is a schematic partly sectional view of an objective which embodies one form of the invention; and

FIG. **2** illustrates a detail in the objective of FIG. **1**.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

For the sake of simplicity, the device which embodies the invention will be described as though the farthest boundary point were focused first. However, the improved device can also operate in such a way that the nearest boundary point is focused first.

FIG. **1** is a section through the improved objective with certain parts shown in elevation. This is a modern objective in which, in a manner similar to that in the Nikkor-H Auto 1:1.8 f=35 mm No. 23 73 19 lens, a knurled focusing ring **1** can be rotated to move the tube **19** for the lenses of the optical system **19***a* forwardly by means of two equally steep threads **1***a* **1***b* in order to advance the lenses through a distance approximating twice its own advance. The rotary member or sleeve **3***a* in which the external thread **1***a* of the knurled ring **1** is guided is threadedly connected to the base **2** of the objective (as at **2***a*, **4**) in a manner known from conventional objectives. The base **2** is secured to the camera body, for instance by means of a slide lock. However, in the illustrated embodiment of the invention, this sleeve **3***a* is a composite body and the base **2** holds the sleeve **3***a* for the knurled ring **1** and optical elements or lenses of the system **19***a* (hereinafter called mount **3**) by means of the thread **2***a*. This thread **2***a* has the same slope as the two threads **1***a*, **1***b* of the knurled ring **1**. Upon completion of rotation in the direction indicated by the arrow **17***r* or **18***r*, the mount **3** is caused to perform a movement in a direction towards the camera housing through a distance which is exactly half the distance covered by the lenses if the angular movement of the tube **19** in the opposite direction amounts to the same number of degrees as that through which the knurled

ring 1 was rotated while causing the lenses to move forwardly. In order to insure that the angular movement which is carried out by the knurled ring 1 from focusing of the one boundary point to focusing of the other boundary point is converted into an equally large angular movement of the mount 3 with respect to the base 2 of the objective, discrete information storing rings 5 and 14 are mounted on the base 2 and on the mount 3, respectively. The ring 5 is mounted in a guide 6 on the base 2. It can be arrested by a lock 7 on the base 2 in response to depression of an actuating button 8. FIG. 2 illustrates the arresting means in detail. A springy strip 9 having a detent notch or recess 10 is provided on the ring 5 and is engaged by an arm 11 of the knurled ring 1. A resilient element in the form of a helical spring 12 is installed between the right-hand ring 5 and the ring 14. This spring is secured on the one hand to the ring 5 and on the other hand to an arm 13 of the second ring 14. The arm 13 has freedom of movement with respect to the ring 5 through a distance which is determined by two abutments 17 and 18 and corresponds exactly to the distance between the two outermost graduations of an imaginary depth of field scale. Moreover, this distance (which can subtend an arc of 55°) is identical with the extent of movement which is needed to adjust the diaphragm from the largest aperture (1.8) to the smallest aperture (22). A prerequisite for the correspondence of the angular movement of the mount 3 with the required diaphragm closure is the operation of the diaphragm adjusting lever in such a way that, in order to change the diameter of the diaphragm aperture from one diameter to a diameter one and a half times the one diameter, the lever is moved through identical angles. This is the case in modern objectives such as, for instance, the Nikkor-H Auto 1:1.8 f=35 mm. The ring 14 can be arrested by a locking device 15 which is actuated by depressing a button or key 16. In order to make it accessible from the outside, the key 16 extends through a slot 16*a* of the knurled ring 1. The manner in which the key 16 can initiate a locking action is shown in FIG. 2. The mount 3 is directly connected to the diaphragm adjusting lever and is held in the normal position with respect to the base 2. In the illustrated embodiment, the thread 4 between the rotary member 3*a* of the mount 3 and the base 2 is designed for easy movement with respect to the threads of the knurled ring 1. In order that, during return movement of the mount 3, the threads of the knurled ring 1 remain in their positions, they are designed for hard movement.

The operation of the illustrated embodiment of the invention is as follows: The selected depth of field is assumed to be between 15 m and 3 m from the camera and, upon the depth of field adjustment, the objects within this range shall be imaged on the negative with stray circles not exceeding 1/30 mm. By means of the knurled ring 1, the farthest point at 15 m is focused. During this movement, for instance, from the infinity, the ring 5 of the base 2 is carried along because the knurled ring 1 has its arm 11 engaged in the notch 10 of the strip 9. Moreover, the spring 12 pulls the ring 14 by way of the arm 13 so that the arm 13 engages the abutment 17. When the image of an object located at the distance of 15 m becomes sharp, the key 16 is depressed. This key is very close to the left forefinger which was used to rotate the ring 1 together with the thumb of the left hand. The ring 14 is thereby locked against the mount 3. By means of the knurled ring 1, an object at a distance of 3 m is now sighted. When the image of the object becomes sharp, the key 8 is depressed, also with the left forefinger, and the grip upon the knurled ring 1 is relaxed. This locks the ring 5 to the base 2, and secondly the arm 11 of the knurled ring is disengaged. Together with the ring 5, the abutment 17 has moved to the position 17*a*, this causing the spring 12 to store energy. As soon as this has occurred, a lock (not shown) which caused the mount 3 to engage the base 2 is released so that the parts 2 and 3 can move with respect to each other. The spring 12 pulls the mount 3 into the base 2 to the extent determined by the space which is allotted by the stop 17 in the position 17*a*. The mount 3 returns through about half the distance and the diaphragm which is coupled thereto is adjusted accordingly. The camera is ready to make an exposure. In another embodiment, the lock for the mount 3 is disengaged only when actuating the camera release. In such embodiment, a fully automatic diaphragm is superfluous since it remains open anyway until the camera release is actuated. Regardless of whether the one or the other embodiment is resorted to, several shots of the same depth of field can be made in response to repeated winding of film and actuation of the camera release. When another range is to be selected, the knurled ring 1 is returned in a direction towards the infinity. Its arm 11 soon enters the recess 10 of the strip 9 and thereby releases the lock 7 by way of a lever, not shown. The knurled ring 1 now again carries along the locking arrangement 7 on the ring 5. Shortly thereafter, the abutment 17 contacts the arm 13 as soon as it reaches the solid-line position of FIG. 1 whereby the ring 14 on the mount 3 is unlocked by means of a releasing lever, not shown. The ring 14 is now free to move again with the knurled ring 1, either in response to a push by the abutment 17 or in response to a pull by the spring 12, depending upon whether the ring 1 moves forwardly or backwards. Thus, the farthest point of another depth of field range can be focused out.

The objective can be designed to indicate that the selected range of the depth of field is too wide and to correct this by engagement against suitable abutments. The objective is also useful for exposures without any depth of field as well as for exposures with maximum sharpness outside of the point midway between the two boundary points. In the latter case, refocusing is necessary either by maintaining the mount 3 in engagement with the abutment or by providing a lock which locks the arm 13 when the arm contacts the abutment 17 in the position 17*a*.

The invention is claimed as follows:

1. A method of preparing a photographic camera for the making of exposures of objects within a selected depth of field range between two boundary points, comprising the steps of focusing the lens system of the objective upon one of said boundary points, including moving the lens system in the direction of the optical axis to a first position; storing in the objective information denoting said first position; focusing the lens system upon the other boundary point, including moving the lens system of the objective in the direction of the optical axis to a second position; storing in the objective information denoting said second position; and thereupon utilizing the stored information denoting said first and second positions to automatically shift the lens system to an exposure position substantially midway between said first and second positions.

2. A method as defined in claim 1, further comprising the step of adjusting the diaphragm of the photographic

camera in automatic response to shifting of the lens system to said exposure position so that the aperture size is a function of the exposure position of the lens system.

3. An objective for photographic cameras, comprising an optical system; means for focusing said optical system upon objects located at different distances from the objective, including means for moving said optical system in the direction of the optical axis; means in the objective for storing information pertaining to various positions of said optical system; means for actuating said information storing means; and means for automatically shifting said optical system to an exposure position substantially midway between spaced-apart first and second positions in each of which said information storing means was actuated so that the photographic camera embodying the objective is ready to make an exposure of objects located within the depth of field range bounded by points upon which said system was focused in said first and second positions thereof.

4. An objective as defined in claim 3, further comprising an adjustable diaphragm and means for adjusting said diaphragm in response to shifting of said optical system to said exposure position.

5. An objective as defined in claim 4, wherein said shifting means includes resilient means.

6. An objective as defined in claim 4, wherein said optical system comprises a rotary member and further comprising a base member supporting said rotary member, said information storing means including first and second rings respectively supported by said rotary member and said base member, each of said rings being rotatable relative to the associated member and said actuating means including arresting means for interrupting the rotary movements of said rings, said shifting means including means for turning said rotary member to the extent determined by relative angular positions of said rings upon interruption of the rotary movement thereof.

7. An objective as defined in claim 6, wherein said means for turning said rotary member includes a spring, one of said rings having an arm and the other of said rings having abutment means in the path of movement of said arm, said spring being arranged to move said arm against said abutment means or vice versa on disengagement of one of said arresting means.

[57] **ABSTRACT**

In an automatic focusing system for a camera having an exchangeable lens, the camera body includes a control mechanism for controlling the focus of the exchangeable lens in accordance with an output of a photoelectric focus or distance detecting element. The control mechanism is interlocked by an intermediate elongated member with a lens displacing mechanism in the exchangeable lens, with the intermediate member extending within an aperture of the lens mount. The exchangeable lens may be of the type wherein a rear lens group is moveable for focusing.

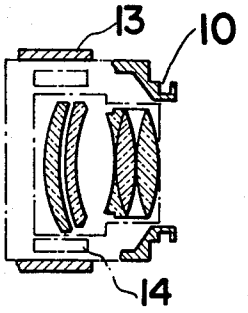

FIG.5

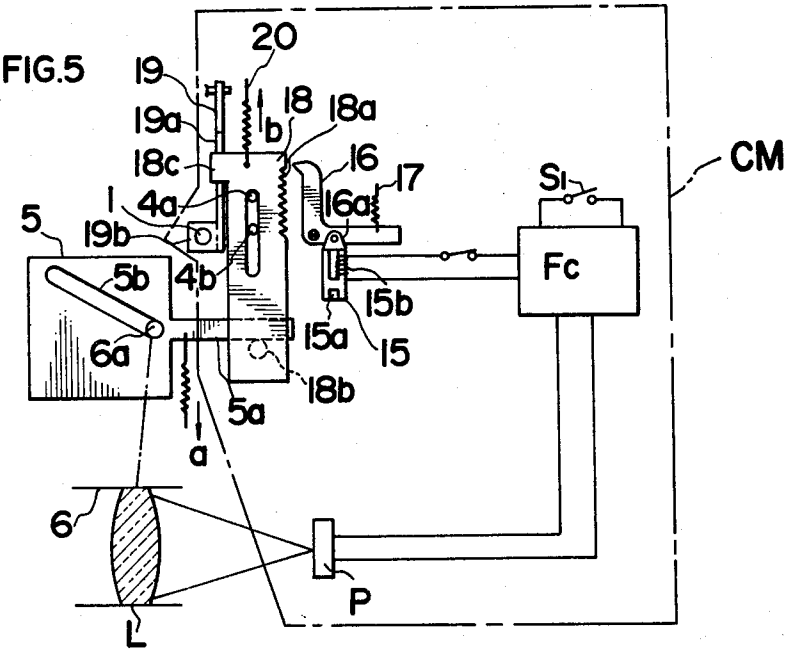

FIG.6

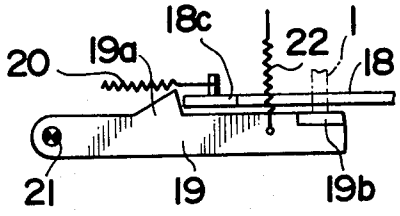

FIG.7

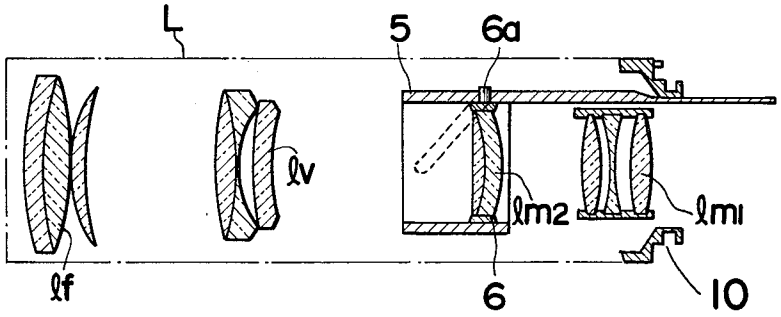

FIG.8

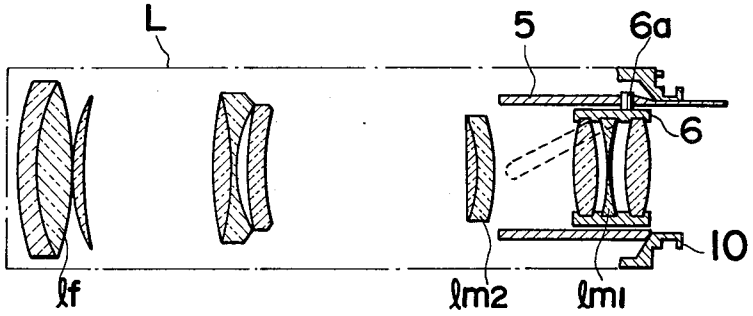

FIG.9

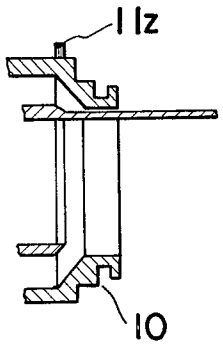

AUTOMATIC FOCUS CONTROL DEVICE FOR OBJECTIVE LENS EXCHANGEABLE CAMERAS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to an automatic focusing or focus control device for use in a camera with which exchangeable objective lenses are selectively and detachably mounted, and more particularly it pertains to a coupling mechanism between a focus control mechanism in the camera and a lens driving mechanism in the exchangeable objective.

2. Description of Prior Art

An automatic focusing device for an objective lens exchangeable camera has been proposed by a Japanese Laid-Open Patent No. 48-53718. In the known device, however, an objective lens is axially displaced by a lens mount which supports an objective lens and is moved along the optical axis of the objective. Because of its arrangement, such device is applicable only to a specific type of objective in which focusing is made by the entire lens system being integrally moved. In addition, it is difficult for such device to avoid increases of its weight and size because the lens mount and a bearing or support for it must be made large and steady in order to displace a comparatively heavy objective in a predetermined incremental displacement range (which is generally large in may interchangeable lenses) without tilting the optical axis of the objective.

Further difficulties may be encountered when such an automatic focus device is to be associated with an objective which, as is common with single lens reflex cameras, has a so-called automatic diaphragm aperture control device wherein, in response to a shutter release operation, the diaphragm is stopped down to an aperture value manually preset or an aperture value to be automatically determined in accordance with scene brightness. For example, a coupling pin interlocking a diaphragm mechanism in the objective with a camera mechanism has to be made long enough to maintain the interconnection even when an objective mount is displaced fowardmost to a hyperfocal position. On the other hand, the coupling pin must not interfer with any mechansim inside the camera, e,g, a reflex mirror for a single-lens reflex camera when the objective is displaced rearmost to an infinity (focused position). Thus, the known mechanism imposes great restrictions on the mechanisms incorporated in a camera or provided between the camera and the objective, and restricts the variety of combinations between camera bodys and exchangeable lenses.

SUMMARY OF THE INVENTION

Accordingly, the primary object of the present invention is to provide an automatic focusing device which may be used for an objective lens exchangeable camera but which is free from the above mentioned disadvantages inherent to the prior art structure.

Another object of the present invention is to provide an improved coupling or interlocking mechanism for controlling focus of an exchangeable lens by a mechanism incorporated in a camera body.

Still another object of the present invention is to provide an automatic focusing device for use in an objective lens exchangeable camera which enables a wide variation of the combination of camera and exchangeable lens.

A further object of the present invention is to provide an automatic focus control device which controls focusing of an exchangeable lens without moving the whole structure of the exchangeable lens.

BRIEF DESCRIPTION OF THE DRAWINGS

The above and other objects and features of the invention will appear more fully hereinafter from a consideration of the following description taken in connection with the accompanying drawing wherein exemplary embodiments are illustrated.

FIG. **1** is a schematic illustration of an embodiment of the present invention;

FIG. **2** shows schematically an optical system to be used with the device shown in FIG. **1**;

FIG. **3** is a partial enlarged sectional view of a switch operating pin of FIG. **2**;

FIG. **4** is a diagramatical sectional view of a manually focused exchangeable lens;

FIG. **5** is a schematic illustration of another embodiment of the present invention;

FIG. **6** is a side elavational view of a portion of the mechanism shown in FIG. **5**.

FIGS. **7** and **8** shows schematically exchangeable lenses to be used in the present invention.

FIG. **9** shows another embodiment of a switch operating pin.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

With reference to FIG. **1** showing a schematic diagram of a focus control mechanism according to an embodiment of the present invention, shutter release button **1** has on the top surface thereof a finger-touch responsive switch including electrodes **1***a* and **1***b* isolated by insulator **1***c*. Electrode **1***b* is connected through resistor **R1** to the positive electrode of battery Eo, and to the base of transistor **T1**, while electrode **1***a* is grounded to the camera body and connected to the negative electrode of battery Eo. To the collector of transistor **T1** are serially connected resistors **R2** and **R3** which constitute a voltage divider, with the node between resistors **R2** and **R3** connected to the base of amplifier transistor **T2**. Connected in series to the collector of transistor **T2** are resistors **R4** and **R5** for biasing the base of transistor **T3**. Transistor **T3** is used for energization, and its collector is connected through resistor **R6** to focus control circuit Fc. Light receiving element P detects the focusing condition of objective lens L, and it is located at a position optically equivalent to the film plane with respect to objective lens L. The output of light receiving element P is transferred to focus control circuit Fc. When objective lens L is in an out-of-focus condition, focus control circuit Fc operates to drive electric motor Mc.

When electric motor Me is driven, gear **2** rotates, causing slide plate **3** with tooth portion **3***a* to laterally move under the guide of pins **4***a* and **4***b* received in a slot of slide plate **3**. Pin **3***b* is spring-biased in the direction of arrow a, engaging coupling arm **5***a* of lens drive ring **5**. Coupling arm **5***a* is then moved laterally or rotationally inside a mount on the lens barrel, and at the same time inside the opening of an objective mount on camera body Cm, whereby the rotational position of lens drive ring **5** is determined in accordance with the position of slide plate **3**. Formed on lens drive ring **5** is

cam groove **5***b*, which in turn receives pin **6***a* interconnected with objective lens L. Thus rotation of the lens drive ring **5** moves lens frame **6** along the optical axis, which hold a lens group of objective lens L to be moved for focusing and when objective lens L is in focus, focus control circuit Fc stops electric motor Mc, whereby the movement of the lens group is stopped. FIG. **2** shows an optical system of the above mentioned embodiment in more detail as, for example, used in a single-lens reflex camera. Referring to FIG. **2**, light coming from a scene to be photographed and passing through objective lens L of standard focal length is reflected at reflex mirror **7** and introduced through condenser lens **8** and pentagonal prism **9** to eyepiece E, and at the same time is focused on light receiving element P by means of concave semi-transparent mirror **8***a* in condenser **8**. Thus, the light receiving surface of light receiving surface of light receiving element P is at the position optically equivalent to the focal plane (film plane). Objective lens L is mounted on camera body Cm with mount **10** of the lens coupled with the objective mount of the camera (not shown). Signal pin **11** is forced by spring **12** to project rearward, as shown in enlarged size in FIG. **3**, and when objective lens L is coupled to camera body, Cm signal pin **11** extends into the hole formed at a given place on camera body Cm to close power switch So. It should be noted that in case the objective L is coupled with camera body Cm through a bayonet type objective mount with which the coupling between object lens L and camera body Cm is secured by rotating objective lens L for a predetermined angle after their mounting and the objective mount have been fitted together, signal pin **11** remains pushed inside a lens barrel against the action of spring **12** until objective lens L is rotated into a predetermined angular position.

With objective lens L attached to camera Cm body, signal pin **11** closes power switch So, causing focus control circuit Fc to be operative. When the operator touches shutter release button **1** looking into a viewfinder through eyepiece E to aim at any desired object, transistor T1 turns on, causing power of battery Eo to be applied through output transistor T3 to focus control circuit Fc and light receiving element P. As a result, electric motor Mc is driven, causing lens frame **6** to be moved via coupling arm **5***a* for focusing. When objective lens L reaches focus condition, electric motor Mc is stopped and the movable lens group of objective lens L is set at a focusing position.

As shown in FIG. **4**, when a manual type objective lens, in which a lens group is displaced through helicoid **14** by manual rotation of a distance adjusting ring not shown without using a connecting arm and a signal pin, is attached to a camera having the focus control mechanism, power switch So is not closed by a signal pin, and focus control circuit Fc remains inoperative. In this case, manual focusing may be possible using a distance adjusting ring or manual focusing ring.

FIG. **5** shows another embodiment concerning a focus control mechanism, wherein the same reference symbols are used for the members corresponding to those of FIG. **1**, and description thereof is omitted. With reference to FIG. **5**, power switch S1 may be of a finger-touch responsive type or constructed such that it is closed at the early stage of a shutter release button depression. Electromagnetic member **15** has permanent magnet **15***a* which normally attracts armature **16***a* of stop lever **16**. When electromagnetic coil **15***b* is energized by an output from focus control circuit Fc, the magnetic force field of the permanent magnet is counterbalanced by the magnetic field caused in the coil **15***b*, allowing stop lever **16** to rotate counterclockwise under the action of spring **17**. Slide plate **18** corresponding to slide plate **3** in FIG. **1** has toothed or serrated portion **18***a* on its side with which claw **16***b* of stop lever **16** is engaged. Slide plate **18** is slidable laterally, i.e. vertically as viewed in FIG. **5** under the guide of guide pins **4***a* and **4***b*. Coupling pin **18***b* corresponds to the pin **3***b* in FIG. **1**. With the camera shutter being cocked, ear portion **18***c* engages triangular projection **19***a* of engaging lever **19**, to restrain slide plate **18** at a charging position against the action of spring **20**. Restraining lever **19** is pivoted on stud **21** and is urged by spring **22** in a counterclockwise direction, as viewed in the side elevational view in FIG. **6**. One side of triangular projection **19***a* opposite to the movement of slide plate **18** under the action of spring **20** has a steep incline, while the other side has a gentle incline so that projecting portion **18***c* of slide plate **18** may climb over triangular projection **19***a* when slide plate **18** is returned to its charging position by means of a mechanism (not shown) in response to a charging operation.

Furthermore, bent portion **19***b* of engaging lever **19** is located under shutter release button **1**, so that it may turn about stud **21** to disengage slide plate **18** from triangular projection **19***a* at a final stroke of shutter release button depression.

With the above arrangement, when shutter release button **1** is touched or lightly depressed, power switch S1 is closed, and with shutter release button **1** further depressed, bent portion **19***b* of engaging lever **19** is depressed down, causing slide plate **18** to be disengaged from its restrained condition and laterally moves under the action of spring **20**, whereby movable frame **6** of objective lens L is displaced along the optical axis of the camera objective for focusing. When light receiving element P detects the best focus condition, electromagnetic coil **15***b* of electromagnetic member **15** is energized by focus control circuit Fc, and stop lever **16** is rotated by spring **17** counterclockwise, with claw **16***a* engaging a tooth of slide plate **18**. As a result, movable frame **6** of objective lens L is stopped at a best focus position. Subsequently, the diaphragm stopped-down operation and mirror retraction are initiated in response to the rotation of stop lever **16**, and upon completion of the operations thereof, the shutter is released by means of a known mechanism (not shown).

FIGS. **7** and **8** show desirable types of objective lenses for use in the embodiments of the present invention. The objective lens shown in FIG. **7** is of a variable magnification lens type, as disclosed in Japanese Laid-Open Patent No. 50-92127, in which lens group lm2 of rear master lens groups lm1 and lm2 is moved for focusing while variator lens group lv is moved for focal length variations. As described earlier, displacement ring **5** has coupling arm **5***a*, and movable frame **6** holds movable master lens group lm2 and is provided with pin **6***a* received in a cam slot of ring **5**. This type of lens system can contain a number of lenses, and although it is long in overall length, a coupling mechanism for automatic focus control can be made simple. In addition, this lens system requires no mechanical compensation means for compensating for the change of focusing since focusing is made by an automatic focusing mechanism even as the focal distance is varied by moving variable magnification lens group lv. Furthermore, this type is advantageous in that the diameter of front lens

group lf may be made smaller in comparison with a conventional front lens group displacement focusing type.

The objective lens shown in FIG. 8 is a telephoto type lens in which focusing is made by moving one, e.g. lml of rear master lens groups lm1 and lm2 along the optical axis of the camera objective. The present invention can be easily applied to even a telephoto lens when it is of the above type. In FIG. 8, the same reference symbols are used for the members corresponding, in operation, to those of FIG. 7.

A slight modification of the above embodiment is shown in FIG. 9, wherein a signal pin a fixed on the outer circumference of a lens barrel at its rear end, and when an objective lens is rotated for a predetermined length relative to a camera body for the lens and camera body to be coupled with each other in position, power switch So may be closed by the signal pin. Needless to say, cameras to which the present invention is applicable are not limited to the single-lens reflex type, and they may be of a rangefinder type and other types as long as they are objective lens lens exchangeable cameras. As in the above embodiments, furthermore, coupling mechanisms between an objective lens and a camera body are not limited to the above depicted mechanism composed of an operating ring, a connecting arm and a slide plate, but any coupling member that functions like the connecting arm may be used as far as it can pass through the opening of a camera's objective mount when an objective lens and a camera body are coupled each other in position. For example, pinions or friction wheels may be provided at both ends of the connecting member for connection to a focus control mechanism in the camera body and a lens displacement mechanism in the objective lens.

What is claimed is:

1. An automatic focusing system for an objective lens exchangeable camera, comprising: an exchangeable lens having a lens group movable for focusing the lens; a fixed member with a mount for mounting said exchangeable lens on said camera, and a lens drive member movable relative to said fixed member for driving said lens group along the optical axis thereof, said mount including an aperture; a camera body including a movable member movable to any position corresponding to any position of said movable lens group, and means for determining the position of said movable member;/an intermediate member for interconnecting said movable member and said lens drive member upon coupling of said exchangeable lens with said camera body such that the position of said movable member determines the position of said movable lens group, said intermediate member being included in said exchangeable lens and extending through said aperture of said lens mount, said movable member including an abutting member abutting with said intermediate member from one direction to form one-directional engagement therewith; and

biasing means for abutting said intermediate member and said abutting member.

2. An automatic focusing system as claimed in claim 1 wherein said intermediate member includes an elongated member provided in said objective lens to move in the plane normal to the optical axis of said lens and extending in the direction of said optical axis.

3. An automatic focusing system as claimed in claim 2 further comprising a light receiving means for detecting the focus condition of said exchangeable lens and an electric circuit for controlling the position of said movable member in accordance with the output of said light receiving means, and said exchangeable lens further includes a signal means for enabling said electric circuit when said exchangeable lens is coupled with said camera body.

4. An automatic focusing system as claimed in claim 3 wherein said electric circuit includes a power switch and said signal means includes means for closing said power switch upon coupling of said exchangeable lens with said camera body.

5. An automatic focusing system as claimed in claim 4 further comprising means for actuating said power switch in response to a finger operated touch mechanism on the camera body.

6. An automatic focusing system as in claim 1 wherein said intermediate member is interconnected with said movable member upon coupling of said exchangeable lens with the camera body and further comprising cam means for transmitting movement of said intermediate member to said movable lens group such that the lateral position of said movable member determines the axial position of said movable lens group.

[57] **ABSTRACT**

An optical objective, usable for reproduction as well as for photographic and cinematographic purposes, consists of five components—two on the object side and three on the image side of a diaphragm space—constituted by a total of seven meniscus-shaped lenses all of whose surfaces are concave toward the diaphragm space, the first object-side component and the middle image-side component being negatively refracting doublets. The objective is bodily movable for focusing purposes and its two object-side components are correlatedly axially shiftable to minimize aberrations over a wide range of magnification ratios.

FIG. 1

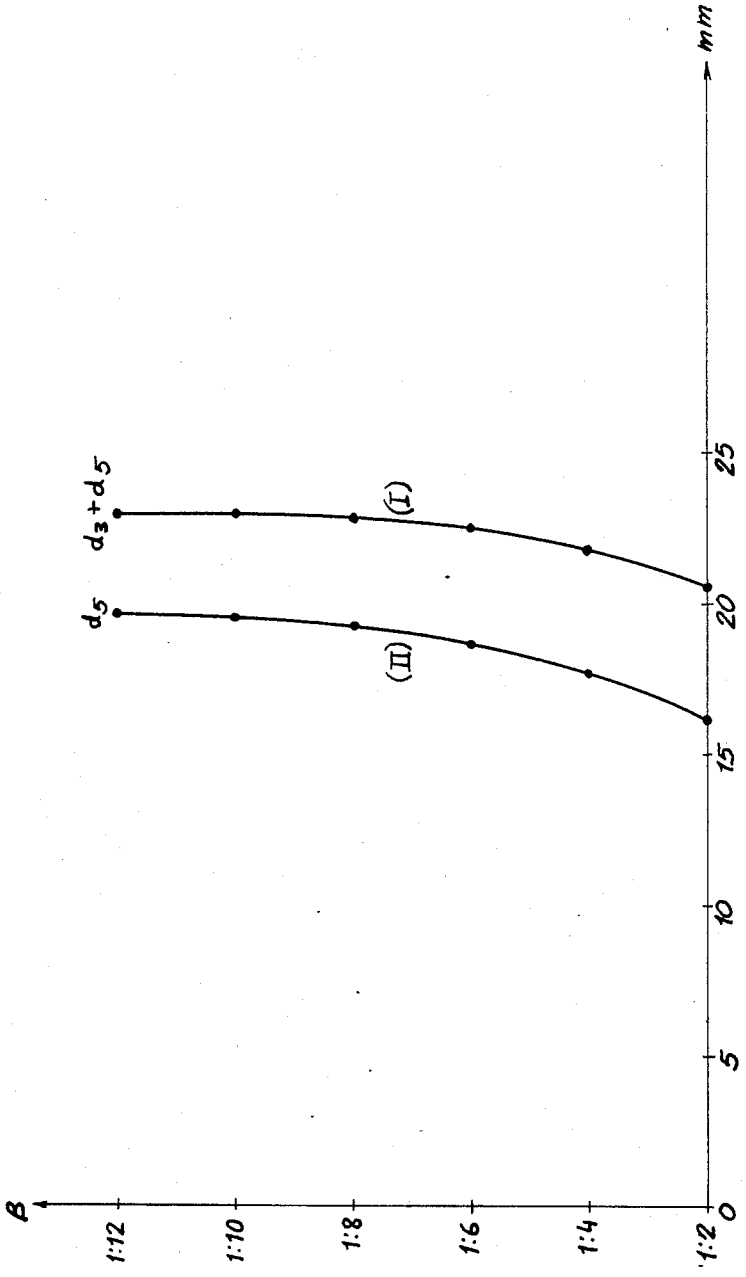

FIG. 2

OPTICAL OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to an optical objective adapted to be used for reproduction of documents or the like as well as for photographic and cinematographic purposes.

BACKGROUND OF THE INVENTION

A known reproduction objective consists of two front components and three rear components separated by an intervening diaphragm space, i.e. a negatively refracting first component and a positively refracting second component on the object side and a positively refracting third component, a negatively refracting fourth component and a positively refracting fifth component on the image side of that space. The two negatively refracting components may be doublets, each composed of two lenses of opposite refractivity, while the others are singlets.

In such an objective it is important to provide satisfactory correction of optical abberrations over the entire field of view, at least for a particular magnification ratio with which it is to be used. When this ratio is subject to variation, the requirements become more stringent.

OBJECT OF THE INVENTION

The object of my present invention, therefore, is to provide an optical objective of this type which can be used over a wide range of magnification ratios with a relatively large aperture, preferably as high as 1:3.5.

SUMMUARY OF THE INVENTION

In accordance with one aspect of my present invention, the constituent lenses of a five-component objective as described above are so dimensioned that their individual focal lengths have absolute magnitudes which, progressing from the first to the fifth component, are related to one another in the ratio of substantially 7.5:1.1:2.7:9.7:1.6, each lens being bounded by spherically curved surfaces which are concave toward the diaphragm space. These individual focal lengths may also be expressed, in terms of the overall focal length F of the objective, by

$$f_I \approx -7.5F,\ f_{II} \approx +1.1F,\ f_{III} \approx +2.7F,\ f_{IV} \approx -9.7F,\ f_V \approx +1.6F.$$

I have found that such an objective, which is bodily movable for focusing purposes between the object plane and the image plane of a reproduction camera, is well corrected for a certain magnification ratio, e.g. of about 1:5, as determined by the positions of these planes in relation to the focal points of the objective. With other magnification ratios above and below this value, however, distortions are encountered which can be corrected, pursuant to a further feature of my invention, by axially shifting the first and second components at different rates but in a correlated manner. More particularly, these components are to be displaced codirectionally, with the first component moving more slowly than the second. Such correlated shifting, pursuant to my invention, could also be used in a differently dimensioned objective of this general type.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 is a diagrammatic view of an objective embodying my invention; and

FIG. 2 is a graph showing the relative motion of the two front components of the objective with variations in the magnification ratio.

SPECIFIC DESCRIPTION

In FIG. 1 I have shown an objective consisting of five components I, II, III, IV and V. Component I is a negatively refracting doublet consisting of a positive lens L_1, with radii r_1, r_2 and thickness d_1, and of a negative lens L_2, with radii r_2, r_3 and thickness d_2. A limitedly variable air space d_3 separates this doublet from component II which is a single positive lens L_3 with radii r_4, r_5 and thickness d_4. Component III, separated from component II by a diaphragm space d_5 which is also limitedly variable, is a similar singlet L_4 with radii r_6, r_7 and thickness d_6. After a fixed air space d_7 there follows component IV which is also a negatively refracting doublet, consisting of a negative lens L_5 (radii r_8, r_9 and thickness d_8) cemented onto a positive lens L_6 (radii r_9, r_{10} and thickness d_9). A further fixed air space d_{10} lies between components IV and V, the latter being again a positive singlet with radii r_{11}, r_{12} and thickness d_{11}. The cemented surfaces r_2 and r_9 are only weakly refractive.

All lenses L_1–L_7 are menisci withe surfaces concave toward diaphragm space d_5 so that their radii have positive sign ahead of that space and negative sign beyond it. A diaphragm D within space d_5 is separated from lens L_3 by a distance d_5' and from lens L_4 by a distance $d_5'' = d_5 - d_5'$. Components I and II may be coupled together by a conventional camming sleeve, not shown, having guide grooves for correlatedly displacing them.

Based upon an overall focal length F of unity value, the radii r_1–r_{12} and the thicknesses and separations d_1–d_{11} of lenses L_1–L_7 have numerical values as given in the following Table A which also lists their refractive indices n_e and Abbé numbers ν_e together with their surface powers $\Delta n/r$.

TABLE A

Lenses	Radii	Thicknesses and Separations	n_e	ν_e	$\frac{\Delta n}{r}$
	$r_1 = +0.311$				$+2.01$
L_1		$d_1 = 0.110$	1.625	56.6	
	$r_2 = +7.784$				-0.005
L_2		$d_2 = 0.084$	1.584	40.6	
	$r_3 = +0.207$				-2.82
		$d_3 = 0.026$	(variable)		
	$r_4 = +0.311$				$+2.20$
L_3		$d_4 = 0.030$	1.685	47.9	
	$r_5 = +0.498$				-1.37
		$d_5 = 0.121$	(variable)		
	$r_6 = -0.912$				-0.75
L_4		$d_6 = 0.023$	1.685	47.9	
	$r_7 = -0.622$				$+1.10$
		$d_7 = 0.030$			
	$r_8 = -0.181$				-3.48
L_5		$d_8 = 0.026$	1.629	35.3	
	$r_9 = -1.243$				-0.03
L_6		$d_9 = 0.056$	1.670	48.1	
	$r_{10} = -0.230$				$+2.91$
		$d_{10} = 0.033$			
	$r_{11} = -1.095$				-0.57
L_7		$d_{11} = 0.033$	1.622	60.0	

TABLE A-continued

Lenses	Radii	Thicknesses and Separations	n_e	ν_e	$\frac{\Delta n}{r}$
	$r_{12} = -0.536$				$+1.16$

On the same basis the individual focal lengths f_I–f_V of components I–V have the numerical values of -7.5, $+1.1$, $+2.7$, -9.7 and $+1.6$, respectively. This objective has a relative aperture of 1:3.5 and, at maximum diaphragm opening, is very well corrected throughout its field of view with a magnification ratio which may range from 1:2 to 1:12, provided that fractional adjustments are made in the air spaces d_3 and d_5.

The following Table B gives the optimum values of spaces d_3 and d_5 for six different magnification ratios β in an objective as shown in FIG. 1. These spacings have also been graphically represented in FIG. 2 which clearly shows that components I and II shift codirectionally, with the former moving more slowly than the latter. The diaphragm D is separated from lens L_4 by a distance d_5'' of 0.061.

TABLE B

β	d_3	d_5	$d_3 + d_5$
1:12	0.021	0.130	0.151
1:10	0.022	0.129	0.151
1:8	0.023	0.127	0.150
1:6	0.025	0.124	0.149
1:4	0.027	0.117	0.144
1:2	0.030	0.106	0.136

The actual value of focal length F may be 150 mm. For the taking of photographic or cinematographic pictures with bodily shifting of the entire objective for focusing purposes, the components are advantageously left in the relative position given for $\beta = 1:12$. The values for d_3 and d_5 given in Table A are for $\beta = 1:5$; the overall shift of components I (d_3+d_5) and II (d_5) amounts to 0.009F and 0.015F, respectively.

I claim:

1. An optical objective consisting of a negatively refracting first component, a positively refracting second component, a positively refracting third components, a negatively refracting fourth component and a positively refracting fifth component, said second and third components being separated by a diaphragm space, said first and second components being coupled for correlated codirectional axial shifts at a relatively slow and a relatively fast rate, respectively, to minimize optical aberrations with different magnification ratios.

2. An optical objective consisting of a negatively refracting first component, a positively refracting second component, a positively refracting third component, a negatively refracting fourth component and a positively refracting fifth component, said components being constituted by meniscus-shaped lenses which are bounded by spherically curved surfaces all concave toward an intervening space separating said second and third components,

said first, second, third, fourth and fifth components having respective individual focal lengths whose absolute magnitudes are related to one another in the ratio of substantially 7.5:1.1:2.7:9.7:1.6.

3. An objective as defined in claim 1 or 2 wherein said first component is a doublet consisting of a positive lens L_1 and a negative lens L_2, said second and third components being single lenses L_3 and L_4, said fourth component being a doublet consisting of a negative lens L_5 and a positive lens L_6, said first component being a single lens L_7.

4. An objective as defined in claim 3 wherein said lenses L_1 to L_7 have radii r_1 to r_{12} and thicknesses and separations d_1 to d_{11} whose numerical values, based upon a value of unity for the overall focal length of the objective, together with their refractive indices n_e and their Abbe numbers ν_e are substantially as given in the following table:

lenses	radii	thicknesses and separations	n_e	ν_e
L_1	$r_1 = +0.31$			
		$d_1 = 0.11$	1.63	57
	$r_2 = +7.78$			
L_2		$d_2 = 0.08$	1.58	41
	$r_3 = +0.21$			
		$d_3 = 0.03$		
L_3	$r_4 = +0.31$			
		$d_4 = 0.03$	1.69	48
	$r_5 = +0.50$			
		$d_5 = 0.12$		
L_4	$r_6 = -0.91$			
		$d_6 = 0.02$	1.69	48
	$r_7 = -0.62$			
		$d_7 = 0.03$		
L_5	$r_8 = -0.18$			
		$d_8 = 0.03$	1.63	35
	$r_9 = -1.24$			
L_6		$d_9 = 0.06$	1.67	48
	$r_{10} = -0.23$			
		$d_{10} = 0.03$		
L_7	$r_{11} = -1.10$			
		$d_{11} = 0.03$	1.62	60
	$r_{12} = -0.54$			

5. An objective as defined in claim 2, usable for photographic reproductions, wherein said first and second components are coupled for correlated codirectional axial shifts at a relatively slow and a relatively fast rate, respectively, to minimize optical aberrations with different magnification ratios.

6. An objective as defined in claim 4 wherein said first and second components are correlatedly shiftable to vary their air spaces d_3 and d_5 in opposite senses by up to about 0.015 times said overall focal length.

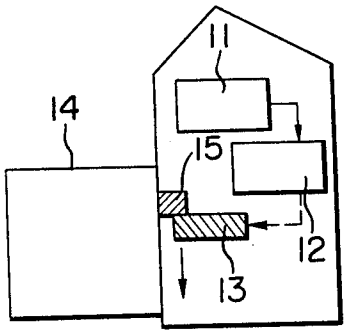

FIG. 2

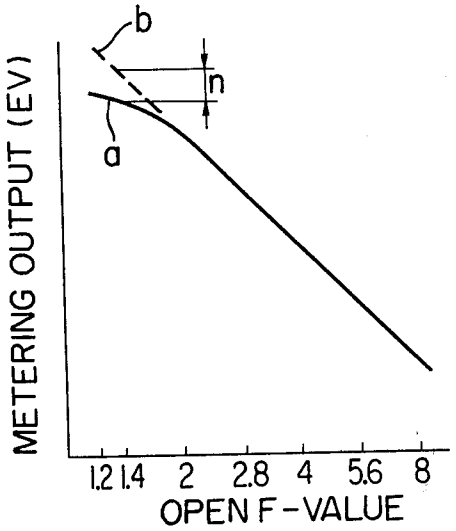

FIG. 3

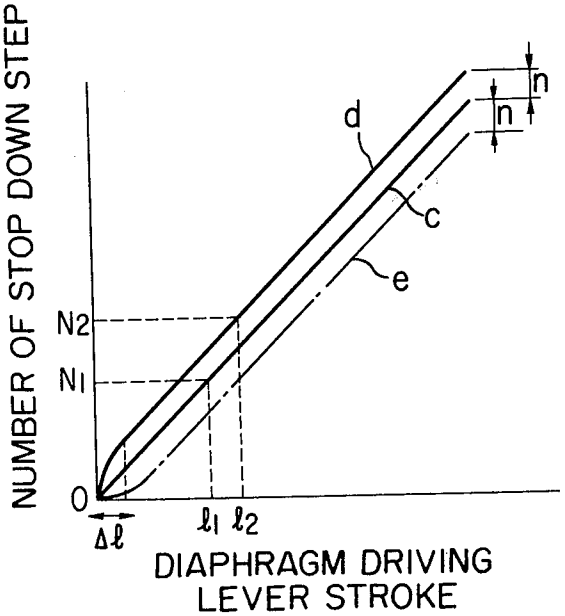

FIG. 4

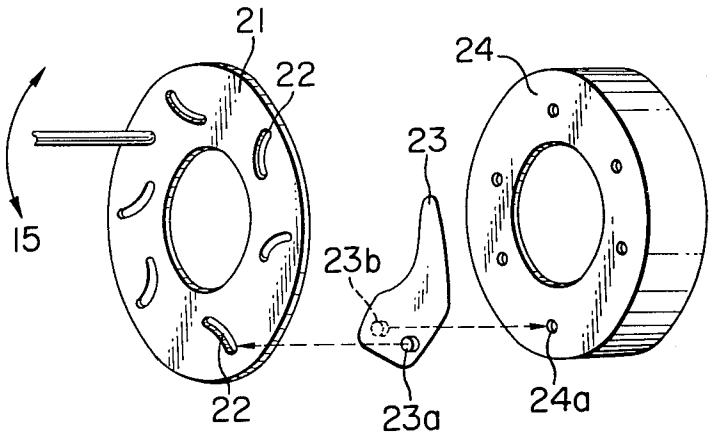

FIG. 5

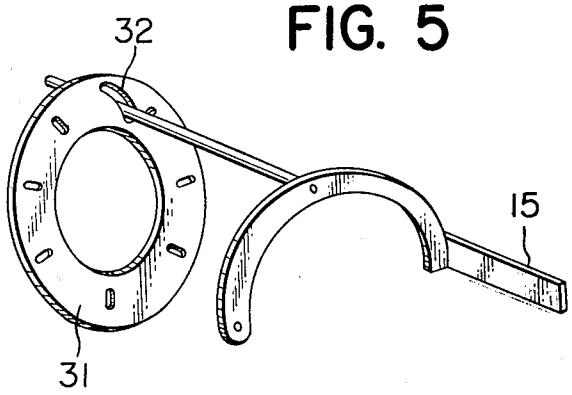

FIG. 6

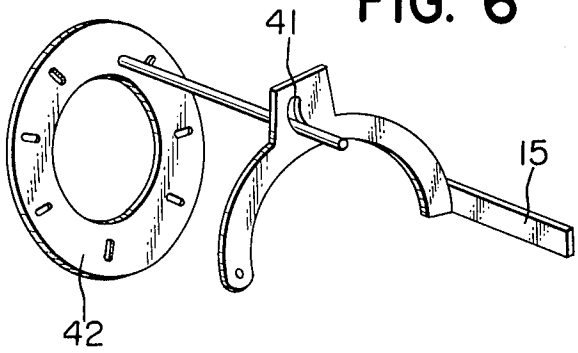

DIAPHRAGM CORRECTING MEANS OF AN OBJECTIVE LENS MOUNTED ON A SINGLE LENS REFLEX CAMERA OF THE TTL FULL APERTURE EXPOSURE MEASUREMENT TYPE

BACKGROUND OF THE INVENTION

1. Field of The Invention

This invention relates to diaphragm correcting means of an objective lens mounted on a single lens reflex camera of the TTL full aperture exposure measurement type. The expression—full aperture exposure measurement—refers to a system for measuring the light transmitted through the objective lens when the lens aperture is fully opened.

2. Description of the Prior Art

In a single lens reflex camera of the TTL full aperture exposure measurement type wherein, for example, shutter speed priority automatic exposure control is effected, the preset diaphragm ring of the lens is set to a position in which a minimum aperture may be obtained to enable the stop-down of the diaphragm from its maximum aperture to its minimum aperture. Then, it is required to stop down the diaphragm from its maximum aperture to a proper aperture value determined by a preset shutter speed, film sensitivity, brightness of an object, etc. The metering output of a metering circuit included in the automatic exposure control circuit of TTL full aperture exposure measurement type of such a single lens reflex camera is substantially proportional to the area of the aperture formed by the diaphragm, but in lenses having a small open F-value such as F/1.2 or F/1.4, the aforementioned proportional relationship tends to become imprecise in the vicinity of the maximum aperture to thereby reduce the metering output. As the reason therefore, mention may be made of a reduction in the quantity of marginal light of the lens, and the characteristic of the construction of the metering optical system; for example, the fact that the greater the maximum aperture of the objective lens, the more difficult it is for a condenser lens of the metering optical system to condense the marginal light of the lens. In the case of the TTL full aperture exposure measurement, such imprecision of the mentioned proportional relationship appears directly as an exposure error. To correct such exposure error attributable to the open F-value of the lens, German Patent No. 1,258,727 discloses a technique in which a correcting cam is operatively associated with the preset diaphragm ring of the lens and an exposure meter needle is corrected and displaced by a lever following the correcting cam. This technique is effective in the case of an aperture priority system in which the photographer presets the aperture value and determines the diaphragm aperture by an aperture ring interlock member, but is not effective in the case of a shutter speed priority system in which a lever on the camera housing side determines the area of the aperture opening through a diaphragm driving lever on the lens side.

SUMMARY OF THE INVENTION

I have conceived and contribute by the present invention, correcting means for an objective lens adapted to be mounted on a single lens reflex camera of the TTL full aperture exposure measurement type which permit one to effect the aforementioned correction on the lens side without affecting the error of the metering output.

There has thus been outlined rather broadly the more important features of the invention in order that the detailed description thereof that follows may be better understood and in order that the present contribution to the art may be better appreciated. There are, of course, additional features of the invention that will be described hereinafter and which will form the subject of the claims appended hereto. Those skilled in the art will appreciate that the conception upon which this disclosure is based may readily be utilized as a basis for the designing of other structures for carrying out the several purposes of the invention. It is important, therefore, that the claims be regarded as including such equivalent constructions as do not depart from the spirit and scope of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

Specific embodiments of the invention have been chosen for purposes of illustration and description, and are shown in the accompanying drawings, forming a part of the specification wherein:

FIG. **1** shows a conceptual construction of a shutter priority type automatic exposure control camera;

FIG. **2** illustrates the relationship between the metering output of a metering circuit and the open F-value of each interchangeable lens;

FIG. **3** illustrates the relationship between the displacement of a diaphragm driving lever and the number of stop down steps; and

FIGS. **4**, **5**, and **6** illustrate embodiments which show the location whereat a correcting cam is installed.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. **1** shows a conceptual construction of a shutter speed priority type automatic exposure control camera wherein an automatic exposure control circuite **11**, including a metering circuit, measures the light transmitted through a lens when a diaphragm forms a maximum aperture, and produces an output corresponding to an aperture value determined by a preset shutter speed and film sensitivity. An aperture control mechanism **12**, in response to shutter release, displaces an interlock lever **13** from an initial position corresponding to said maximum aperture to a position corresponding to the output of the auotmatic exposure control circuit **11**. A diaphragm driving lever **15** connected to the diaphragm of a lens **14** is displaced following the interlock lever **13**, to stop down the aperture. The stop down is stopped at a position whereat the displacement of the interlock layer **13** is stopped. In this manner, the shutter speed priority automatic exposure control may be accomplished. Of course, the positional relationship between the interlock lever **13** and the diaphragm driving lever **15** is pre-adjusted so as to be convenient for the exposure control. FIG. **2** illustrates in a logarithmic graph the relationship between the metering output (EV display) of the metering circuit included in the automatic exposure control circuit **11** and the open F-value of each interchangeable lens when the object brightness and the set shutter speed and film sensitivity are constant. From the output characteristic curve *a* of FIG. **2** showing the actual metering output, it is seen that the metering output is not proportional to the area of the aperture opening in lenses having great open apertures such as lenses of F/1.2 or F/1.4. For example, in a lens having an open F-value of F/1.4, it is seen from the theoretical output characteristic curve *b* in which

the area of the aperture opening at the open F-value of each interchangeable lens is proportional to the metering output and from the output characteristic curve *a* showing the actual metering output that the actual metering output is lower than the theoretical metering output by *n* steps (N<1).

Such reduction in output by *n* steps is to be corrected. The correction will hereinafter be described in detail.

In FIG. **3**, *c* is the characteristic curve representing the stroke of the diaphragm driving lever and the number of steps of aperture value variation of a lens having an open F-value of F/2, namely, according to FIG. **2**, a lens in which the theoretical metering output is coincident with the actual metering output. The curve *d* is the characteristic curve representing the stroke of the diaphragm driving lever **15** and the number of steps of aperture value variation of a lens having an open F-value of F/1.4, namely, according to FIG. **2**, a lens in which the actual metering output is reduced by *nEV* from the theoretical metering output. As compared with *c*, *d* is such that the number of steps of aperture value variation at the same stroke is stopped down by the aforementioned *n* steps more in EV value from the vicinity of the open aperture to the minimum diaphragm aperture.

Now, assume that there is an object for which the aperture value F/4 is a proper exposure under a certain shutter speed. At this time, when full aperture expsoure measurement is effected through a lens having an open F-value of F/2, the interlock lever **13** is positioned by the automatic exposure control circuit **11** and the aperture control mechanism **12** so that the diaphragm driving lever **15** can be displaced by a stroke l_1 to stop down the aperture by $N_1=2$ is stopped down by two steps from the open aperture. Thus, the aperture is stopped down by two steps from the open F-value F/2 along the characteristic curve *c* and controlled to F/4. On the other hand, when full aperture exposure measurement is effected on the same object by the use of a lens having an open F-value of F/1.4, the automatic exposure control circuit **11** judges the number of stop down steps to be (3−n) steps and controls the interlock lever **13** through the aperture control mechanism **12** so that the diaphragm driving lever **15** can be displaced by a stroke l_2 to stop down the aperture by (3−n) steps from the open aperture. However, since the stroke of the diaphragm driving lever of the lens having an open F-value of F/1.4 is set as shown by the characteristic curve *d* of FIG. **3**, the actual number of the stop down steps is $N_2=(3-n)+m=3$ and after all, the aperture is stopped down by three steps from the open F-value of F/1.4 and controlled to F/4. Thus, proper exposure is obtained.

If the above-described correction is also made on other interchangeable lenses having great open apertures such as F/1.2, proper exposure control may be secured even for these interchangeable lenses. The stroke characteristic of FIG. **3** need not always be linear. Also, if the stroke characteristic of a lens having an open F-value of F/2 is such as indicated by *e*, the stroke characteristic of a lens of F/1.4 may of course be such as indicated by *c*. That is, design should only be made such that the difference in the number of stop down steps is *n* for the same stroke.

As shown in FIG. **3**, the difference in the number of stop down steps between the characteristic curve *d* and the characteristic curve *c* is small between the stroke O and Δ1 and the difference in the number of stop down steps approaches *n* from 0 as the stroke becomes Δ1 from 0. This is a measure taken because the aperture of each lens must be fully open or maximum in the position in which the aperture lever stroke is 0. Even if so constructed, the exposure error of the lens having the characteristic curve *d* can be suppressed to ½ to ⅓ step in the vicinity of the open or maximum aperture and so, there is no practical problem.

The number of stop down steps and the stroke characteristic of the diaphragm driving lever **15**, as described above, may be obtained by providing a correcting cam in the drive transmission path leading from the diaphragm driving lever **15** to the diaphragm. FIGS. **4** to **6** illustrate embodiments showing the location whereat the correcting cam is installed. In FIG. **4**, the correcting cam **22** is provided on a diaphragm driving ring **21** rotated by the diaphragm driving lever **15**. A diaphragm blade **23** has a pin **23***a* provided on the surface thereof adjacent to the diaphragm driving ring **21** fitted in the correcting cam **22** and a pin **23***b* provided on the back surface thereof and fitted in a hole **24***a* formed in a fixed ring **24**, and when the diaphragm driving ring **21** is rotated, the diaphragm blade **23** is controlled through the correcting cam **22** as shown by the characteristic curve *d* of FIG. **3**. The correcting cam **22** may be provided on the diaphragm balde **23** or the fixed ring **24**.

In FIG. **5**, the correcting cam **32** is provided on a diaphragm driving ring **31** and the rotation of the diaphragm driving ring **31** itself is controlled by the diaphragm driving lever **15**, as shown by the aforesaid characteristic curve *d*. In FIG. **6**, the correcting cam **41** is provided no the diaphragm driving lever **15** and a diaphragm driving ring **42** is rotated through the correcting cam **41**, whereby control is effected as shown by the characteristic curve *d*. The shape of the correcting cam **22**, **32** or **41** may be easily designed by those skilled in the art and need not be described in detail.

According to the present invention, as has hitherto been described, there is provided an objective lens in which aperture correcting means for imparting a correction of the stop down step number corresponding to the difference between the theoretical metering output calculated from the open F-value of the lens and the object brightness and the actual metering output, to the relationship between the displacement of the means for driving the diaphragm of the objective lens and the variation in area of the aperture opening, is provided on at least one of the diaphragm driving means and the diaphragm member. Therefore, if the objective lens provided with the correcting means is mounted on a single lens reflex camera of the TTL full aperture exposure measurement type, proper exposure may be obtained irrespective of the magnitude of the open F-value.

I believe that the construction and operation of my novel diaphragm connecting means of an objective lens mounted on a single lens reflex camera of the TTL full aperture exposure measurement type will now be understood and that the advantages thereof will be fully appreciated by those persons skilled in the art.

I claim:

1. In an objective lens removably mountable with respect to a single lens reflex camera housing, said lens having a diaphragm member forming an aperture, and diaphragm driving means displaceable to stop down said diaphragm member in a range over which the area of said aperture is from maximum to minimum, said

housing having a metering circuit for measuring the light transmitted through said lens when said aperture is maximum, the improvement comprising:

diaphragm correcting means provided on at least one of said diaphragm driving means and said diaphragm member to impart a correction of the stop down step number corresponding to the difference between a theoretical metering output calculated from the open F-value of said lens and the brightness of an object and the actual metering output of said metering circuit.

2. The objective lens according to claim **1**, wherein said camera has interlock means responsive, when said lens is mounted, to shutter release operation to displace the diaphragm driving means of said lens, and said diaphragm driving means includes a first member engaged with said interlock means, and a second member engaged with said first member and said diaphragm member.

3. The objective lens according to claim **2**, wherein said diaphragm correcting means is a cam provided at the portion of engagement between said second member and said diaphragm member.

4. The objective lens according to claim **2**, wherein said diaphragm correcting means is a cam provided at the portion of engagement between said first member and said second member.

5. In an objective lens removably mountable with respect to a single lens reflex camera housing, said lens having a diaphragm aperture control mechanism and said housing having a metering circuit for measuring the light transmitted through said lens when said diaphragm aperture is maximum, automatic exposure control means for calculating a proper diaphragm aperture based on output from the metering circuit and a member interlocking with the shutter release operation and a displaceable corresponding to output from said exposure control means,

the improvement wherein:

said aperture control mechanism includes diaphragm means for defining the diaphragm aperture, means for driving the diaphragm means from said maximum aperture to said proper aperture, the amount of displacement of said driving means being defined by the amount of displacement of said interlocking member, and means for transmitting driving force from said driving means to said diaphragm means, said force transmitting means comprising means for correcting the amount of displacement of said diaphragm means in correspondence with the difference between a theoretical metering output calculated from the open F-value of the lens and the brightness of an object and the actual metering output of said metering circuit.

6. The structure according to claim **5**, wherein the amount of correction by said correcting means is continuously increased from the maximum diaphragm aperture to a predetermined diaphragm aperture and is constant from the predetermined diaphragm aperture to the minimum aperture.

7. The structure according to claim **6**, wherein said driving force transmitting means includes a ring formed with a plurality of slots;

said diaphragm means includes pins engaging the respective slots, said ring being rotatable in association with the displacement of said diaphragm driving means so that said diaphragm means varies said diaphragm aperture through said pins; and

said correcting means is formed by a cam-shaped contour of each slot.

8. The structure according to claim **6**, wherein said driving force transmitting means includes a ring formed with a plurality of slots; said diaphragm means includes pins engaging the respective slots; said ring being rotatable in association with the displacement of said diaphragm driving means so that said diaphragm means varies said diaphragm aperture through said pins; and said correcting means includes a cam disposed between said diaphragm driving meand and said ring.

[57] **ABSTRACT**

A camera has an objective which can be moved from an extended, operative position to an inoperative position retracted into the camera housing for dimensional compactness. The objective is driven by a motor from one to the other of those two positions and moved by hand back in the other direction, or is motor driven in both directions. The motor employed is the film transport motor anyway present. The objective is coupled to and decoupled from the drive motor in dependence upon the setting of a manual selector, so that the objective not be driven at improper times, and is preferably coupled and decoupled in automatic response to the setting of a manual selector used to implement other camera functions, so that extension and/or retraction of the camera objective occur automatically as a logical incident to the other camera functions selected by the user.

STILL CAMERA WITH AN OBJECTIVE WHICH CAN BE RETRACTED INTO THE CAMERA HOUSING FOR DIMENSIONAL COMPACTNESS

BACKGROUND OF THE INVENTION

The present invention concerns photographic still camera of the type having an objective which can be moved from an extended, operative position in which it projects out from the camera housing to a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera, e.g., when the camera is being carried about and not in use.

With known cameras of this type the objective is moved between extended and retracted position by hand, the extended position into which the objective is manually brought generally being its infinite-subject-distance focal setting.

SUMMARY OF THE INVENTION

It is a main concept of the invention to provide a motorized system which implements motorized movement of the objective at least from its retracted to its extended position, and preferably also motorized movement of the objective back into its retracted position.

It is a further concept of the invention to power the movement of the objective between its retracted and extended positions by utilizing a drive motor already contained in the camera for other purposes, most typically the camera's film transport motor, or the camera's shutter-resetting motor.

The invention also contemplates various interlocks and automatic features, which will be best understood from the detailed description of presently preferred embodiments, below.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective illustration of one embodiment of the present invention;

FIG. **2** depicts a second embodiment of the invention;

FIG. **3** is a section taken along line III—III of FIG. **2**;

FIG. **4** is a section on line IV—IV of FIG. **2**;

FIG. **5** depicts the rotary motor-direction switching mechanism of the embodiment of FIG. **2**, in the setting which it assumes for forwards film transport; and

FIG. **6** depicts the switching mechanism of FIG. **5**, in the setting which it assumes for causing the camera objective to be motor driven from extended, operative position to retracted, inoperative position.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In FIG. **1**, numeral **1** denotes the housing of a still camera, the housing being shown mostly broken away. A non-illustrated reversible electric motor drives the shaft **2** of a pinion **3**. Also mounted on shaft **2**, for rotation therewith, is a springy pawl **4**. Pawl **4** is so oriented as to cooperate with the ratchet teeth of a ring of ratchet teeth or ratchet wheel **5**. Ratchet wheel **5** is connected with a film take-up spool **6**, or else with a rotation-imparting member which can be brought into rotation-imparting engagement with the take-up member internal to a film cassette. When the electric drive motor operates in its normal direction, so as to effect take-up of the film **7** (which is to say, clockwise in FIG. **1**), ratchet pawl **4** drives the ratchet wheel **5** and thereby effects film take-up. When the drive motor rotates in the opposite direction, the ratchet pawl **4** idles across the ratchet teeth of ratchet wheel **5**.

The camera **1** is provided with an objective **8** which can be retracted into the camera housing, for the sake of small overall camera dimensions when the camera is not in use, and which can be extended out of the camera housing into operative position when the camera is to be used. FIG. **1** depicts objective **8** in its extended, operative position, which here coincides with its infinite-subject-distance focal setting. If the objective **8** is to be set to shorter subject-distance settings, then this can be effected, for example, by manually rotating focus adjuster ring **8**, which rotation, in cooperation with non-illustrated means, serves to effect controlled partial retraction of the objective back into the camera. In the exemplary embodiment depicted in FIG. **1**, the objective **8** is motor-driven from its inoperative setting (in which it is fully retracted in the camera housing **1**) out to its fully extended setting, and then, when the camera is no longer to be used, is manually pushed back into the camera. In particularly, the (non-illustrated) drive motor which rotates shaft **2** and effects film transport is also used to drive the objective **8** out to its extended, operative position.

The outer surface of the objective housing is accordingly provided with two parallel rack portions **8***b*. As shown in FIG. **1**, the rear ends of the two racks **8***b*, i.e., the portions of the racks which are located internal to the camera housing, include untoothed or recessed portions **8***c*. Each of the two racks **8***b* is engaged by a respective gear **9**, both gears **9** being mounted on a shared shaft **10**. One of the two gears **9** is in engagement with a gear **11**. Gear **11** and a further gear **12** are mounted on a shared shaft **13**. Shaft **13** is movably mounted in a slot **1***a* of the housing structure **1** and is biased by weak spring **14**. Spring **14** urges **13** in a direction to bring the gear **12** into engagement with the gear **9**. The orientation of slot **1***a* relative to a line connecting the gear shafts **2** and **13** is such that, when the gear **3** is driven in the film take-up direction (clockwise in FIG. **1**), the interaction forces as between the gears **3** and **12** cause the gear **11** and its shaft **13** to be moved, against the force of biasing spring **14**, out of engagement with gear **9**. Conversely, when gear **3** is driven opposite the film take-up direction (i.e., is driven counterclockwise in FIG. **1**), not only does the ratchet detent idle across the teeth of ratchet wheel **5**, but additionally gear **11** is pressed into engagement with and drives gear **9**. Accordingly, when gear **3** is driven opposite to the film take-up direction, the gears **12**, **11** and **9** are driven, with gears **9**, in particular, rotating counterclockwise. As a result, when the motor starts in this direction, the objective **8** via its rack portions **8***b* is driven out of the camera housing **1** into its illustrated, extended position, the gears **9** idling once they are reached by the untoothed or recessed portions **8***c* of the racks **8***b*. In principle, it would be possible to make use of only a single rack **8***b* and a single rack drive gear **9**. However, it is preferred to use a pair of racks and a pair of drive gears, as shown, in order to prevent any tendency to impart to the objective **8** a downwards or upwards tilt.

In order to be able to switch over the transmission or the drive motor from its film-transport operation to its objective-drive action or so as to make possible pushing of the objective **8** into its retracted position in the camera housing, use is made in this embodiment of a slider **15** which extends and is mounted for movement in a

direction perpendicular to the optical axis of objective **8**. A spring **16** pulls slider **15** against an elastic stop member **17**. Slider **15** is provided with a switch-activating projection **15***a*, an inclined cam portion **15***b* and at least one control arm portion **15***c*.

The rear end of the housing of objective **8** is provided with a blocking portion **8***d*. When objective **8** is in its fully extended position, the blocking edge **18***a* of a blocking lever **18** snaps into place behind blocking potions **8***d* under the action of a biasing spring **19**, to prevent accidental pushing of the objective back into the camera housing. When the blocking lever **18** snaps into blocking position in this matter, it additionally switches off the drive motor. Here, too, use is preferably made of two blocking portions **8***d*, located at diametrally opposite portions of the objective housing, and two blocking levers **18** mounted on coaxial shafts **20**. The ends **18***b* of the blocking levers **18** are located in the paths of motion of the control arms **15***c*. Accordingly, when the slider **15** moves towards the objective **8**, i.e., rightwards in FIG. **1**, the control arms **15***c* push the ends **18***b* of the blocking levers away from the blocking portions **8**, the blocking levers **18***d* are swung away out of the path of motion of the blocking portions **8***d*, and the objective **8** can be manually pushed into its retracted position. The control edge **15***b* on slider **15** assures that the gears **9** do not interfere with the objective retraction and do not drive the ratchet pawl **4** in the film-transport direction. Slider **15** is moved in the direction of arrow **21**, against the force of spring **16**, by means of a (non-illustrated) manually shifted member located at the exterior of the camera housing, such member constituting an extension of or else being coupled to slider **15**. As slider **15** is moved in direction **21**, its cam portion **15***b* presses against an untoothed disk **13***a* on shaft **13**, displacing the latter in housing slot **1***a* by such a distance that gear **11** is moved out of engagement with gear **9**, so that as objective **8** is manually pushed into camera housing **1** the gears **9** idle, i.e., are passively driven by the racks **8***b*.

A control rod **23** is pivotally coupled, at **22**, to the upper blocking lever **18** and carries two pairs of control pins **23***a* and **23***b*. Each pair of control pins **23***a*, **23***b* confines a respective spring contact **24**, **25**, contacts **23** and **25** being respectively connected to the positive and to the negative terminal of the (non-illustrated) electric drive motor. Two stationary contacts **26**, both connected to the positive terminal of a (non-illustrated) battery, are each located to a respective first side of a respective one of the two contact springs **24**, **25**. Two stationary contacts **26***b*, both connected to the negative battery terminal, are each located to the respective other side of the respective contact spring **24** or **25**.

As already stated, in FIG. **1** the objective **8** is shown in its extended, operative position. After user activation of a (conventional and therefore non-illustrated) shutter released mechanism, the camera's shutter performs an exposure operation, and upon completion of the exposure operation a film-transport operation should next occur. Accordingly, in any appropriate, conventional manner, one or more (non-illustrated) motor-connect switches connected in circuit with the drive motor are closed, to permit motor energization, either by manual activation or else in automatic response to exposure completion. As shown in FIG. **1**, the positive terminal of the drive motor is presently connected, via spring contact **24** and its association contact **26***a*, to the positive battery terminal, whereas the negative drive motor terminal is presently connected, via spring contact **25** and its associate contact **26***b*, to the negative battery terminal. Accordingly, the motor is energized for rotation in the direction required for film take-up operation, and gear **3** is rotated clockwise. The initiation and termination of motor energization can be controlled by any of the various switching and/or transmission expedients so well known in the art, and accordingly, it is only the motor-direction control switches which are depicted in FIG. **1**.

Thus far, it has been explained how, with the objective **8** in extended position, a film transport operation is permitted to occur, and also how the objective **8** can be pushed by hand from its extended position back into its retracted position. Next to be explained is how the objective **8** is driven out from its retracted position to its illustrated, extended position. Slider **15** is moved by spring **16** opposite to direction **21** and compresses the elastic stop member **17**. Because the objective **8** is in retracted position, the edges **18***c* of the blocking levers **18** bear against the blocking portions **8***d* of the objective housing; accordingly, blocking levers **18** do not interfere with movement of the objective to extended position. With objective **8** not in fully extended position and levers **18** accordingly displaced somewhat clockwise, control slide **23** is displaced in the direction of arrow **21** by a distance such that the positive-terminal contact **24** of the motor engages the associated negative-battery-terminal contact **26***b*, whereas the negative-terminal contact **25** of the motor engages the associated positive-battery-terminal contact **26***a*, i.e., the settings opposite to those shown for film transport in FIG. **1**. When slider **15** is moved leftwards and compresses the elastic stop member **17**, the second (and illustrated one) of the aforementioned two, parallel-connected motor-energization switches, i.e., switch **27**, closes, so that the motor begin to turn and drive gear **3** counterclockwise. For this rotary direction, gear train **3**, **12**, **11**, **9** is engaged, and accordingly the gears **9** rotate counterclockwise and drive the objective **8**, via the racks **8***b*, into the illustrated extended position thereof. At the end of the extension movement of objective **8**, the blocking levers **18** snap into place, with their blocking edges **18***c* snapping into position behind the blocking portions **8***d* of the objective housing, thereafter preventing accidental depression or retraction of the objective **8**. Also, the control slide **23** is moved opposite to direction **21**, to set the motor direction back to the film-transport mode. The mode of operation causing the objective to move out to extended position has now been completed. When the user lets go of slider **15**, the elastic stop member **17**, acting as a compression spring, pushes the slider **15** a small distance rightward, i.e., back to the illustrated setting of slider **15**. If the motor does not come to an immediate stop as a result of the aforementioned direction-reversing action, the gears **9** can in any event idle in the untoothed portions **8***c* of the racks **8***b*.

Accordingly, in the embodiment of FIG. **1**, an electric film-transport motor drives the film take-up spool, or the like, through the intermediary of a coupling which transmits rotation to the take-up spool only when rotated in one of two rotary directions, and when the direction of the drive motor is reversed no film-transport action occurs and instead the camera's objective is driven out from retracted to extended position.

FIGS. **2**–**6** depict a modification of the FIG. **1** embodiment, in which the drive-motor rotation direction opposite to that which effects forward film transport is utilized to drive the camera objective out to extended

position but additionally to pull the camera objective back into retracted position and also to effect reverse or rewind transport of the film, especially in the case of miniature film in type-135 cartridges.

In FIGS. 2–6, the camera housing is denoted by **101**, the reversible electric drive motor by **102**, the motor output shaft by **102***a* and the motor drive pinion by **103**. Pinion **103** is engaged by a gear **104***a* mounted on a shaft **104**. Gear **104***a* is coupled to a film-transport gear **104***c* via a coupling **104***b* operative for transmitting rotation from pinion gear **104***a* to gear **104***c* only when drive pinion **103** is rotating in the direction associated with forward film transport. The film-transport gear **104***c* meshes with internal toothing **105** provided on a film take-up spool **106**. The drive motor **102** is located interiorly of and coaxial with the film take-up spool **106**. If the motor **102** turns counterclockwise, then the gears **104***c* and **105** and accordingly the take-up spool **106** turn clockwise, as a result of which the (non-illustrated) film will be pulled from the (non-illustrated) cartridge in film-supply compartment **101***a* and be taken up on the take-up spool **106**. To avoid pictorial complexity, there are omitted from these Figures the film-perforation-engaging sprocket wheel, the step-by-step transmission between motor **102** and such sprocket wheel, and the control means employed to activate the camera's shutter mechanism and to initiate and terminate the forward film transport operation, inasmuch as such mechanisms come in a variety of types all exceedingly familiar to persons skilled in the art. However, the rewind shaft **107**, which engages the (non-illustrated) film spool internal to the (non-illustrated) film-supply cartridge, is shown.

In FIGS. 2–6, as in FIG. **1**, in order to reduce the overall dimensions of the camera when it is not in use its objective can be retracted into the camera housing **101** and extended out to operative position when the camera is actually to be used. The housing of objective **108** is provided with two diametrally oppositely located rack portions **108***b*, located on a diameter of the objective housing which extends generally parallel to the film-transport direction.

The gear transmission for the motorized movement of the camera objective will now be described. Gear **104***a* meshes with a gear **109**, and the latter meshes with a gear **111** provided on a shaft **110**. Gear **111** engages a gear **112** mounted on a shaft **113**, the rotation axis of gear **112** intersecting the optical axis of the objective **108**, perpendicular thereto as shown. Gear **112** in turn meshes with a gear **115***a* provided on a shaft **114**. Shaft **114** also carries a further gear **115***b*, identical to gear **115***a* but axially spaced a small distance from the latter. A gear shaft **106**, mounted shiftable in the direction parallel to the longitudinal axis of take-up spool **106**, carries a further gear **117** so arranged that normally, i.e., during motor-powered forwards film transport, it is located axially intermediate the two gears **115***a*, **115***b*; however, if gear shaft **106** is displaced downwardly, then gear **117** comes into mesh with gear **115***b*, and also into mesh with a further gear **118** which is located at about the level of gear **115***b* and is connected to the film rewind shaft **107**, thereby establishing a complete power train from motor **102**, **103** to the rewind shaft **107**. The gear power train **103–118** is so designed that, when the motor **102** turns in the direction (clockwise) opposite to that for forward film transport, gear **118** turns counterclockwise, i.e., so as to drive the spool internal to a film-supply cartridge in the forward film-transport direction, with the shafts **110**, **114** likewise turning counterclockwise. The power train **103**, **118** can, as shown, be located beneath the objective **108** and the motor **102**.

The hollow shafts **119**, **120** are located to either side of objective **108** and extend parallel to the longitudinal axis of the film take-up spool **106**. The hollow shafts **119**, **120** carry respective pairs of identical gear **119***a*, **119***b* and **120***a*, **120***b*. The gears **119***a* and **120***a* mesh with respective ones of the two racks **108***b*. The hollow shafts **119**, **120** accommodate respective coupling shafts **121** and **122**. Each of coupling shafts **121**, **122** is axially shiftable within the interior of the respective hollow shaft **119**, **120** but is not rotatable relative to the respective hollow shaft. The ends of the coupling shafts **121**, **122** which face towards the shafts **110**, **114** are configured as coaxial shaft couplings **121***a* and **122***a*. The ends **121***b*, **122***b* of these coupling shafts located above the objective **108**, and also the shiftable shaft **116**, are passed by (non-illustrated) biasing springs upwards against a manual slider **123**. Located intermediate the two, identical gears **119**, **120***b* there are disposed two gears **124**, **125**, identical to each other, interengaged such that the two gears **119***b*, **120***b* rotate in opposite respective directions. The gear train **119***b*, **124**, **125**, **120***b* is advantageously disposed above the objective **108**, in the manner shown.

If drive motor **102** is set for rotation in such a direction that pinion **103** turns clockwise, and if the shaft **121** is in downwardly displaced setting and therefore in engagement with shaft **110**, then in the illustrated embodiment the other coupling shaft **122** is disengaged from shaft **114**, and the shaft **116** is in elevated setting so that gear **117** is disengaged from the gears **115***b* and **118**. If then the motor commences to turn, then due to the one-way coupling **104***b* no film-transport action occurs, and instead the gears **111**, **119***a*, **119***b* turn counterclockwise and accordingly the gear **120***a* clockwise. As a result, the objective **108** is driven out to the extended position shown in FIG. **4** via the rack portions **108***b*. In the other mode of operation, shaft **121** is disengaged as is also gear **117**, and shaft **122** is engaged with shaft **114**, shaft **122** being in its downwardly displaced position. As a result, gear **120***a* turns counterclockwise and gear **119***a* turns clockwise, and the objective **108** is then driven back into its retracted position retracted into the camera **1**. In a third mode of operation, shaft **116** is in its downwardly displaced position, both the coupling shafts **121**, **122** are in decoupled condition, and clockwise rotation of the motor drive pinion **103** effects reverse or rewind film transport via the gear **118**.

In order to be able to select from among these modes of operation, some sort of control means must be provided, and preferably including a manual selector member moved by the user of the camera. In the illustrated embodiment, the control means employed comprises the aforementioned slider **123**, the slider **123** having an arm **123***a* which projects out to the exterior of the camera to constitute the manual selector member. In the illustrated embodiment, the slider **123** is guided for sliding motion parallel to the film transport direction, by means of, for example, the illustrated pin-and-slot connections (no reference numeral). In FIG. **2**, slider **123** is in its setting F, for film transport, and the upper shaft ends **121***b*, **122***b* and **116***b* are located in recesses of the slider **123**, so that these shafts will not be pressed down into their downwardly displaced settings. As shown in FIG. **2**, to the right of the upper shaft end **121***b*

the slider 123 has a cam portion 123*b* with slanted ends, so that when slider 123 is shifted leftward into its setting A, the coupling shaft 121 come into engagement with the shaft 110, in which case the objective 108 is driven out to extended position. In FIG. 2, to the left of upper shaft end 122*b* the slider 123 has a cam portion 123*c* with a similar slanted end portion; the cam portion 123*c* is bent in such a configuration that it does not cooperate with upper shaft end 122*b* but instead only with upper shaft end 116*b*. Shown to the right of shaft end 122*b* is a further inclined camming portion 123*d* on slider 123; camming portion 123*d* is located a certain distance out of the way of shaft 116, so that it does not cooperate with shaft 116 but instead cooperates only with shaft end 122*b*. To the left of camming portion 123*c* is another recess 123*e*. If slider 123 is shifted rightwards from its film-transport setting F to its setting E, then shafts 121 and 116 are in their decoupled settings, whereas the camming portion 123*c* presses the shaft 122 into its setting engaged with the shaft 114; accordingly, in setting E of slider 123, the objective is pulled inwards into its retracted position. If slider 123 is shifted further rightward to setting R, then the upper shaft end 122 is located in recess 123*e*, whereas the camming portion 123*d* presses the shaft 116 downwards into its setting for a film-rewind operation.

In addition to the implementing operations described above, it is necessary that motor direction be controlled, here in dependence upon the setting of slider 123, suth that one motor direction is established for slider settings A, E and R and other motor direction for slider setting F. In order to achieve this in a simple way, in the illustrated embodiment the motor 102 is provided with a rotary switch 128 (see FIGS. 5 and 6) having a positive contact 128*a*, two negative contacts 128*c* and 128*d* each spaced 45° from the positive contact but located at opposite sides of the latter, and two further negative contacts 128*b* and 128*e* located to opposite sides of the positive contact and spaced therefrom by 125°. All these contacts 128*b*–128*e* are connected to the negative motor terminal and contact 128*a* to the positive motor terminal. Two switching circuits branch off from battery 217, one containing the switch S1 which serves to close the motor current path to effect forward film transport; this switch is, for example, in very familiar manner closed by an element of the camera's shutter mechanism upon completion of an exposure and then, for example, in equally familiar manner is reopened upon completion of a film-transport operation in response to the performance of one rotation of the camera's film-transport sprocket wheel. The second switching circuit which branches off from battery 127 contains the switch S2, which must be closed whenever the objective is to be driven out or retracted or when the film is to be rewound. The positive and negative terminals of battery 127 are connectable to various ones of these contacts 128*a*–128 via four stationary wipers 129*a*, 129*b*, 129*c*, 129*d*. The wipers 129*b* and 129*c* are connected in common to the negative terminal of battery 127, and are spaced apart 90°. Wiper 129*a* is located intermediate the two wipers 129*b*, 129*c* and is connected to the positive battery terminal. Wiper 129*d* is connected to the positive battery terminal, and is located diametrically opposite to wiper 129*a*. Rotary switch 128 is provided with a tab 128*f* (see FIG. 2). A tension spring 130 is at one end connected to tab 128*f* and at its other end is connected to a pin on slider 123. Spring 130 pulls tab 128*f* against a pin 123*f* on slider 123. When slider 123 is in the forward film-transport setting F, the rotary switch 128 occupies the setting depicted in FIG. 5, the motor 102 turns counterclockwise. If slider 123 is shifted to setting A, the pin 123*f* on slider 123 carries rotary switch 128 with it, turning the latter 45° to the left to the setting shown in FIG. 6. When switch S2 closes (switch S1 is shown open, because it is assumed for simplicity that no shutter triggering action has occurred), objective 108 is driven out to extended position, because motor 102 now turns in the direction opposite that for forward film transport. If slider 123 is shifted to setting E, rotary switch 128 follows slider pin 123*f* until it reaches a stationary stop member 101*b*, whereupon the rotary switch 128 will have reached a setting which is symmetrical (relative to contact 129*a*) to the setting shown in FIG. 6. In this setting too, the motor 102 turns in the direction opposite that in which it turns for forward film transport, so that when switch S2 is closed the objective 108 is pulled in to retracted position. If slider 123 is shifted further rightward to film-rewind setting R, then due to stationary stop member 101*b* the setting of rotary switch 128 just described, is maintained, and when switch S2 is closed the film rewind operation commences.

The switch S2, for driving the objective in and out and for film rewind, could be closed by a separate manually operated switch-control element on the exterior of the camera. However, it is more advantageous that it be closed in automatic response to the slider 123 assuming the settings for driving the objective and for film rewind. To this end, use can be made of two switches S2, connected in parallel to each other, one being formed by the stop member 101*b* and the other being formed by a further such switch located symmetrically relative to the first, considered with respect to rotary switch 128. The two parallel switches S2 are shown in FIG. 2, and when slider 123 is shifted into either setting A or setting E, one or the other of these two switches is closed, as the case may be, the tab 128*f* serving as the shared moving contact for this double switch arrangement.

In order that the objective 108, when it has been brought out to its extended, operative position, be secured against unintentional pushing of it back into the camera housing, the upper end 122*b* of shaft 122 is provided, as shown, with a conical portion 122*c*, against which two blocking levers 131, 132 are pressed by a biasing spring 133 (see FIG. 4). When the objective 108 is in its extended position, the blocking levers 131, 132 are located behind respective pins 124*a*, 125*a* provided on respective ones of the two gears 124, 125, and thereby prevent unintentional retraction of the objective 108. When slider 123 is shifted to setting E, the conical portion 122*c* presses these blocking levers 131, 132 out of the path of motion of the pins 124*a*, 125*a*, so that the objective 108 can then be pulled into retracted position in the camera 101 by means of the gears 119*a*, 120*a*.

It will be understood that a great variety of modifications of the foregoing are within the scope of the invention, although not illustrated herein. Thus, for example, the construction shown in FIG. 2 could be modified by omission of the gear train 116, 117, 118 for the film-rewind mode of operation, in the event no such mode of operation is needed, e.g., in the case of type-110 or -126 cassette films whose cassettes have not only a film supply compartment but a film take-up compartment as well. In such event, the motor 102, unlike the case shown in FIG. 2, of course could not be located in the

film take-up compartment of such cassette, but would instead need to be located at some other place, e.g., alongside the space which accommodates the cassette's take-up compartment. Likewise, instead of the rotary switch **128** described above, which implements motor-direction reversals in reliance upon the motor actually rotating to bring the moving contacts and stationary wipers of switch **128** into and out of engagement with each other, use could instead be made of a set of contacts forming three parallel switches, with the moving contact of such three switches being located in the path of motion of a respective one of the shiftable shafts **121**, **122** and **116**, so that these latter shafts close their associated switches as they respectively move into engagement with the shaft **110**, the shaft **114** and the gear **115***b*. Similarly, in the construction shown in FIG. **1**, the relationships could be reversed, with the objective **8** being motor-driven for its retracting movement, and being manually brought out to its extended, operative position, although such alternative is not presently preferred. As a further example of the various modifications which could be effected, instead of the racks provided on the objective housing or tube use could instead be made of an eccentric drive or a worm drive driven in two opposite directions by the camera's gear train.

It will be understood that each of the elements described above, or two or more together, may also find a useful application in other types of constructions and circuits differing from the types described above.

While the invention has been illustrated and described as embodied in preferred embodiments in which the extension and retraction of the camera objective is derived from the camera's film-transport motor, it is not intended to be limited to the details shown, since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features that, from the standpoint of prior art, fairly constitute essential characteristics of the generic or specific aspects of this invention.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims:

1. In a photographic camera of the type having a camera housing and an objective including an objective housing and being mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means including two racks provided on the objective housing, two rack drive gears which engage respective ones of the two racks, and means transmitting motion from the drive motor to both rack drive gears simultaneously, the two racks and the two rack drive gears being so located and dimensioned that when the rack drive gears are driven by the drive motor they apply balanced drive forces to the objective housing.

2. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including a reversible rotary electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means comprising at least one unidirectional transmission means operative for transmitting motion from the motor to the objective only when the motor rotates in one respective rotary direction, and the unidirectional transmission means comprising first and second gears, the first gear imparting motion to the objective, the second gear receiving motion from the drive motor, a further intermediate gear driven by the first gear and mounted for movement between a position engaging the second gear and a position not engaging the second gear and biasing means applying to the intermediate gear a biasing force biasing the intermediate gear towards said engaging position thereof, the direction in which the intermediate gear is movable between said positions thereof and the spatial locations of said first and second gears relative to said intermediate gear being such that when the first gear is driven by the drive motor in a first rotary direction the interaction force between said first and intermediate gears permits said biasing force to maintain said intermediate gear engaged with said second gear whereas when the first gear is driven by the drive motor in the opposite rotary direction the interaction force between the first and intermediate gears moves the intermediate gear out of engagement with the second gear against the action of said biasing force.

3. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means including a disengageable coupling and manually activated means for engaging and disengaging the coupling.

4. The camera defined in claim **3**, the objective being provided with an objective housing, the transmission means comprising at least one rack on the objective, the rack extending parallel to the optical axis of the objective, and means engaging the rack and driven by the motor.

5. In a photographic camera of the type having a camera housing and an objective including an objective housing and being mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means being capable of deriving from the

motor either motion which drives the objective to extended position or to retracted position without a change of motor rotation direction and comprising two racks provided on the objective housing located diametrically opposite to each other, two rack drive gears meshing with respective ones of the two racks, two intermediate gears meshing with each other and each coupled to a respective one of the two rack drive gears, each of the two rack drive gears being provided on a respective gear shaft, two drive shafts to respective ones of which the two gear shafts can be coupled, two gears each provided on a respective one of the drive shafts and a further intermediate gear meshing with each of the two gears just mentioned, and manual means for causing one or the other of the two gear shafts to be coupled to the respective one of the two drive shafts.

6. The camera defined in claim **5**, furthermore including two coupling shafts each of which is axially shiftable between a coupling position in which it couples a respective one of the gear shafts to the respective drive shaft and an uncoupling position in which it decouples the respective one of the gear shafts from the respective drive shaft, the manual means comprising a manually operated slider provided with cam portions operative for axially shifting the coupling shafts.

7. The camera defined in claim **6**, the coupling shafts bearing against and being directly cammed by the cam portions.

8. In a photographic camera of the type having a camera housing an an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means including disengageable coupling means coupling the drive motor to the objective.

9. The camera defined in claim **8**, the camera including means guiding photographic film from a supply compartment to a take-up compartment and take-up means rotatable in a predetermined direction for effecting film take-up, the disengageable coupling means comprising means engageable with the objective and with the take-up means.

10. The camera defined in claim **8**, the camera including means guiding photographic film from a supply compartment to a take-up compartment and rewind means rotatable in a predetermined direction for effecting film rewind, the disengageable coupling means comprising means engageable with the objective and with the rewind means.

11. The camera defined in claim **10**, the disengageable coupling means including rewind-action coupling means operable for coupling the rewind means to the objective so that both the rewind means and the objective be simultaneously driven by the drive motor.

12. The camera defined in claim **10**, the transmission including a gear driving the objective, the rewind-action coupling means comprising a gear mounted axially shiftable into and out of engagement with the gear driving the objective.

13. The camera defined in claim **12**, the gear of the rewind-action coupling means being provided on a gear shaft, furthermore including a manually operated slider having a cam portion which cooperates with the gear shaft for axially shifting the latter.

14. In a photographic camera of the type having a camera housing an an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensiona compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means including disengageable coupling means capable of coupling the drive motor to the objective irrespective of the rotary direction of the drive motor.

15. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including a reversible electric drive motor, and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former; take-up means rotatable in a predetermined direction for effecting film take-up; and a one-way coupling coupling the drive motor to the take-up means to rotate the latter in said predetermined direction when the drive motor rotates in one respective direction, the transmission means including disengageable coupling means for coupling the drive motor to the objective at least when the drive motor rotates in the opposite direction.

16. The camera defined in claim **15**, the transmission means furthermore including manual means for engaging and disengaging the disengageable coupling means, the drive motor being a reversible electric motor, and furthermore including electric motor-direction-reversing switches responsive to operation of said manual means.

17. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former, the transmission means including disengageable coupling means for coupling the drive motor to the objective, the drive motor being a reversible electric motor, and furthermore including electric motor-direction-reversing switches responsive to operation of said manual means.

18. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to

the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former; film transport means operative for effecting forward film transport under the drive action of the drive motor when the latter is operated in a first direction; and two motor-direction control switches of which one is closed to cause the motor to rotate in said first direction and the other to cause the motor to rotate in the opposite second direction, the camera being of the type in which the first direction control switch is closed upon the completion of an exposure to initiate film transport and then reopens after completion of film transport, the transmission means including disengageable coupling means coupling the objective to the drive motor and manual means operable for disengaging and engaging the coupling means, the second motor direction control switch closing in response to at least one predetermined setting of said manual means.

19. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former; a manually operated element having one setting which enables the objective to be moved out to extended position and another setting which enables the objective to be moved inward into retracted position; and blocking means operative when the manually operated element is in said one setting for preventing unintentional retraction of the objective.

20. The camera defined in claim **19**, the blocking means comprising a blocking element and biasing means causing the blocking element to move into a position preventing objective retraction when the manually operated element is in said one setting and means moving the blocking element out of said blocking position when the manually operated element is moved to the other setting thereof.

21. In a photographic camera of the type having a camera housing and an objective mounted for movement between a retracted, inoperative position in which it is retracted into the camera housing for dimensional compactness of the camera and an extended, operative position in which it extends out from the camera, a drive mechanism for driving the objective from one to the other of said positions, the drive mechanism including an electric drive motor and transmission means coupled to the drive motor and to the objective and operative for transmitting motion to the latter from the former; the transmission means including disengageable means disengageable for disengaging the objective from the drive motor; and manual means operable for disengaging the disengageable means and permitting the objective to be moved from one to the other of its positions by hand.

[57] **ABSTRACT**

A retinal response recorder that is fully automatic, comprises a light stimulator, with means for a patient to position his head, such that his eye is on the horizontal axis of the stimulator. Means are provided for selecting any one of the selected number of light beams directed from the stimulator to the eye of the patient at selected angular positions above and below the horizontal and left to right of the vertical plane through the axis of the stimulator. Appropriate electrodes are positioned on the skin surface of the patient to record electro-muscular potentials generated by the retina of the eye. Means are provided for a prearranged program of selection of stimulator spots. If the eye sees the spot of light a retinal response potential is generated and/or a visually evoked response is generated. These signals, one or both, go to amplifiers with selected filter characteristics, and then to a display-recorder apparatus, so that the magnitude of the response can be determined with regard to the specific position of the spot of light.

OBJECTIVE RETINAL RESPONSE RECORDER

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention lies in the field of study of the human eye. More particularly it concerns a process of determining the physiological condition of the retina of the eye, and of measuring the field of vision of the eye, by entirely objective automatic means irrespective of arbitrary eye movements of the patient.

2. Description of the Prior Art

In the prior art, ophthalmologists have routinely made measurements on the eyes of patients, such as determining the visual field by seating a patient before a blackened board and have a test person move a small whitened sphere along radial lines from the outer extreme of the board toward the central portion, in such a manner that the patient responds when he sees the spot, being cautioned to maintain the eye constantly fixed along the axis of the board. In other cases, semi-automatic stimulators have been used in which a plurality of small lamps are positioned at selected locations on a board or hemisphere. These lights are illuminated momentarily in selected succession and the patient indicates by closing a switch or pressing a button that he does or does not see the spot of light.

Also in the study of the visual process, research personnel have made measurements of the potential generated by the retina in response to a visual stimulus. These measurements have been made at various positions on the face and forehead of the patient by means of thin metal electrodes which are attached to the skin surface.

There are two particular types of potentials which are measured, namely, the electro-retinal potential and the visual evoked response.

These and other measurements can be made on the apparatus of this invention by the use of suitably placed electrodes, as are well known in the art.

SUMMARY OF THE INVENTION

It is the primary object of this invention to provide an electronic apparatus which is fully automatic, and on a prearranged program can provide any one of a plurality of separate light beams projected into the eye of the patient, at selected angles, with appropriate measurements being made of the visual evoked response (VER), and the electro-retinal potential (ERP), or other types of electrical measurements, which in one way or another may be responsive to the process of recognition by the eye and the brain of the optical stimuli.

It is a further object of this invention to provide means to digitize and make amplitude measurements on these potentials, and to display these potentials as a function of angular position of the stimulus spot with respect to the axis of the stimulator and to the axis of the eye so that a record may be made for future comparison.

These and other objects are realized and the limitations of the prior art are overcome in this invention by providing an apparatus which includes specific elements, including an optical spot stimulator, an eye fixation monitor, a spot control memory means which can produce a series of address locations which can be selected sequentially, or at random, to mark the location of successive light stimuli, In response to the output of the spot control memory, a selection is made in a stimulus selector of an individual electric lamp, or optical beam, at the selected angle with respect to the axis of the stimulator, and the optical axis of the eye of the patient.

By means of the eye fixation monitor and the crossed pairs of photocells, even though the eye of the patient may wander from the optical axis of the stimulator, the actual position of the eye in angular coordinates, or other incremental measurements, can be observed, and the selection of the beams from the stimulator can be modified so that the actual position of the beam in the stimulator is modified by the differential movement of the eye, as observed by the fixation monitor, so that the direction of passage of the light beam through the lens to the retina will be in the precisely desired direction. Several types of automatically positioned light beams will be described.

Means are provided to take the potentials observed on the electrodes attached to the surface of the skin, and to filter, amplify, determine the amplitude of the response, digitize the wave shape of the response if desired, and to display on a cathode ray tube or other display/record means at a position which corresponds to the angular or rectangular position of the beam of the stimulator. Conventional means are provided for placing a camera and camera hood, over the cathode ray tube, in order to record the positions of the spots, and some parameter of the response to the light, at those specific locations.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects and advantages of this invention and a better understanding of the principles and details of the invention will be evident from the following description taken in conjunction with the appended drawings in which:

FIG. **1** represents in block diagram form, one embodiment of an apparatus for stimulating the eye of a patient with a preselected sequence of angular beams.

FIGS. **1A**, **1B** and **1C** illustrate further details of the stimulator.

FIG. **2** illustrates in block diagram form the amplifying, processing, and display features of one embodiment of this invention.

FIG. **3** illustrates an alternative design of stimulator.

FIG. **4** illustrates a detail of FIG. **3**.

FIGS. **5** and **6** illustrate two methods of applying electrodes for measuring the evoked potentials.

FIG. **7** illustrates a manner in which the stimulated light beam can be modulated to provide an improved potential response curve for the ERG.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring now to the drawings and in particular to FIGS. **1**, **1A**, **1B** and **1C**, there is illustrated in FIG. **1C** a simple model of the eye indicated by the numeral **42**, with a lens **37** on the front of the eyeball and a retina **47** which covers a selected angular area of the back inside wall of the eye. An optic nerve **35** departs from the eyeball and the retina at a selected angle. The horizontal axis of the eye and of the stimulator is indicated by the numeral **43**. A selected stimulator light beam **38** is shown at an angle to the optical axis of the stimulator and of the eye.

In the testing of the retina it is important that the condition of the eye at each small area of the retina must be measured separately from each of the other areas.

Thus the eye must be held as closely as possible at a position so that the eye is on the axis of the stimulator, and the axis of the eye is directed constantly to the point of intersection of this axis and the wall of the stimulator. If the eye can be maintained in that position, then as different light beams are produced at known angles to the axis **43**, then the exact position of the inpingement of the light beam on the retina is also known and the response can be plotted as a function of the coordinates of the retina.

However, it is difficult for a patient to maintain the eye beam directed constantly at the axis of the stimulator, and there is a tendency for it to move up or down, or sideways, through some small angle. This variability of the position of the eye is determined by measurement on the eye, by means of a fixation monitor. The output reading of that monitor in terms of a voltage, which is a function of the angular movement of the eye away from axis **43** is then used to correct the selected position of the beam being generated by the stimulator, so that the point of impingement of the light beam on the retina will be the prescribed angle, that the beam would have reached if the eye had not wandered from the axis of the stimulator.

FIG. **1** illustrates schmetically the apparatus that produces the desired optical beams in a selected sequence. One type of stimulator is shown in FIG. **1**. This has a hemispherical shell, indicated generally by the numeral **12**, the spherical surface **40** is blackened inside, and has a plurality of small openings **45** (FIG. **1A**) through the wall, into which appropriate small lamps **46** can be inserted. The diameter of the hole and of the lamp is such that the angle subtended at the center of the hemisphere will be one second of arc. Thus the corresponding lighted area of the retina likewise will be one second of an arc, which has been selected as a standard unit area for examination of the retina.

There are a network of conductors **36A**, **36B**, **36C** . . . **36N** which are carried, and the lines **36**, from a stimulus selector **24**, which will be described in detail later. A spot control memory **32** comprises a paper tape reader, or equivalent memory source, such that by selecively moving from one address to another, the coordinates of the selected lamp attached to the wires **36** will be chosen by the stimulus selector **24**, in response to the address provided over leads **34** from the spot control memory. The selector **24** will switch in the proper lamp **36A** over the leads **36** so that a beam will then originate from the lamp, say **36D** for sample, to the eye **42** positioned on the axis **43** of the hemisphere **40**.

Appropriate means may be provided on the stimulator **40** such as resting the chin on an adjustable support, and holding the head in a specified position so that the beam which is relatively narrow in breadth, will pass through the center of the lens of the eye, at the proper angle, and on to the retina.

The fixation monitor **14** is a commercial device which comprises a microscope, which receives light from the eye over dashed line **44**, and magnifies the image of the eye. By means of two pairs of crossed photocells it can determine the movement of the eye, over a selected angular range. The output of the fixation monitor is provided by two pairs of leads **18** and **20** which represent, for example, the Y axis movement and the X axis movement of the eye relative to the axis **43** of the stimulator and of the eye.

The output of the spot control memory **32**, for any given address may be in any desired form. In one form it can be two voltages, an X voltage and a Y voltage. These go by lead **34** to a differential control **16**. There are means for adding to the X and Y values on line **34**, the X′ and Y′ values on lines **20** and **18**, in a proper algebraic manner, to provide an output signal on leads **22**, which provide the sum of the two values of $X+X'=X''$ and $Y+Y'=Y''$. This controls a stimulus selector to move or switch to another spot, such that the position of the image of the light spot on the retina will be at the true angular position X and Y desired.

Power for the output of the stimulator, that is, power to the lamps on leads **36**, is provided over leads **26**, and may for example go through a pulser switch **28**, and through leads **30** to the selector. The purpose of the pulser **28** is to provide a sequence of pulses such as shown for example in Part B of FIG. **7**, where a sequence of five or more square wave pulses of light are provided, each pulse of light say 100 milliseconds in duration, for example, and each space another 100 milliseconds. Thus the whole sequence may operate for a second or for several seconds. It is then possible to determine from the received signal what the component of signal there may be that has a periodicity, or frequency, equal to that of the imposed light pulsations. That portion of the signal picked up at the electrodes on the skin of the patient, which has this desired periodicity, can then be verified as a true signal, which is responsive to the light generated by the stimulator, and not a noise.

Referring now to FIG. **1A** there is shown a small portion of the wall **40** of the hemisphere stimulator, and a pair of openings **45** of selected diameter drilled through the wall. In one of them, a lamp **46** is inserted which is supplied with current by leads **36**. The diameter of the opening **45** is such that at the radius of the sphere **40**, is subtends at angle of 1°.

In FIG. **1B** is shown a portion of the eye in which the iris and the shaded portion of the eye, known as the limbus are shown. There is a circumferential line **89** marking the outer edge of the limbus against the white area of the eye. At a point on the perimeter **89** which is approximately 70° down from the horizontal the fixation monitor is focused with the cross-hairs, or crossed photocells **91** positioned with their axes horizontal and vertical. As they eye moves and the edge of the limbus **89** moves up or down or sideways, voltages will be generated in the photocells such that on the leads **18** and **20** they will represent the actual displacement in the X and Y directions with reference to the point **91**, the point of fixation of the monitor.

While there are many ways in which the stimulator can be built one of these has been shown in FIG. **1** which comprises a plurality of separate lamps, which are switched in, sequentially. These lamps are positioned in a grid, of selected design, either measured in angle radiating out from the axis, and angles of rotation between vertical and horizontal, for example, or they can be positioned in a selected rectangular grid of any desired spacing, for example.

Shown in FIGS. **3** and **4** is another embodiment in which the stimulator can be a hemisphere **40A**, as compared to the hemisphere **40** in FIG. **1**. At the position just below the eye, is a mirror **82** which receives light from a laser **84** of, selected intensity, which goes by way of mirror **86′** and beam **86**, to the mirror **82** and then by beam **86A** to the wall of the hemisphere **40A**, where it impinges upon a metal plug **21** (FIG. **1A**) inserted into the opening **45**. The front face **23** of the plug is a

brightly polished metal surface, which reflects the light backwardly to the eye **42** of the patient. In other words by rotating the mirror in azimuth and elevation, the light beam **86A** can be made to contact any one of the plurality of plugs **21**, at fixed desired locations in the shell **40A** and the light will then be reflected back to the eye at substantially the desired angle.

By referring to FIG. **4** there is shown schematically a type of small mirror **82** that has a horizontal axis **83** that can rotate in the direction of arrow **87**. The axis **83** is supported in a yoke with two upright arms **85** and a central vertical arm **86**, which is set in bearings (not shown) such that it can rotate the entire assembly in accordance with arrow **88**. Thus by driving the mirror and the yoke about the two axes **83** and **86**, by selected angular increments such as by step motors or servo motors, for example, in the well known manner, the beam can be positioned to any selected angle in azimuth or in elevation, with respect to the axis **43** of the hemisphere.

As previously stated, the apparatus consists of two essential parts. The first is an apparatus for producing a spot of light at a selected location on the wall of a hemisphere, for example, at selected angular location with respect to the axis of an eye positioned at the center of the hemisphere. This can be accomplished in many ways.

The feature that is very important in an automatic machine is to provide the fixation monitor **14** to provide adequate signs for the measurement of any deviation of the axis of the eye from the axis of the stimulator, so that the position of the light spot can be varied, such that with the known displacement of the eye the resultant angle of the image of the spot on the retina will be at the desired angular position, irrespective of how much the eye has drifted from its proper axial direction.

In order to make this apparatus fully objective and automatic it remains then to provide a means for generating a potential which is a function of the reception of the light spot signal to the retina, and to amplify and process this signal, to determine its validity, that is, to determine whether that signal is due to the light spot of the stimulator or is due to some other noise source, and so on. One way of determining the validity of the signal, as has been discussed, is by using a pulsating light spot and to search in the produced evoked response for that frequency of signal, and to display and record that particular component of the signal, the understanding being that any other electrical signal is a noise and should be disregarded.

Referring now to FIG. **2** there is shown one type of detecting and processing apparatus. This comprises an input lead **52** from one or another of a group of electrodes, which can be attached to the face and head of the patient. The purpose of amplifying and processing the signal, is to infer from the character of that potential, what the condition of the retina is, and what physiological problems may be present in the retina, the optic nerve or the brain for example. As will be explained in connection with FIGS. **5** and **6** there are a number of possible positions to place electrodes, and the potential of these electrodes will arrive on lead **52** from the electrode.

The received signal may pass through a filter **54** of selected band pass. The filter can of course be equivalent to a phase lock means **71** driven by the pulsing frequency of the current **28** that powers the light spot, or any other filtering apparatus. The filtered signal then goes by line **56** to a high-gain, low-noise amplifier **58**, of which a number of examples are available on the market. These would be the equivalent of electroencephalograph type amplifiers, and so on. The amplified output then may go to an analog to digital (A/D) converter **62**, where the particular wave shape of the evoked potential is digitized, and is stored in a digital memory **66**.

Reference is made to part A of FIG. **7** where there is shown a sample wave shape representing the electro-retinal potential, which occurs whenever a light is suddenly received on the retina. This wave form lasts about 60 milliseconds, and then drops to 0, and remains at 0 even though the light stimulus may still be on the eye. Such a wave form as this would be digitized, and of course its amplitude thereby determined, and its wave shape stored in the digital memory **66**. This can always be withdrawn from the memory over lead **68** to a digital-to-analog (D/A) converter **70**, and then over lead **74**, can be displayed on a cathode ray tube, as is well known in the art. Alternatively the potential brought in on lead **52** and after amplification delivered on lead **60**, can then be brought over lead **72** to the cathode ray tube. These would go to the Z axis of the tube in order to produce a spot of a selected brilliance, which would be some function of the observed voltage, for example, as might be the case for a visual evoked response measurement (VER) of the eye.

The cathode ray tube **76** would have input on leads **41** corresponding to the angular position of the light spot in the stimulus selector **24**, so that the spot which is presented on the cathode ray tube will be positioned at the coordinates X and Y in accordance with the precise angular position of the image of the spot on the retina of the patient.

The type of amplifying, filtering, processing and display apparatus illustrated in FIG. **2** is only by way of example, and other equivalent types of display can, of course, be utilized. The particular display apparatus also will vary with the type of coordinates of the stimulus light beams, whether generated by the lamps as in FIG. **1** or by the laser beam in FIG. **3**. Of course, if a different type of stimulator, with a plane board is used as the surface, then some combination of rectangular and polar coordinates may be required. As is well known, a camera **80** with a hood **78** placed over the cathode ray tube **76**, can be used for making a permanent record of the response of the eye at each of the stimulus positions.

Also shown in FIG. **2** is a lead **61** taken from the amplifier **58** and a corresponding lead **30** from the pulser **28** of FIG. **1**, to a phase lock device **71**, such that an output on lead **63** would indicate that the evoked response shows the pulsation frequency of the light stimulus provided, which would be verification that the measurement is a valid measurement of the eye.

In FIGS. **5** and **6** are shown two of many ways in which electrodes can be attached to the skin of the patient, on the face, forehead or scalp, in order to detect electrical potentials, which can be proven to be functions of the response of the retina, or optic nerve, or of the brain, in the processing of electrical signals from the retina. The ERG, or electro-retinal potential, it has been found, can be picked up readily by means of a thin metal plating on a flexible strip of plastic **92**, to which is attached a silver wire lead **94**, which goes to the line **52** of FIG. **2**. This strip **92** is attached to the skin surface by means of adhesive tape placed over it in a manner similar to that by which electrodes are attached to the scalp for purposes of EEG measurement, for example. They

are placed just below the lower lid of the eye **90** shown in FIG. **5**. They can be placed at other positions also.

The VER potential or visual evoked response potential, can be detected by means of a similar silvered plastic strip **98** FIG. **6**, which is positioned on the bony structure immediately behind the lower part of the ear. This potential is taken off by means of a silver wire **99**, for example, to lead **52**. The art of positioning these electrodes forms no part of this invention, and is well known in the art of medical testing.

Not shown but well known in the art is the manner in which electrodes may be attached to the scalp to indicate the response of certain areas of the brain, and in the same way that the ERG and VER potentials are utilized, the potential generated on the scalp electrodes can likewise be used for the same purpose.

Whereas, the present invention has been described in particular relation to the drawings attached hereto, other and further modifications apart from those shown or suggested herein may be made within the spirit and scope of the invention.

What is claimed is:

1. In an apparatus for making a non-manual, objective retinal response display, responsive to light stimulus to a human eye; an improved apparatus for providing a selected light stimulus, at selected positions relative to the retinal axis, comprising;

(a) stimulator means comprising means to supply, on command, a selected one, of a selected plurality of possible beams of light, each positioned so as to enter the lens of an eye of a patient positioned on the axis of said stimulator, at a difficult selected angle to the axis of said stimulator; and means to position the eye of a patient on the axis of said stimulator means;

(b) machine readable spot control memory means for storing in selected order each of the position parameters of said selected plurality of beams of light; and

(c) in which said selected beams of light are produced by means of small reflecting surfaces positioned at selected locations on the surface of said stimulator, and a focused beam of light reflected from a small mirror near the axis of said stimulator adapted to be rotated selectively about two perpendicular axes.

2. The apparatus as in claim **1** including display/record means for displaying the position parameters of said selected beam of light.

3. The apparatus as in claim **1** including;

(a) eye fixation monitor means, and means to direct the optical axis of said fixation monitor means to a selected point on said eye of said patient;

(b) output means from said fixation monitor means for providing;

(1) a first electrical signal responsive to the movement of said eye in the X direction;

(2) a second electrical signal responsive to the movement of said eye in the Y direction.

4. The apparatus as in claim **3** including differential positioning control means, responsive to said machine readable spot control memory means, for supplying to said selector means, a modified position parameter signal, comprising the sum of said recorded selected position parameter from said memory, plus said first and second electrical signals; whereby the actual angle of approach of said selected beam of light to the axis of said eye, will be the same as that which would be supplied by said selected position parameter, if the eye had not moved.

5. The apparatus as in claim **1** including means to modulate said selected one of said selected plurality of beams of light.

6. The apparatus as in claim **5** in which said modulation is amplitude modulation at a constant frequency; and including means to record said constant frequency.

7. The apparatus as in claim **5** in which said modulation is amplitude modulation at a variable frequency; and including means to record said variable frequency.

8. The apparatus as in claim **2** including:

(a) electrode means attached to the skin of said patient at a selected position; whereby a third electrical signal will be produced which is responsive to the passage of said selected beam of light to a selected portion of the retina of said eye of said patient; and

(b) means to utilize said third electrical signal.

9. The apparatus as in claim **8** in which said means to utilize includes means to determine the amplitude of said third electrical signal.

10. The apparatus as in claim **8** in which said means to utilize comprises means to digitize and store said third electrical signal.

11. The apparatus as in claim **8** in which said means to utilize comprises means to display/record said third signal in association with said position parameters of said selected beam of light.

12. The apparatus as in claim **8** in which said electrode means is attached to the skin below the lower lid of the eye; whereby said third electrical signal is the electro-retinogram (ERG) of the eye.

13. The apparatus as in claim **8** in which said electrode is attached to the skin behind the lower part of the ear; whereby said third electrical signal is the visual evoked response (VER) of the eye.

14. The apparatus as in claim **8** in which said electrode is attached to the scalp; whereby said third electrical signal is an EEG.

15. The apparatus as in claim **1** in which said focused beam of light comprises a laser beam of selected frequency.

[57] **ABSTRACT**

An objective of the expanded Tessar type is disclosed. Five elements form four components of which the first counting from the front is positive and convex toward the front, the second is a bi-concave lens, the third is a positive doublet consisting of a negative lens element and a bi-convex lens element cemented together at their adjoining surfaces, and the fourth is a bi-convex lens. The objective fulfills the following conditions:

$$0.55 < \left| \frac{R_8}{R_9} \right| < 1.4, \text{ where } R_9 < 0 \quad (1)$$

$$D_4 < 0.056f \quad (2)$$

$$0.08 < N_1 - N_2 \quad (3)$$

$$0.16f < D_5 + D_6 < 0.21f \quad (4)$$

$$\frac{0.08}{f} \leqq \frac{N_4 - N_3}{R_6} < \frac{0.3}{f} \quad (5)$$

$$0.48f < |R_3| < 0.62f, \text{ where } R_3 < 0 \quad (6)$$

wherein f is the focal length of the entire lens system; Ri is the radius of curvature of the i-th surface counting from the front; Di is the axial thickness of the i-th glass or air lens element; and Ni is the refractive index of the material of the i-th lens element.

FIVE ELEMENT PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to photographic objectives and more particularly to objectives of standard or quasi-standard field angle.

Triplet objectives of the Tessar type, though widely having used in photographic devices tend to exhibit large longitudinal deviation from an ideal image field in the sagittal plane. At the same time, their astigmatism is quite large.

Various proposals for improving the aberrations of the Tessar type objectives have been made. One of these proposals, disclosed in U.S. Pat. No. 3,011,401 makes use of an additional lens element of bi-convex form positioned at the rear of the objective. With this Tessar type of objective system it is quite difficult to achieve a good compromise between the requirements of increasing the back focal length and of minimizing the various aberrations. Another proposed system is disclosed in Japanese Patent Application Laid-Open No.Sho 51-143326 where the additional lens element is in the form of a positive meniscus lens.

SUMMARY OF THE INVENTION

An object of the present invention is to provide an objective lens system of the expanded Tessar type having a standard or quasi-standard field angle.

Another object of the invention is to provide the objective lens system of the type described with a long back focal length suited for use with a single lens reflex camera, while simultaneously minimizing increases in dimensions of the entire system particularly in the axial direction.

A further object of the invention is to provide an improved objective lens system of the type described in which the positive supplemental lens at the rear of the Tessar type objective is utilized for facilitating flatness of the image field throughout an included angle of more than 50° and in which the image field curvature is corrected to a minimum and the astigmatism reduced by a front group of the Tessar type with a suitable arrangement and choice of glass materials.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is an axial sectional view of a first embodiment of an objective lens system according to the present invention.

FIG. 2 is a similar view showing a second embodiment of the invention.

FIG. 3 is a similar view showing a third embodiment of the invention.

FIGS. 4A to 4C are graphic representations of spherical aberrations for the d line and g line of the sodium spectrum, astigmatism with the sagittal and meridional fans, and distortion of the lens of FIG. 1, respectively.

FIGS. 5A to 5C are similar representations concerning the lens of FIG. 2.

FIGS. 6A to 6C are similar representations concerning the lens of FIG. 3.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIGS. 1 to 3, the objective lens system of the present invention comprises a triplet objective of the Tessar type followed by a positive lens element in bi-convex form. The triplet comprises, from front to rear, a positive first lens with the front surface convex toward the front, a second lens of bi-concave configuration and a positive third lens which is a doublet consisting of a negative lens element and a bi-convex lens element cemented together at their adjoining surfaces.

The system of the invention fulfills the following requirements:

$$0.55 < \left| \frac{R_8}{R_9} \right| < 1.4, \text{ where } R_9 < 0 \quad (1)$$

$$D_4 < 0.056f \quad (2)$$

$$0.08 < N_1 - N_2 \quad (3)$$

$$0.16f < D_5 + D_6 < 0.21f \quad (4)$$

$$\frac{0.08}{f} \leqq \frac{N_4 - N_3}{R_6} < \frac{0.3}{f} \quad (5)$$

$$0.48f < |R_3| < 0.62f, \text{ where } R_3 < 0 \quad (6)$$

wherein f is the focal length of the entire system; R_8 and R_9 are the radii of curvature of the front and rear surfaces of the fifth or supplementary lens element respectively; D_4 is the axial air separation between the bi-concave lens and the doublet; N_1 and N_2 are the indices of refraction of glasses from which the first and second elements are made up; D_5 and D_6 are the axial thicknesses of the elements in the doublet respectively; N_3 and N_4 are the indices of refraction of the elements in the doublet; R_6 is the radius of curvature of the cemented surface; and R_3 is the radius of curvature of the front surface of the bi-concave lens element.

The requirement (1) represents the configuration of the surfaces of the rearmost positive lens element set forth to assist in bringing the image plane to a flatness in good balance. When the upper and lower limits of the range are violated, the image plane is over- and under-corrected at the marginal and intermediate zones respectively.

Statement (2) defines the axial air separation between the second and third components. This plays an important part in controlling halo produced in the sagittal light beam by the second component or bi-concave lens. When this limit is exceeded, the sagittal halo becomes extremely large.

The requirement (3) represents the difference between the refractive indices of the positive first and negative second lenses, which, when below 0.08, leads to substantial enlargement of the longitudinal deviations for the position of the sagittal image points.

Statement (4) defines the axial thickness of the doublet. This most seriously affects coma and astigmatism. When the upper limit is exceeded, the outward coma becomes extremely large. When the lower limit is exceeded, the substantial astigmatism appears in the picture field.

The requirement (5) represents the refractive power of the adjoining surfaces of the lenses of the doublet, and affects field curvature, astigmatism and coma aberration.

When the upper limit is exceeded, a large amount of coma is produced. When the lower limit is exceeded, good correction for field curvature and astigmatism becomes difficult to achieve.

The requirement (6) serves for minimizing the increase in dimensions of the system as the back focal length is increased while simultaneously achieving good correction of image field. When the lower limit is exceeded, large flare is produced. When the upper limit is exceeded, it becomes difficult to correct the image field while keeping the size of the system to a minimum.

Three examples of specific objective lens systems each having a large relative aperture of 1:2.5 with a total field angle of 50°, a back focal length of 0.8 f or more, and a total longitudinal length of less than 1.44 f measured from the front to the rear vertex can be constructed in accordance with the numerical data given in the following tables for the radii of curvature, R, the axial separations, D, between the successive surfaces along with the indices of refraction, Nd, for the d line of the sodium spectrum and the Abbe numbers, νd, for the various lens elements.

EXAMPLE 1

Focal length f = 100 F-number: 2.5 2ω = 50°				
	R	D	Nd	νd

$D_5 + D_6 = 20$
$(N_4 - N_3)/R_6 = 0.0029$

What is claimed is:

1. An objective lens system comprising, from front to rear, a positive first lens with the front surface convex toward the front, a bi-concave second lens, a positive third lens consisting of a negative element and a bi-convex lens element cemented together at their adjoining surface, and a bi-convex fourth lens, and fulfilling the following requirements:

$$0.595 \leqq |R_8| / |R_9| < 1.34, \text{ where } R_9 < 0 \quad (1)$$
$$0.0287f \leqq D_4 \leqq 0.0551f \quad (2)$$
$$0.095 \leqq N_1 - N_2 \leqq 0.156 \quad (3)$$
$$0.1669f \leqq D_5 + D_6 \leqq 0.20f \quad (4)$$
$$\frac{0.08}{f} \leqq \frac{N_4 - N_3}{R_6} \leqq \frac{0.29}{f} \quad (5)$$
$$0.5f \leqq |R_3| \leqq 0.53799f, \text{ where } R_3 < 0 \quad (6)$$

wherein f is the focal length of the entire lens system; Ri is the radius of curvature of the i-th surface counting from the front; Di is the i-th axial thickness or air separation; and Ni is the index of refraction of the i-th lens element.

2. An objective lens system according to claim 1, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

Focal length f = 100 F-number: 2.5 2ω = 50°				
	R	D	Nd	νd
1	66.915	12.98	$N_1 = 1.757$	$\nu_1 = 47.9$
2	−895.23	9.98

[57] **ABSTRACT**

The disclosed camera objective has a fixed rear lens group preceded by a four-component front group with negatively refracting second and third components which are axially shiftable between positively refracting first and fourth components to establish a minimum overall focal length F_{min} and a maximum overall focal length F_{max} with a ratio of about 1:2. The substantially stationary first component consists of a negative front lens (which may be limitedly shiftable for focusing purposes) followed by three positive lenses while the movable second component consists of two negative lenses followed by a positive lens; the movable third component and the fixed fourth component are constituted by a negative and a positive lens, respectively. The range of overall focal lengths, the image diagonal and the back-focal length of the objective as well as the individual focal lengths of the first and fourth components and of the rear lens group all lie between the absolute magnitudes of the individual focal lengths of the second and third components.

FIG. 4

VARIFOCAL OBJECTIVE FOR PHOTOGRAPHIC CAMERA

FIELD OF THE INVENTION

My present invention relates to an objective of the varifocal type for a photographic camera.

BACKGROUND OF THE INVENTION

Varifocal camera objectives of the type here envisaged are divided into a variable-focus front lens group and a fixed-focus rear lens group; the front group consists of four distinct components, namely a multilens first component of positive refractivity (considered stationary even though one or more of its lenses may be limitedly shiftable for focusing purposes), axially shiftable second and third components of negative refractivity, and a stationary positively refracting fourth component.

For certain cameras, such as those producing middle-sized still photographs of 60×60 mm or 45×60 mm, such objectives have hitherto been difficult to design in view of dimensional considerations imposing limitations upon total axial length and maximum lens diameter.

OBJECTS OF THE INVENTION

The general object of my present invention is to provide a varifocal objective of the type referred to which, with due regard to these dimensional restrictions, satisfies the requirements for good optical performance, simple construction and large relative aperture (preferably 1:4.5) with a focal-length ratio of about 2:1.

A more particular object is to provide a lens assembly for the purpose set forth whose minimum overall focal length, defining the wide-angle end of the varifocal range, is less than the image diagonal so as to provide a large field angle.

SUMMARY OF THE INVENTION

Let f_I, f_{II}, f_{III}, f_{IV} and f_V be the individual focal lengths of the four components I, II, III, IV of the adjustable front group and of the fixed rear group V, respectively. The absolute values of these individual focal lengths in my improved objective all are of the order of magnitude of the diagonal FD of the image projected upon a receiving surface, such as a film, positioned in a transverse plane separated by an invariable back-focal distance from the lat vertex of the rear lens group. The first component consists of a negative front lens **L1** followed by three positive lenses **L2**, **L3** and **L4**, while the second component consists of two negative lenses **L5**, **L6** followed by a positive lens **L7**; the third and fourth components respectively consist of a negative lens **L8** and a positive lens **L9**. I have found that, in order to realize the aforestated objects, the following requirements should be satisfied by the individual focal lengths f_I–f_{IV}, the radius **r2** of the rear surface of lens **L1**, the radius **r3** of the front surface of lens **L2**, the air spaces **d10** and **d12** respectively separating lens **L6** from lenses **L5** and **L7**, the radii **r10** and **r12** of the rear surfaces of lenses **L5** and **L6**, and the radius **r13** of the front surface of lens **L7**:

(1) $|f_I| \geqq FD$,
(2) $|f_{II}| \leqq FD$,
(3) $|f_{III}| \geqq FD$,
(4) $f_{IV} \leqq 0.5(|f_{II}| + f_{III}|)$,
(5) **r3**<**r2**,
(6) **d10**>2**d12**,
(7) **r13**<0.6(**r10**+**r12**).

Moreover, the stroke of the second component (i.e. the difference of its distances from the first component in the two limiting positions defining the wide-angle and the telephoto ends of the varifocal range) should be less than 0.6FD while the distances of the two movable components from each other in their two limiting positions should differ from each other by less than $0.5f_{II}$.

Relationships (1) through (4) establish the desired varifocal range. Relationship (5) minimizes the spherical zonal aberration in multilens component I. Relationships (6) and (7) help correct coma and astigmatism whereas the last two conditions lead to favorable dimensions for the total axial length and the lens diameters of the objective.

In the objective more particularly described hereinafter, not only the minimum and maximum overall focal length F_{min} and F_{max} but also the image diagonal FD and the individual focal lengths f_I, f_{IV} and f_V as well as the back-focal distance s′ lie between $|f_{II}|$ and $|f_{III}|$. Radius **r13**, moreover, lies roughly midway between radii **r10** and **r12**.

With each of the lenses **L1**,**L9** of the adjustable front group designed as a singlet, the objects of my invention are also satisfied if the front and rear surfaces of these lenses, identified by the radii **a1**–**a18**, have surface powers (n−1)/r—with r based on a value of unity for individual focal length f_V—within the following ranges:

(**r1**) +0.050 to +0.075
(**r2**) −0.820 to −0.940
(**r3**) +0.780 to +0.860
(**r4**) +0.060 to +0.080
(**r5**) +0.540 to +0.600
(**r6**) −0.160 to −0.200
(**r7**) +1.000 to +1.150
(**r8**) −0.560 to −0.650
(**r9**) +0.180 to +0.210
(**r10**) −2.800 to −3.100
(**r11**) −0.400 to −0.470
(**r12**) −1.050 to −1.250
(**r13**) +1.750 to +2.050
(**r14**) +0.040 to +0.050
(**r15**) −0.680 to −0.800
(**r16**) +0.020 to +0.030
(**r17**) +0.900 to +1.050
(**r18**) +0.270 to +0.330

Referred to the same value of f_V=1, the axial thickness of the lenses, their fixed separations and the main values of their variable separations are all equal to 0.1 or less.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** diagrammatically illustrates a varifocal objective embodying my invention;

FIG. **2** is a view similar to FIG. **1**, showing a modified rear lens group;

FIG. **3** is a graph representing the displacement of the shiftable components of the front lens group having parameters substantially as given hereinafter in Tables I and II;

FIG. **4** is a set of graphs similar to FIG. **3** but relating to a front lens group having parameters substantially as given hereinafter in Table III.

SPECIFIC DESCRIPTION

In FIG. 1 I have shown a varifocal objective according to my invention with a front lens group consisting of a substantially stationary first component I of positive refractivity, an axially shiftable second component II of negative refractivity, a similarly shiftable third component III also of negative refractivity, and a positively refracting stationary fourth component IV; these components are followed by a fixed rear lens group V.

Component I consists of a negative front lens L1, with radii r1,r2 and thickness d1, separated by an air space d2 from three positive lenses L2 (radii r3, r4 and thickness d3), L3 (radii r5,r6 and thickness d5) and L4 (radii r7,r8 and thickness d7), the intervening air spaces being designated d4 and d6. Component II consists of a negative lens L5 (radii r9, r10 and thickness d9) separated by an air space d10 from a negative lens L6 (radii r11, r12 and thickness d11) which in turn is separated by an air space d12 from a positive lens L7 (radii r13, r14 and thickness d13). Component III is a single negative lens L8 with radii r15,r16 and thickness d15; component IV is a single positive lens L9 with radii r17,r18 and thickness d17. Rear group V consists of a positive lens L10 (radii r19, r20 and thickness d19) separated by an air space d18 from lens L9, a negative lens L11 (radii r21,r22 and thickness d21), another negative lens L12 (radii r23,r24 and thickness d23), a doublet formed from a negative lens L13 (radii r25,r26 and thickness d25) cemented onto a positive lens L14 (radii r26,r27 and thickness d26), and a final positive lens L15 (radii r28,r29 and thickness d28); the intervening air spaces have been designated d20, d22, d24 and d27.

Three variable air spaces d8, d14 and d16 exist between lenses L5/L6, L7/L8 and L8/L9. In the illustrated position, air space d8 has its minimum value while air space d14 and d16 are at a maximum; this corresponds to the wide-angle end of the varifocal range. The variations of spaces d8 and d14 throughout that range have been shown in FIGS. 3 and 4 for different sets of parameters tabulated hereinafter.

The objective shown in FIG. 2 differs from that of FIG. 1 only by the substitution of a modified rear lens group V' for group V. Group V' consists of a doublet formed from a positive lens L10 (radii r19', r20' and thickness d19') cemented onto a negative lens L11' (radii r20', r21' and thickness d20'), a negative lens L12' (radii r22', r23' and thickness d22'), another doublet formed from a negative lens L13' (radii r24', r25' and thickness d24') cemented onto a positive lens L14' (radii r25', r26' and thickness d25'), and a final positive lens L15' (radii r27', r28' and thickness d27'); the intervening air spaces have been designated d21', d23' and d26'.

Representative values for the radii r1–r18 and the thicknesses and separations d1–d17 of lenses L1–L9, based on a value of unity for the individual focal length f_V of lens group V or V', have been given in the following Tables I, II and III together with the refractive indices n_e and the Abbé numbers ν_e of these lenses as well as their surface powers $\Delta n/r$ (with $\Delta n = n_e - I$) and with r representing the respective radii r1–r18.

The lens assemblies for Tables I, II and III may be combined with either of the lens assemblies given in Tables IV and V to yield a varifocal objective having a relative aperture of 1:45 and a varifocal ratio of about 2:1.

More particularly, the objective represented by a combination of Tables I and IV has overall focal lengths $F_{min}=0.617$ and $F_{max}=1.233$; the same is true of the combinations of Table II with Table IV and Table III with Table V. The back-focal length s' varies slightly in these three instances, being 0.84 in the first, 0.88 in the second and 0.85 in the third case.

In FIGS. 3 and 4, where the left-hand curve represents the variable air space d8 and the right-hand curve represents the sum of air spaces d8 and d14 so as to show the actual positions of components II and III relative to component I, I have given the values of the overall focal length F (along the ordinate axis) in terms of the ratio F/F_{min} and also, for the limiting values F_{min} and F_{max}, in terms of the ratio F/f_V corresponding to the reference value used in the preceding Tables.

Similarly, the variable distances have been given (along the abscissa axis) in terms of d/F_{min} and also, for the limiting positions, in terms of d/f_V. It will be noted that the values given for distances d8 and d8+d14 in FIG. 3 correspond to those of Table I and closely approximate those of Table II; the values of FIG. 4 agree with those of Table III.

It will be apparent that some of the singlets L1–L9 of the varifocal group I–IV could be replaced by equivalent doublets with cemented surfaces, for better correction of chromatic aberrations, as is well known per se.

I claim:

1. In an optical objective with an adjustable front group and a fixed rear group, said front group consisting of a substantially stationary positive first component, an axially shiftable negative second component, an axially shiftable negative third component and a fixed positive fourth component, said second and third components having first limiting positions relatively close to said first component and remote from each other for establishing a minimum overall focal length F_{min} and having second limiting positions relatively remote from said first component and close to each other for establishing a maximum overall focal length F_{max}, the axial shifting of said second and third components between said first and second limiting positions thereof being correlated to project an image of an object upon a receiving surface in a plane separated from said rear group by an invariable back-focal distance,

the improvement wherein said first, second, third and fourth components and said rear group having respective individual focal lengths f_I, f_{II}, f_{III}, f_{IV}, f_V whose absolute values are of the order of magnitude of the diagonal FD of the projected image, said first component consisting of a negative front lens L1 followed by three positive lenses L2, L3, L4, said second component consisting of two negative lenses L5, L6 followed by a positive lens L7, said third component consisting of a negative lens L8, said fourth component consisting of a positive lens L9, said front lens L1 having a rear surface of radius r2, said lens L2 having a front surface of radius r3, said lens L6 being separated from lenses L5 and L7 by respective air spaces d10 and d12, said lenses L5 and L6 having rear surfaces of respective radii r10 and r12, said lens L7 having a front surface of radius r13, the following conditions being satisfied:

$f_I \geqq FD$,
$|f_{II}| \leqq FD$,
$|f_{III}| \geqq FD$,
$f_{IV} \leqq 0.5(|f_{II}|+|f_{III}|)$,
$r3 < r2$,
$d10 > 2d12$,
$r13 < 0.6(r10+r12)$,

the distances of said second component from said first component in said first and second limiting positions differing from each other by less than 0.6FD, the distances of said third component from said second component in said first and second limiting positions differing from each other by less than $0.5f_{II}$.

2. The improvement defined in claim 1 wherein the ratio of said overall focal lengths $F_{max}:F_{min}$ is substantially 2:1.

3. The improvement defined in claim 2 wherein said overall focal length F_{min} and F_{max}, said diagonal FD, said individual focal lengths f_I, f_{IV}, and f_V and said back-focal distance all lie between $|f_{II}|$ and $|f_{III}|$.

4. The improvement defined in claim 3 wherein $r10 < r13 < r12$.

5. The improvement defined in claim 4 wherein the surface radii r1 to r18 and the refractive indices n or the lenses L1 to L9 of said front group are so chosen, with reference to a value of unity for the individual focal length f_V of said rear group, as to have surface powers $(n-1)/r$ within the following ranges for the surfaces thereof defined by their respective radii:

(r1) +0.050 to +0.075
(r2) −0.820 to −0.940
(r3) +0.780 to +0.860
(r4) +0.060 to +0.080
(r5) +0.540 to +0.600
(r6) −0.160 to −0.200
(r7) +1.000 to +1.150
(r8) −0.560 to −0.650
(r9) +0.180 to +0.210
(r10) −2.800 to −3.100
(r11) −0.400 to −0.470
(r12) −1.050 to −1.250
(r13) +1.750 to +2.050
(r14) +0.040 to +0.050
(r15) −0.680 to −0.800
(r16) +0.020 to +0.030
(r17) +0.900 to +1.050
(r18) +0.270 to +0.330

6. The improvement defined in claim 5 wherein the thicknesses of said lenses L1 to L9, the fixed separations thereof and the mean values of their variable separations do not exceed substantially $0.1f_V$.

7. The improvement defined in claim 6 wherein the radii r1 to r18 and the thicknesses and separations d1 to d17 of said lenses L1 to L9, based upon said value of unity for f_V, their refractive indices n and their Abbé numbers ν have numerical values substantially as given in the following table:

LENSES	RADII	THICKNESSES AND SEPARATIONS	n	ν
L1	r1 = +14.1	d1 = 0.02	1.79	26
	r2 = +0.9	d2 = 0.04

[57] ABSTRACT

The wide angle objective disclosed is composed of eight components. The first counting from the front is a negative meniscus lens of forward convexity. The second component is a positive lens with a front surface of strong positive power, and the third is a biconcave lens having a strong surface facing the rear. The fourth component is a positive lens with a front surface of strong positive power and the fifth is a doublet lens of positive power with its front surface convex toward the front and with its cemented surface of positive power convex torward the rear. The sixth component is a biconcave lens, the seventh is a positive doublet lens convex toward the rear and consisting of a negative lens element and a positive lens element cemented together at their adjoining surfaces, and the eighth is a positive lens with its rear surface being stronger in power than its front surface. In focusing the objective, as the entire lens system is axially moved as a whole relative to the image plane, the first and second components and moved as one fixed group and the third to eighth components as another fixed group are moved as another fixed group in differential relation to the first fixed group.

COMPACT RETROFOCUS TYPE WIDE ANGLE OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to retrofocus type objectives of long back focal length suited for use in single lens reflex cameras, and more particularly to retrofocus type wide angle objectives of minimized bulk and size.

The retrofocus type objective, because of its intent of lengthening the back focal length, uses a negative lens of strong power at the front. This produces the drawback of increasing the distortion, coma, halo of sagittal rays, and other abberrations. To minimize the bulk and size of the objective as in the present invention, the negative power of the front component is required to be stronger than that of the ordinary retrofocus type objective. Thus, the various aberrations tend to increase further. Particularly with an objective of large relative aperture, the halo of sagittal rays becomes serious, and good correction of the aberrations becomes difficult.

A wide variaty of retrofocus type objectives have already been developed. Examples of an objective comprising a negative front group, a positive middle group, a diaphragm, and a positive rear group, the front group including negative, positive and negative lenses, and the rear group including negative, positive, positive lenses, are shown in U.S. Pat. No. 3,736,049 and No. 3,982,823.

SUMMARY OF THE INVENTION

A first object of the present invention is to provide a compact retrofocus type objective.

A second object is to provide for a retrofocus type objective with an increased relative aperture.

A third object is to achieve good correction of the various aberrations.

The retrofocus type objective according to the present invention comprises, from front to rear, a negative first lens in the meniscus form of forward convexity, a positive second lens whose front surface is of strong positive power, a biconcave third lens whose surface strong in power faces the rear, a positive fourth lens whose front surface is stronger in power than its rear surface, a positive fifth lens in doublet form with its frontmost surface convex toward the front and with its cemented surface of positive power convex toward the rear, a biconcave sixth lens, a positive seventh lens in meniscus doublet form convex toward the rear and consisting of a negative lens element and a positive lens element cemented together at their adjoining surfaces, and a positive eighth lens whose rear surface is stronger in power than its front surface, and is characterized by fulfilling the following conditions:

$$\frac{0.33}{f} < \left|\frac{N_5 - N_6}{r_{10}}\right| < \frac{0.42}{f} \quad (1)$$

$$1.4 < \left|\frac{f_{5-6}}{f_{7-11}}\right| < 1.82 \quad (2)$$

$$0.4 < \frac{r_7}{r_9} < 0.64 \quad (3)$$

$$0.75 < \frac{d_6}{d_{11}} < 0.95 \quad (4)$$

$$20 < \nu_9 - \nu_8 < 28 \quad (5)$$

$$-0.1/f < 1/f_{1-4} < 0.15/f \quad (6)$$

where

f: the focal length of the entire system;

r_i: the radius of curvature of the i-th surface;

dj: the axial lens thickness or air separation between the j-th surface and the (j+1)th surface;

N_k: the index of refraction for the k-th lens element;

νl: the Abbe number for the l-th lens element; and

f_{m-n}: the overall focal length of the m-th to n-th surfaces.

These conditions have now been found to be effective for realization of a high performance retrofocus type photographic lens system having a back focal length of at least 1.02f and as large a relative aperture as F2 with the limitation of the bulk and size to 2.47f in the physical length and 0.9f in the diameter of the front lens member.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a sectional view of one embodiment of a retrofocus type objective according to the present invention.

FIG. 2 is a similar view showing another embodiment of the invention.

FIG. 3 is a similar view showing still another embodiment of the invention.

FIGS. 4A to 4C are graphs showing the spherical aberration, astigmatism and distortion of the objective of FIG. 1 respectively, when focused at infinity.

FIGS. 5A to 5C are similar graphs for the objective of FIG. 2.

FIGS. 6A to 6C are similar graphs for the objective of FIG. 3.

FIGS. 7A and 7B are graphs showing the spherical aberration and astigmatism of the objective of FIG. 1 when focused down to shorter object distances without variation of the lens separation between the first and second lens groups.

FIGS. 8A and 8B are similar graphs for the objective of FIG. 1 when the lens separation is varied during focusing.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The embodiments of the objectives represented in FIGS. 1 to 3 individually satisfy the above-defined conditions, each of which is explained below in detail.

In designing a wide angle objective for use in a single lens reflex camera, the shorter the total optical length of the objective, the stronger must be the negative power of the front part and the positive power of the rear part in order to assure the necessary back focal length. This intensifies the degree of curvature of the spherical aberration curve. Since the central bundle of light rays expands most widely in a space which the fifth lens component is intended to occupy, the curvature of the spherical aberration curve can be flattened to an acceptable degree by constructing the fifth component in the cemented form to satisfy condition (1). As the positive lens element is made from a glass material having a high index of refraction and the negative lens element from a glass material having a low index of refraction, this cemented lens contributes to correction of field curvature. In order to effect production of as little coma as possible, it is preferable to position the cemented surface adjacent the diaphragm. When the upper limit of condition (1) is exceeded, an unacceptable coma will be produced and deteriorate the image quality. When the lower limit is exceeded, the spherical aberration will be under-corrected, and the curvature of image field will also become large.

From a reason to be described later, since the composite system of the first and second components is

almost afocal, a large proportion of the negative power of the front part in the retrofocus type lens system must be concentrated only in the third component. This in turn causes the third component to produce very large distortion, coma and halo of sagittal rays. Particularly at the large relative aperture of F2, the halo of sagittal rays is very pronounced. In general it is advantageous to compensate for the halo of sagittal rays by those of the components at which the bundle size of sagittal rays is most widely expanded. To allow for this, conditions (2), (3) and (4) are set forth.

Condition (2) is a compromise between the requirements of lengthening the back focal length and shortening the total optical length and of well compensating for the halo of sagittal rays. In the latter connection, the powers of the fourth and fifth components must be strengthened to a moderate degree. When the lower limit of condition (2) is exceeded, though the back focal length becomes longer, the third component introduces too large a halo of sagittal rays to be properly corrected for by the fourth and fifth components. When the upper limit of condition (2) is exceeded, the assurance for the necessary back focal length becomes difficult, and very large coma and field curvature are produced.

Even if condition (2) is satisfied, an unbalanced power distribution over the fourth and fifth components will lead to the production of very large spherical aberration and coma. On this account, an optimum power distribution is set forth in condition (3) within a framework in which both components are positive lenses with their front surfaces convex toward the front and stronger in curvature than their rear surfaces. Under condition (3) the halo of sagittal rays can be effectively compensated for, while simultaneously suppressing the production of the other aberrations. When the upper limit of condition (3) is exceeded, the halo of sagittal rays will be insufficiently compensated for, and the spherical aberration will also be under-corrected. When the lower limit of condition (3) is exceeded, very large astigmatism and coma will be produced.

In effectively compensating for the halo of saggital rays, the arrangement of the fourth and fifth components is also important. When they are positioned in an air space between the third and sixth components at almost the center of the axial separation thereof, a good aberrational correction can be performed. This is condition (4). When the upper limit of condition (4) is exceeded, the diameter of an effective light bundle at the fourth and fifth components will become so large that very large spherical aberration is produced. The entire length is also increased so that one of the objects of the invention cannot be achieved. When the lower limit of condition (4) is exceeded, the axial separation between the third and fourth components will become so narrow that not only good correction of the halo of sagittal rays is difficult to perform. However, the back focal length is not lengthened.

Thus, the halo of sagittal rays introduced by the preceding components has been cancelled out by the suitable design of the fourth and fifth components.

The lateral chromatic aberration introduced by the preceding components is, however, not yet compensated for yet. Then, seventh component is constructed in the cemented form consisting of negative and positive lens elements for which the dispersive indices are controlled to differ greatly from each other in accordance with condition (5). When the upper limit of condition (5) is exceeded, over-correction of lateral chromatic aberration will result. When the lower limit of condition (5) is exceeded, it will be difficult to perform good correction.

On account of the large relative aperture, the front part tends to produce large aberrations. To avoid this, it is very effective for the first and second components to form a system nearly afocal. With the first component of negative power and the second component of positive power, such system assists in lengthening the back focal length while nevertheless permitting little distortion, astigmatism and coma be produced to. Then, condition (6) is set forth. When the upper limit of condition (6) is exceeded, it will become impossible to assure the sufficiently long back focal length. When the lower limit is exceeded, the back focal length can be advantageously lengthened, but very large distortion is produced.

Retrofocus type objectives generally exhibit the drawback that when they are focused upon shorter object distances, the astigmatic difference is greatly increased. It is particularly true that where the relative aperture is large, as the depth of focus is narrow, substantial deterioration of the image quality will be noted. To preserve high grade imaging performance even for objects at shorter distances, according to the present invention, whilst the entire system is axially moved forwards, the axial separation between the first group and the second group is narrowed, where the first group is composed of the first and second components and the second group is composed of the third to eighth component. Since the light bundle in this variable separation, namely, d_4 is made almost afocal based on the condition (6), the focal length of the entire system remains almost unchanged throughout the focusing range, and the variation with focusing of coma is limited to a minimum. How such focusing provision affects the imagery can be seen by comparison of FIGS. 7A–7B with FIGS. 8A–8B, where the object distance corresponds to an image magnification of −0.171, and the axial separation d_4 for that shorter object distance is different from that for object at infinity by 1.53.

The three specific objective lens systems can be constructed in accordance with the numerical data given below for the radii of curvature, r, of the lens surfaces, the axial lens thicknesses or air separations, d, along with the indices of refraction, Nd, for the spectral d line of sodium and the Abbe numbers, νd, for the spectral d line of sodium, for the various lens elements. The character f denotes the focal length of the entire system, b.f. the back focal length, L the total optical length and D the diameter of the front member.

What is claimed is:

1. A compact retrofocus type wide angle objective lens system comprising: from front to rear, a negative meniscus first lens convex toward the front, a positive second lens with its front surface having a strong positive power, a bi-concave third lens with its strong power surface facing the rear, a positive fourth lens with its front surface having a strong positive power, a positive cemented fifth lens with its cemented surface being convex toward the rear and having a positive power, and with its first surface being convex toward the front, a bi-concave sixth lens, a positive meniscus cemented seventh lens convex toward the rear, and a positive eighth lens with its strong power surface being faced toward the rear, and satisfying the following relationships:

$$\frac{0.33}{f} < \left| \frac{N_5 - N_6}{r_{10}} \right| < \frac{0.42}{f} \quad (1)$$

$$1.4 < \left| \frac{f_{5-6}}{f_{7-11}} \right| < 1.82 \quad (2)$$

$$0.4 < \frac{r_7}{r_9} < 0.64 \quad (3)$$

$$0.75 < \frac{d_6}{d_{11}} < 0.95 \quad (4)$$

$$20 < \nu_9 - \nu_8 < 28 \quad (5)$$

$$-0.1/f < 1/f_{1-4} < 0.15/f \quad (6)$$

where f is the focal length of the entire system; r_i is the radius of curvature of the i-th surface; d_j is the j-th axial lens thickness or air separation; N_k is the index of refraction of a material from which the k-th lens element is made; νl is the Abbe number of a material from which the l-th lens element is made; and f_{m-n} is the overall focal length of the m-th to n-th surfaces.

2. An objective lens system as described in claim 1, wherein said first and said second lenses are combined in fixed spatial relation as a group I, and said third to said eighth lenses are combined in fixed spatial relation as a group II, and wherein during focusing, whilst the entire system is axially moved relative to the film plane, said two groups I and II are axially moved in differential relation to each other.

3. An objective lens system as described in claim 1, and wherein said system has the following numerical data as related to a focal length of 100.

[57] **ABSTRACT**

A camera housing carries an objective whose optical axis O is tiltable and/or transversely shiftable with respect to a reference line A passing centrally through an exposure window for adjusting the position of an object plane and/or eliminating perspective distortion with shots taken at certain angles. A presettable iris diaphragm and an adjoining shutter in the lens assembly of the objective are tripped, at the instant of exposure, by a deformable linkage in the shape of an articulated or flexible shaft extending generally parallel to the optical axis from the housing to the objective.

CAMERA WITH TRANSVERSELY DISPLACEABLE OBJECTIVE

FIELD OF THE INVENTION

Our present invention relates to a photographic camera whose objective is transversely displaceable (i.e. tiltable and/or shiftable) for the purpose of adjusting the position of an object plane and/or eliminating perspective distortion.

BACKGROUND OF THE INVENTION

In a camera whose objective has a optical axis coinciding with a reference line perpendicular to the surface of a film or other photosensitive medium, generally at the center of an exposure window formed by the camera housing, the object plane lies parallel to the image plane constituted by the film surface. When the objective is tilted so that the optical axis includes an angle other than 90° with the image plane, the image and object planes as well as the diaphragm plane of the objective intersect (according to Scheimpflug's law) along a common line at a finite distance from the axis. Such a tilting can therefore be used to bring objects into sharp focus which do not all lie in a relatively narrow zone transverse to the field of view.

A parallel shifting of the objective from its normal position is useful for the purpose of suppressing perspective distortion, e.g. when it is desired to take pictures of a tall building.

Objectives capable of either or both types of transverse adjustment are already well known. In such camera, however, it is generally not possible to trip the shutter of the objective by operating a pushbutton or similar release means on the camera housing. The setting of the diaphragm to a preselected stop during the taking of a picture, from a wide-open position in which the diaphragm is placed for view-finding and focusing purposes, also requires manipulation of a trigger at the objective in lieu of the more convenient operation of a control element (usually coupled with the release button) on the housing.

OBJECT OF THE INVENTION

The object of our present invention is to facilitate, in a camera of the character described, the actuation of exposure-controlling means on the objective (such as a shutter possibly associated with a presettable diaphragm) with the aid of release means on the camera housing.

SUMMARY OF THE INVENTION

We realize this object, in accordance with our present invention, by the provision of a deformable linkage extending generally parallel to the optical axis from the release means on the housing to the exposure-controlling means on the objective.

Such a linkage, pursuant to a more particular feature of our invention, comprises a shaft which is rotatable upon operation of the release means and has extremities that are independently tiltable relatively to a central portion. While a flexible shaft may be used for this purpose, we prefer to employ an articulated one with two universal joints enabling a mutually parallel displacement of opposite shaft extremities as well as a relative tilting thereof.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** is a side view, partly in axial section, of a camera embodying our invention;

FIG. **2** is a view similar to FIG. **1** but showing the camera objective tilted with respect to its housing; and

FIG. **3** is another view similar to FIG. **1** in which the objective has been transversely shifted from its normal position.

SPECIFIC DESCRIPTION

In FIG. **1** we have shown a camera with a housing **1** and a preferably exchangeable objective **2** having lens members **5**, **6**, **7**, **8** supported by front and rear lens mounts **4'**, **4''**. The two lens mounts are interconnected by an internally threaded ring **9** which is rigid with a front tube **18**. This tube is connected with an annular supporting body **3** through the intermediary of a pair of cross-slides constituted by three dovetailed members **19**, **20** and **22**, member **20** being an annular disk integral with a skirt **46** which is threaded into tube **18**. Members **19** and **20** are relatively slidable, in a vertical direction, under the control of a driver **21** including a knob whose stem is journaled in an extension of member **19** and threadedly engages member **20**. A similar driver **23** with a knob (not shown) and a threaded stem analogously coacts with members **19** and **22** for relatively displacing them in a horizontal direction. Thus, the lens-supporting tube **18** can be shifted in two dimensions with respect to body **3** which is pivoted to a coupling ring **48** by a pair of horizontally separated wings **39** (only one shown) for swinging in a vertical plane about respective pins **17**. A bellows **14** bridges the gap between housing **1** and objective body **3** in a lighttight manner; the camera-side end of the bellows is received within the ring **48** which is secured to the camera housing via the usual bayonet coupling.

The swinging of objective body **3** together with front tube **18** is manually controllable by a knurled wheel **15** which projects slightly from body **3** and is rigid with a gear **43** meshing with another gear **44** on a spindle **16** threadedly engaging a swivelable nut **45** (FIG. **2**) on a forward extension of coupling ring **48**.

Mounting ring **9** carries a conventional iris diaphragm **10** and a shutter **11** closely juxtaposed between lens members **6** and **7**. Diaphragm **10** is of the presettable type; in a manner known per se, it is held in a wide-open position during focusing and snaps into a preselected stop position just prior to the opening of the shutter **11**. The preliminary adjustment of the diaphragm is carried out with the aid of a presetting ring **12** while focusing is performed by a rotation of tube **18** via a ring **13** about its optical axis O, such rotation causing a relative axial shift between the lens support and the cylindrical skirt **46** threadedly engaged thereby.

The camera housing **1** carries a viewfinder **41**, illuminated through a nonillustrated reflex prism or mirror in line with the objective, and a release button **42**. A rotatable knob **29** on housing **1** serves for the advance of a film (not shown) whose photosensitive surface is perpendicular to a reference line A passing substantially midway through an exposure window at the front of the housing.

In accordance with our present invention, a displacement of release button **42** is transmitted to the dia-

phragm **10** and the shutter **11** by an articulated linkage including a shaft **24** extending generally parallel to optical axis O alongside the rear lens mount **4''**, thus outside the field of illumination. Shaft **24** has two extremities **34** and **38** connected with its central portion by a pair of universal joints **32** and **33** facilitating a relative tilting of these extremities (FIG. **2**) and/or a relative shifting thereof parallel to each other (FIG. **3**) under the control of wheel **15** and slide drivers **21, 23**. Rear extremity **38** is journaled in a bearing **47** fixedly secured to coupling ring **48** and is rotatably connected via a pair of meshing gears **30, 31** with a stub shaft **26**. Upon connection of objective **2** to housing **1** by its bayonet coupling, a tongue **25** on stub shaft **26** fits into a groove **27** of an extension shaft **28** which is drivingly connected with release button **42** so as to rotate upon depression of the latter. The front extremity **34** of shaft **24** terminates in a tongue **34'** slidably received by a transverse slot **35** (FIG. **3**) in the hub of a gear **36** which is journaled in mounting ring **9** and meshes with another gear **37** forming part of the otherwise nonillustrated, conventional shutter-trip mechanism. Thus, actuation of release button **42** causes the shaft **24** to rotate and to trip the shutter **11** along with the diaphragm **10**, placing that diaphragm in its preselected position while the picture is being taken. Button **42** may also retract the reflector of the viewfinder during the exposure.

In the normal position of FIG. **1**, optical axis O is aligned with reference line A so that the objective **2** is centered on the exposure window **40**. When it is desired to focus the camera on certain objects in a zone which is not parallel to the film plane, i.e. nonvertical in the case here assumed, the user operates the wheel **15** to adjust the objective to a tilted position such as that shown in FIG. **2**. When the object to be photographed requires an eccentric positioning of the objective to minimize perspective distortion, the user relatively shifts the dovetailed members **19, 20** and/or **19, 22** with the aid of driver **21** or **23**, e.g. as shown in FIG. **3**. The extent of these various adjustments, which may also be carried out concurrently, can be read on respective scales not shown.

The tongue **34'** of extremity **34** and the mating slot **35** of gear **36** form an extensible coupling which allows for changes in the effective length of the deformable linkage **24**. Thus, the position of FIG. **2** requires a deeper penetration of slot **35** by tongue **34'** whereas the position of FIG. **3** calls for a partial withdrawal of the tongue from the slot. These coupling elements, however, are so dimensioned as to remain interengaged in all operating positions, thus insuring positive torque transmission from pushbutton **42** to the shutter-trip mechanism. A similar effect is achievable if the tripartite link **24, 34, 38** is replaced by a continuous flexible shaft.

It will be apparent that such a linkage may also be used to control only the presettable diaphragm if the shutter is carried on the camera housing or on the coupling ring **48**, for example.

We claim:

1. In a camera comprising a housing with an exposure window and an objective secured to said housing for illuminating a photosensitive medium through said window, said objective being provided with exposure-controlling means and defining an optical axis normally aligned with a reference line passing substantially centrally through said window, adjustable mounting means securing said objective to said housing with freedom of disalignment of said optical axis from said reference line, and release means on said housing for initiating a picture-taking operation,

the combination therewith of a mechanical linkage extending generally parallel to said optical axis from said release means to said exposure-controlling means for actuating same upon operation of said release means, said linkage including a rotatable shaft having a central portion, a first extremity connected with said central portion on the side of said housing, and a second extremity connected with said central portion on the side of said objective, said extremities being independently tiltable relatively to said central portion.

2. The combination defined in claim **1** wherein said exposure-controlling means includes a drive member on said objective forming an extensible coupling with said second extremity.

3. The combination defined in claim **2** wherein said exposure-controlling means comprises a presettable diaphragm and a shutter disposed between two lens members forming part of said objective.

4. The combination defined in claim **1, 2** or **3** wherein said extremities are articulated to said central portion by a pair of universal joints.

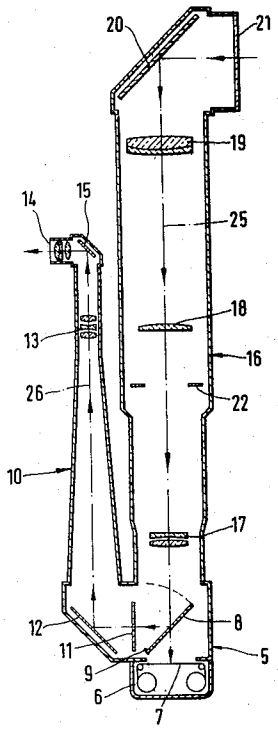
[57] **ABSTRACT**

In a photographic camera having a long focal length objective, both the objective and a tubular viewfinder extend vertically upwardly adjacent one another from the film carrying part of the camera which facilitates support of the camera in use. Preferably the objective and viewfinder are formed as a periscope arrangement with the light-admitting end of the objective being higher than the eyepiece of the viewfinder.

5 Claims, 2 Drawing Figures



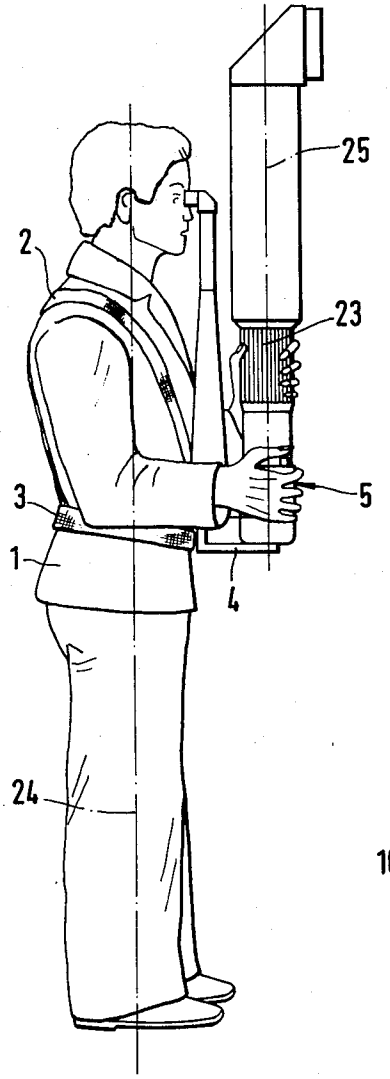


FIG. 1

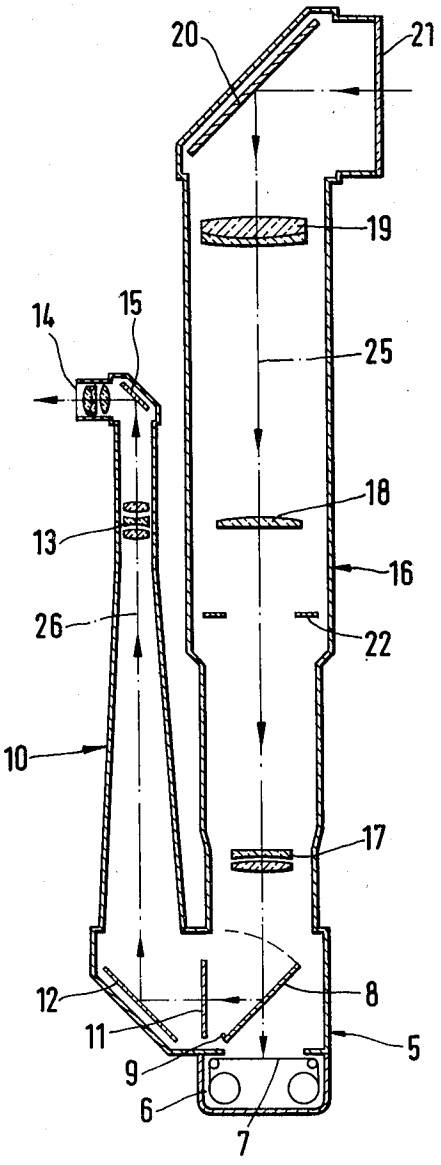
FIG. 2



PHOTOGRAPHIC CAMERA HAVING LONG FOCAL LENGTH OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to a photographic camera having a long focal length objective and a tubular viewfinder.

Photographic cameras with long focal length objectives are of considerable weight. In use, the unit comprising the objective and the camera must be held at eye level and directed towards the object which is being photographed. This holding at eye level in some cases must be maintained for a long time, since for example, in sports photography, the image must be captured at a very precise instant. The handling of a camera with a long focal length objective is therefore often fatiguing. At the same time, it is important that the objective and the camera be held very steady during release of the shutter.

Chest and shoulder braces are known by which the manipulation of such photographic assemblies is somewhat facilitated. However, since the center of gravity of the unit formed by the camera and the objective is located at some distance from the body of the photographer, where the apparatus extends horizontally from the photographer's eye, such supports are of limited effectiveness.

The additional use of a tripod is often not possible due to the local situation, and additionally, has the disadvantage that the mobility to direct the device at the object is reduced. In addition, a tripod is an extra load for the photographer if he wishes to change location.

There have been suggestions as to how to shorten the overall length of the objective lens assembly. This can be accomplished, for example, by the use of special optical systems in which the objective is in the form of a reflecting objective and/or the light path is deflected by means of a mirror or mirrors. The possible reduction in overall length by these techniques is however, limited. Furthermore, they have the disadvantage of increasing the diameter and weight of theobjective. They do not achieve a decrease in the burden on the photographer and moreover, such shortened objectives are also accompanied by optical disadvantages.

An object of this invention is to provide a photographic camera having a long focal length objective which as a result of its structure is less fatiguing on the photographer to handle than present designs. In particular, it is an object of the invention to provide a system or configuration which does not diminish the quality of the resulting photograph.

SUMMARY OF THE INVENTION

According to the invention, in photographic camera apparatus including a tubular objective of long focal length, the viewfinder is also in the form of a tube located next to the objective. In use, both the tubular objective and the viewfinder extend upwardly adjacent one another from the film carrying part of the apparatus and a light-deflecting mirror assembly is provided at the junction between the objective and the viewfinder for directing light from the light-admitting end of the objective to the viewfinder.

With this arrangement, the photographer does not have to hold the whole camera up to his eye or in front of his face while photographing but rather the camera can be held in a more comfortable position with its bulk situated below the photographer's eyes. Further, if the viewfinder is located next to the objective, the camera is in use in a position in front of the body of the photographer with the photographer looking down into the viewfinder and the optical axis of the objective assumes an essentially vertical position. The center of gravity of the device as a whole is relatively close to the photographer so that the resulting force moments are of low magnitude and can be easily managed by the photographer. This is of particular importance in a photographic session of lengthy duration.

An advantage which attaches to apparatus in accordance with the invention is the fact that light beams required for the photography are only reflected by a mirror which is in a location resulting in minimal effect on the image quality.

The additional cost occasioned by the construction of the viewfinder in the form of a tube is moderate.

The arrangement according to the invention makes it easy to bring the eyepiece of the viewfinder to eye level while the camera itself remains in a position which allows good support. The support of the camera can be facilitated, for example, by appropriate carrying straps in the form of a shoulder harness or body straps or even by the photographer wearing an item of clothing such as a vest or the like equipped with supporting means.

The viewfinder can be in the form of a telescope or in a further embodiment of the invention, it is proposed that the viewfinder be constructed in the form of a periscope. The result of the latter construction is that the photographer can maintain his normal head attitude in which he looks at the image in the viewfinder with one eye and may direct the other eye directly at the target. With a periscope viewfinder, as a rule, the light being passed is deflected by 90° twice, each time by a mirror assembly. While this may diminish the optical quality of the viewfinder image, the photograph itself is unaffected.

It is clear that the erect, normal body position in which the arms assume a position which can be maintained without fatigue, establishes conditions for a good photograph, since the danger of blurring resulting from unsteadiness is greatly reduced in this body position. Also, it is possible to maintain this body position for a relatively long time and thus to watch the object through the viewfinder for a long time as necessary for many photographs.

It is advantageous for the top part of the objective to project above the viewfinder. In the arrangement according to the invention, this results in the light-admitting end of the objective being at a height which for example, can extend over a crowd. This creates additional opportunities for picture taking under unfavorable external conditions.

The use of mirrors in photography is known as is the use of the above-mentioned type of mirror in the light-admitting end of the objective. The construction of the prior art devices have as their objects, for example, taking pictures "around a corner" or from a more or less concealed position, or by means of a kind of foxhole periscope or other periscope to establish a more favorable position for the entrance opening of the objective. The solution of a problem which would be comparable to that of the invention has not been attempted by these means.

In a preferred embodiment of the invention the objective has a light deflecting mirror at the light admitting

end with the light-admitting opening of the objective having an axis perpendicular to the general length of the tubular objective, i.e., with the axis of the opening being substantially parallel to the film plane.

DESCRIPTION OF DRAWINGS

FIG. **1** shows camera apparatus according to the invention with the objective and viewfinder in the positions in which they are used, and

FIG. **2** is a cross-sectional view of the apparatus.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENT

As shown in FIG. **1**, the photographer **1** carries for example, shoulder and hip straps **2** and **3**, to which a support element **4** is attached which serves to support the camera **5**. This camera comprises a viewfinder **10**, an objective **16**, and a film carrier in the form of a cassette **6** with a film **7** which in the arrangement shown is in the typical horizontal use position. A swinging mirror **8** is pivotal around a hinge **9** and a ground glass plate **11** is provided on which the image is viewed by means of the viewfinder.

The viewfinder, which is in the form of a periscope, has a mirror **12** at its lower end. It includes an optical system **13** and an eyepiece **14**. Deflecting mirror **15** is placed between the optical system and the eyepiece.

The entire viewfinder **10** can, if desired, be assembled as a unit which would include the mirror **12** and this unit may be removably attached to the camera. The viewfinder can also be integrally affixed to the camera and/or can have a telescopic i.e., collapsible construction in order to minimize the space requirement in the event of transport.

The objective of long focal length is designated **16** and comprises an optical system consisting of parts **17**, **18**, and **19**. At the upper end of the objective is a mirror **20** and a light-admitting opening **21** which is preferably covered with a transparent disc, not shown, in order to keep out contamination. The diaphragm of the objective is designated **22**.

The objective **16** has a focusing device which is not shown in detail and which for example is adjustable by means of a cylindrical tube **23**, FIG. **1**.

FIG. **1** makes clear the advantages of the invention. The camera with the objective and viewfinder is in such a position in front of the photographer **1** that the camera can be easily operated with one hand while the other hand operates the focusing device. The distance between the central plane **24** of the photographer and the optical axis **25** of the main part of the objective is relatively small so that the photographer basically need only support the weight of the device, i.e., he need not exert himself against substantial turning moments as when the objective is held horizontally. This is substantially facilitated by the straps **2** and **3**.

The optical axis **26** of the viewfinder is parallel to the optical axis **25** of the objective.

The invention can be modified in various ways although it is suggested that the embodiments according to the drawing affords the most satisfactory result. As an example of a modification, the viewfinder can be simplified such that the photographer looks down into it, with his head bent. This however, would have the disadvantage of an inconvenient and uncomfortable head position. Also in this case, the target object would not be easily followed with the free eye.

Deviations can be made from the exact parallel configuration of axes **25** and **26** without disadvantage, within limits, and in another variant of the invention the viewfinder can be located beside the objective so that the distances from the optical axes **25** and **26** to the central plane **24** are approximately equal.

In the embodiment shown in the drawings, the objective is longer than the telescopic viewfinder so that the opening **21** is displaced upwardly which affords the advantage of being able to photograph over a crowd. Good results may be achieved, however, if the lengths of the objective and the viewfinder are approximately the same.

The objective can be attached integrally and rigidly to the camera or this attachment can be accomplished removably as is provided by known means so that the objective as well as the viewfinder can be combined with whatever camera might be chosen.

For taking a photograph, the image on the ground glass screen **11** is viewed by a viewfinder in multiple magnification. For exposure, the mirror **8** is flipped away around hinge **9** so that the image can fall on the film **7**.

While only a single preferred embodiment of the invention has been described in detail, it will be appreciated that numerous modifications are possible within the scope of the invention as defined in the appended claims.

What I claimed is:

1. Portable photographic camera apparatus comprising a tubular objective of long focal length having a light-admitting end and a film carrier end, a tubular viewfinder having a junction with said objective between said film carrier end and said light-admitting end, said viewfinder being positioned adjacent said objective, said viewfinder and said objective having parallel longitudinal axes throughout most of their lengths, said viewfinder extending from said junction towards said one end of said objective and terminating in an eyepiece located longitudinally between said carrier end and said light-admitting end of said objective, and a light deflecting mirror means at the junction between said objective and said viewfinder for directing light rays from said light-admitting opening to said eyepiece.

2. The apparatus as defined in claim **1** wherein said viewfinder is detachable from said objective.

3. The apparatus as defined in claim **1** or **2** wherein said viewfinder is in the form of a periscope.

4. The apparatus of claim **1** including a light-admitting opening at said light-admitting end of the objective, said opening having an axis substantially perpendicular to the length of the objective and a further light deflecting mirror means at said light-admitting end for directing light from said opening towards said film carrier end.

5. The apparatus of claims **1**, **2** or **4** further comprising a support element secured to said film carrier end and strap means secured to said support element for supporting the camera on the body of a photographer.

PHOTOGRAPHIC CAMERA WITH A MEANS FOR COORDINATING AND INDICATING DEPTH OF FIELD FOCUSING AND OBJECTIVE SETTING VALUES

BACKGROUND OF THE INVENTION

The invention relates to a photographic or cinematic camera with an objective, a measuring view finder which is coupled to the objective, and a device for coordinating and indicating focal depth range and objective-setting values such as stop and distance. In a camera of this type, the measuring view finder which is coupled to the objective serves for sharply setting the sighted exposure object can also be equipped with a clearness indicator which considerably facilitates sharp focusing.

In one known camera of this type, a distance-setting ring which is provided with distance marks is rotatably arranged on the objective, which is adjustable on an index which is stationarily fixed to the objective. On both sides of the index are fixed in paris, marks for various stop figures. If a certain distance mark of the distance-setting ring coincides with the index, the stop figure marks which are located on both sides of the index, when compared with the other distance-setting marks of the objective-setting ring, indicate the so-called focal depth zone, i.e. the depth of the sharply reflected exposure (photographic) space, which is achieved with a selected stop figure. If, for example, in a camera with certain objective data, the 2 m distance mark is set on the index, the 1.5 m and 3 m distance marks face the two stop figure marks 8 and the distance marks 1.2 m and 6 m face the two stop figure marks 22. It is therefore indicated to the camera user, that with a distance setting of 2 m, the focal depth range which can be expected is from 1.5 m to 3 m with a stop figure 8, and is from 1.2 m to 6 m with a stop figure of 22.

This known device for the optically correct coordination of focal depth range and objective, setting values for stop and distance, which is usually known as a focal depth scale, can be used by the photographer to determine the desired depth of the exposure space which is desired for his motif and therefore the focal depth zone, but this process is very intricate, as no fewer than six time-consuming manipulations have to be mastered for this:

1. Focusing of the far point, that is, of the boundary point of the desired exposure space lying furthest removed from the camera;
2. Reading-off of the distance set on the distance-setting ring and noting of this distance figure;
3. Focusing of the near point and therefore of the boundary point of the desired exposure space situated nearest the camera;
4. Reading-off of the distance set thereby on the objective ring and noting of this distance figure;
5. Rotating of the distance-setting ring to a position where the two noted distance figures each face one pair of stop figure marks located on both sides of the index; and
6. Setting of the stop figure so found in the camera.

In this complicated process, the fact is really basically that the focal depth scale is not used in this way to determine the exact focal depth range, but in most cases serves merely to inform the camera user as to what focal depth can be expected with a set distance and stop. The photographer then estimates this stated focal depth range usually by comparison with the exposure object and judges whether the obtainable focal depth range is adequate for his motif or not.

The problem which therefore underlies the invention is to produce a camera of the type hereinbefore mentioned, with which the focal depth, and therefore the depth of the sharply reflected exposure space can be determined and fixed exactly with few manipulations, and in which the objective-setting values which are necessary for the desired focal depth range are made available rapidly and automatically without the photographer having to undertake time-consuming reflections and calculations. The assembly of the camera and the coordination device must be constructionally simple here, without complicated mechanical gearing, and be advantageous from a manufacturing technological point of view.

SUMMARY OF THE INVENTION

This problem is solved according to the present invention in a camera of the above-mentioned type, in that the device for coordinating and indicating focal depth range and objective-setting values has:
an Is value transmitter, which converts the distance objective-setting value into an electrical signal, a memory device connected to the Is value transmitter, for a first signal corresponding to the objective setting during focusing on a voluntarily selected far point and a second signal corresponding to the objective setting during focusing on a voluntarily selected near point, where the far and near point define the desired exposure space which is to be reflected within the focal depth range, a first calculator connected to the storage (memory) device, for determining the desired stop figure in dependence upon the stored signals, a second calculator connected to the memory device, for determining the desired distance-setting value of the objective in dependence upon the stored signals, a first comparator, which device reacts with coincidence and/or variation in the output signals of Is value transmitter and second calculator.

In the case of the camera according to the invention, the camera user merely needs to determine this focal depth range by focusing the far and near point which determines the focal depth range. Everything else is carried out automatically in the camera. The signals corresponding to the distance setting to the near point and the signals corresponding to the distance setting to the far point are stored in a memory device. From these stored signals, the first calculator calculates the stop figure which is necessary for this focal depth range, and the second calculator calculates the distance setting of the objective which is necessary for this range. The output signal, according to further specific embodiments of the invention, can either be optically, so that the photographer can set the read-off figure on the camera, or, for example, in the case of a camera with exposure time automatics—can be further processed directly for obtaining the exposure time. The output signal of the second calculator is conveyed to a comparator which is permanently connected to the Is value transmitter. The result of the comparison of the output signals of the second calculator and the Is value transmitter, which in each case represent the desired value of the distance setting and the actual value of the distance setting, can be read off by the photographer on the indicator device. The photographer need only actuate

the distance-setting ring until the indicator device signals to him by a stop signal that the exact distance has been set. The photographer must therefore carry out all the following operations:

1. Sharp setting (focusing) of the desired far point in the measuring viewfinder and pressing of the memory device button,
2. Sharp setting of the desired near point and pressing of the memory device button, and
3. Actuating of the distance-setting device until the indicator device delivers a stop signal.

These few manipulations for exact determination of the focal depth range and determination of the necessary objective-setting values can be carried out by the photographer without the camera being taken away from the eye. The stop signal of the indicator device advantageously appears in the camera viewfinder. As the photographer merely had to actuate the distance-setting device and a corresponding memory device button for this, this setting operation can be carried out very rapidly. The necessary few structural elements are all of an electronic nature and in normal commercial use. The electrical connection of such electronic components is unproblematical, so that the construction of the camera is altogether exceptionally advantageous from a manufacturing technology point of view.

One specific embodiment of the invention is distinguished by a second comparator which is connected to the output of the first calculator and which is fed with an electrical signal characterizing the largest stop figure of the objective, and has at least one first output, at which a signal occurs if the desired stop figure ascertained by the first calculator is larger than the largest stop figure of the objective. In this design of the invention, the camera recognizes when the stop figure which is necessary for a focal depth range is larger than the highest stop figure available in the objective and can therefore not be set. According to further specific embodiments of the invention, this result is signalled to the photographer either via an indicator device, so that with a new determinationof the focal depth range, he can reduce the latter, and/or is simultaneously conveyed to an erasing device which is thereby activated and erases the stored signals, so that the photographer is obliged to determine the focal depth range again.

According to a further specific embodiment of the invention, there is connected to the output of the first calculator, a known control circuit for the automatic determination of the exposure time in dependence upon the brightness of the object, sensitivity of the film and the stop.

In this way, the desired stop figure ascertained by the first calculator is used to ascertain the necessary exposure time.

According to a further specific embodiment of the invention, a third comparator which is connected to the output of the control circuit and which is charged with a signal corresponding to a predetermined maximum exposure time, and has at least one first output, at which an output signal occurs if the exposure time which is determined by the control circuit is longer than the predetermined exposure time. A fourth indicator device connected to the third comparator shows coincidence or variation in the two exposure times, so that the camera user, when the warning signal in the indicator device lights up, recognizes that the predetermined maximum exposure time has not been reached. He is again obliged to reduce the focal depth range in order to be able, with the given brightness of the object and the sensitivity of the film which is used, to take an exposure with a maximum predetermined exposure time, for example, 1/30 sec, for manual exposures.

In a further specific embodiment of the invention, the Is value transmitter for the distance objective-setting value is constructed as an incremental path transmitter which is connected to the inputs of a reversible digital counter, also known as an up/down counter, whose reset input is connected to a manually operable pulse switch. Such as incremental path transmitter produces, in known manner, impulses the number of which is proportional to a traveled path. This incremental path transmitter can be connected mechanically, for example, to the objective-setting ring, a distance-setting ring located in the camera body or to the movable part of the objective, so that in each case it comprehends the setting movement of this part. During focusing on the far point, the incremental path transmitter will deliver impulses to the digital counter and set it. By manual closing of the pulse switch, the digital counter is put back into its initial position. If focusing on the near point takes place, the incremental path transmitter delivers an appropriate number of impulses which are counted by the counter, so that after focusing on the near point has taken place, there occurs at the counter output a certain binary combination which represents a dimension of the depth of the exposure space and therefore of the difference in the distance from the far point to the near point. As the counter is constructed as a reversible digital counter, it is of no importance if, during focusing, the actual focal point is overrun several times in different directions.

According to a further specific embodiment of the invention, the memory device is constructed as a digital memory device (latch), whose inputs are connected to the outputs of the digital counter and whose latch-enable input is connected to a manually operable pulse switch. The binary combination which occurs at the outputs of the reversible digital counter as a result of the movement of the objective, is accepted in the memory device by manual closing of the pulse switch and occurs as a corresponding binary combination at the outputs of the memory device. If the pulse switch is opened again, the binary combination at the outputs of the digital counter or at the inputs of the memory device can be varied as desired, without the binary combination at the outputs of the memory device being affected thereby.

According to a further specific embodiment of the invention, the first calculator is composed of a digital analog converter whose digital inputs are connected to the outputs of the digital memory device and of a resistance whose first connection is connected to the analog output of the digital analog converter and whose second connection forms the output of the first calculator. The resistance value represents the input dimension of the permitted circle of divergence in the image space, which is necessary in order to calculate the desired stop figure according to an equation which has still to be explained. It is sufficient for qualitatively useful pictures if this divergence circle diameter is fixed at 50 μ.

According to a further specific embodiment of the invention, this resistance is adjustably constructed and has a settinf scale which is calibrated in diameter dimensions of the permitted circle of divergence of the object point which is reflected in the image (picture) plane. As a result of this, the photographer has the possibility of

varying the size of the diameter of the circle of divergence for certain photographic purposes.

According to a further specific embodiment of the invention, the second calculator and first comparator are combined into one structural unit which is composed of a digital comparator with two input series. The n bit inputs of the one input series are connected to the n bit outputs of the digital counter, the n-1 bit inputs of the second input series are connected to the 2 bit to n bit outputs of the digital memory device and the n bit input of the second input series is connected to zero potential. This simple construction of the second calculator in conjunction with the comparator can be achieved by an approximate calculation of the necessary desired distance setting with a predetermined focal depth range, which is not examined in greater detail in the specification. According to this calculation, the desired distance is half the difference in the distances of the far and near point. As a result of the aforedescribed construction of the second calculator and the comparator, the desired value transmitter must be adjusted until the counter state, i.e. the number of counting impulses comprehended in the counter, is half the impulses stored in the memory device. The first indicator device delivers a signal as soon as this state of the counter is reached, by which the exact distance setting of the objective within the predetermined focal depth range is given.

Further specific embodiments of the invention are represented in the claims, to which reference is expressly made herein.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is explained in greater detail hereafter by reference to an exemplified embodiment which is represented in the drawing wherein:

FIG. **1** shows a block diagram of the fundamental construction of the camera according to the invention;

FIG. **2** shows the schematic diagram of one possible technical exemplified embodiment; and

FIG. **3** shows a graphic representation to explain the definition of the optical computational figures used in the specification.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In the block diagram in FIG. **1**, the camera housing **1** is represented in dot-dash lines. The objective **2** is mounted on the front of the camera, which objective carries a rotatable setting ring **3** for distance-setting. In the camera housing **1** is provided a measuring viewfinder **4** which is constructed as a reflex viewfinder and is composed of a pivotable mirror **5**, a setting disc **6**, a pentaprism **7** and an eyepiece **8**. A clearness indicator, such as for example, a measuring wedge prism or microscreen, can be provided in the measuring viewfinder in order to facilitate sharp setting of the exposure object on the setting disc **6**.

The device **9** for optically correct coordination and indication of focal depth range and stop and distance objective-setting values has a series of structural elements which are described in greater detail hereafter.

An Is value transmitter **10**, which converts the objective-setting value for distance into an electrical signal is coupled in FIG. **1** to the setting ring **3** via a mechanical feeler. The mechanical feeler is responsive to the rotating movement of the setting ring and converts this rotation into corresponding electrical signals. The mechanical feeler of the Is value transmitter **10** can, however, be coupled to a distance-setting mechanism located in the camera housing **1** or directly to the adjustable lens mounting of the objective and in each case be responsive to the adjusting movements of these elements.

The output of the Is value transmitter **10** is connected to a memory device **11**, in which two signals can be stored either individually or in a mathematical combination. The storage of the signals takes place by closing the two memory device switches **12** and **13**, whereby in each case, the signal occurring at the output of the Is value transmitter **10** is accepted in the memory device **11**. If the objective **2** is focused on an optional far point by rotating the setting ring **3**, there occurs at the output of the Is value transmitter **10**, a signal x_v' which corresponds to this distance which signal, through temporary closing of the memory device switch **12**, is accepted in the memory device **11**. Similarly, when focusing an optional near point, there occurs at the output of the Is value transmitter **10**, a signal x_h', which corresponds to the distance of the near point and is accepted in the memory device when the memory device switch **13** is pressed. The desired depth of the exposure space which is to be sharply reflected is fixed by these two points and defined by the signals x_v' and x_h', which are stored in the memory device **11**. As is evident from the graphic representation in FIG. **3**, the signals x_v' and x_h' are a dimension for the spacing of the front or rear clearness plane from the focal point F^x of the objective.

The memory device **11** is connected to a first calculator **14** for determining the desired stop figure $k_{desired}$ in dependence upon the stored signals x_v' and x_h'. The desired stop figure is ascertained by the calculator in accordance with the following equation:

$$k = \frac{x_h' - x_v'}{2z'} \cdot \frac{1}{1 - \frac{x_h' + x_v'}{2x'_{AP}}} \tag{1}$$

where

x'_{AP} = the spacing of the exit pupil AP from the focal point F of the objective, and

z' = the diameter of the permitted circle of divergence in the film plane.

The graphic representation of the values x'_{AP} and z' can likewise be gathered from FIG. **3**. The value x'_{AP} is an objective constant and is introduced into the first calculator **14** as an input figure. In the case of varying objectives, it must be ensured that in each case the corresponding x'_{AP} value is introduced into the calculator. The z' value is essentially standardized, and in normal cameras reaches 50 μ. This z' value is likewise introduced as an input figure in the first calculator **14**. For special purposes it may be desirable for this z' value to be variable. In such cases a setting device must be provided for the z' value, said device being manually adjustable and connected at its output with the first computer **14**.

The memory device **11** is furthermore connected to a second calculator **15**, which determines the desired distance-setting value $x'_{desired}$ of the objective in dependence upon the stored signals x_v' and x_h' in accordance with the following equation:

$$x' = \frac{x_v' + x_h'}{2} \left[1 - \left(\frac{x_v' - x_h'}{x_v' + x_h'} \right) \frac{z' \cdot k}{x'_{AP}} \right] \tag{2}$$

In the graphic representation in FIG. 3, this desired distance-setting value represents the position of the film plane based on the focal point F of the objective, frequently also called the extension length. The values z' and x'_{AP} are likewise introduced into the second calculator **15** as input figures. In order to produce a simple construction of the calculator **15**, the output of the first calculator **14** can be connected to the input of the second calculator **15**—as represented in dotted lines in FIG. 1. In this case, the desired stop figure ascertained by the first calculator **14** from the values x_h', x_v', z' and x'_{AP} can be introduced into the second calculator **15**, so that the latter does not have to carry out the same computing operation again, which, as can easily be seen from the equations (1) and (2), would be the case if the second calculator **15** merely had to process the input figure x_v', x_h', z' and x'_{AP}.

To the output of the second calculator **15** is connected a first comparator **16**, which on the other hand is connected to the output of the Is value transmitter **10**. In this first comparator **16** there occurs a comparison of the desired distance-setting value $x'_{desired}$, ascertained by the second calculator **15**, with the actual Is distance-setting value x'_{actual} which is set on the objective. The result of this comparison is conveyed to a first indicator device **17**, which is connected to the first comparator **16**. This indicator device contains 3 indicator elements **18**, **19** and **20**, which are connected to the outputs of the first comparator **16** in such a way that the indicator element **18** reacts when $x'_{actual}<x'_{desired}$; the indicator element **19** reacts when $x'_{actual}=x'_{desired}$; and the indicator element **20** reacts when $x'_{actual}>x'_{desired}$. If the two indicator elements **18** and **20** are quenched by the preferably optical indicator elements **18**, **19** and **20**, and only the indicator element **18** lights up, the desired distance $x'_{desired}$ is set in the objective.

The output of the first calculator **14** is furthermore connected to a second indicator device **21**, which, in the exemplified embodiment in FIG. **1**, is constructed as a galvanometer. The indicator device has a scale **22** which is calibrated in stop figures, whereby the desired stop figure $k_{desired}$ ascertained by the first calculator **14** can be read off.

The output of the first calculator **14** is furthermore connected to a second comparator **23**, to which a signal denoting the maximum stop figure of the objective k_G is conveyed as an input figure. This maximum stop figure is an objective constant. In a camera with varying objectives, care must be taken that this respective objective constant is introduced into the second comparator **23**. The comparator **23** compares the desired stop figure $k_{desired}$ ascertained by the first calculator **14** with the maximum settable stop figure k_G of the objective. The second comparator **23** has two outputs. At the first output **24** there occurs a signal when $k_{desired}$ ascertained by the first calculator **14** on the basis of the predetermined focal depth range cannot be set with the objective. At the second output **25** of the second comparator **23** there occurs a signal when $k_{desired} \leqq k_G$. To both outputs **24** and **25** of the second comparator **23** is connected a third indicator device **26**, which has two indicator elements **27** and **28**, each of which are connected to one of the two outputs **24** and **25** of the second comparator **23**. The two indicator elements **27** and **28**, which preferably deliver an optical signal, react as soon as a signal occurs at one of the outputs **24** or **25** of the second comparator **23**. To the first output **24** of the second comparator **23** is connected an erasing device **29**, whose output is connected to the erasing input of the memory device **11**. As soon as a signal occurs at the output **24** of the second comparator **23**, the erasing device **29** is activated and the signals x_v' and x_h' are erased.

In the exemplified embodiment in FIG. **1**, the camera is constructed as a known so-called exposure time mechanism. To this end, it has a known control circuit **30** for automatic determination of the exposure time in dependence upon brightness of the object, film sensitivity and stop. The brightness of the object is measured by a photoelement **31** and introduced into the control circuit **30**. This film sensitivity is introduced into the control circuit **30** via a so-called DIN or ASA setter **32**. The input of the stop figure occurs by connecting the output of the first calculator **14** to the corresponding input of the control circuit **30**. From these introduced figures, the control circuit **30** ascertains in known manner the necessary exposure time t.

A third comparator **33** is connected, on the one hand, to the output of the control circuit **30**, and on the other hand, to a setter (not shown) on line **34** for an optionally predeterminable maximum exposure time t_{max}. Such a predetermined maximum exposure time is, for example, 1/30 sec., which constitutes the limit for manual exposures. The third comparator **33** compares the exposure time t ascertained by the control circuit with the predetermined maximum exposure time t_{max}, and delivers a signal at its first output **35** when $t>t_{max}$ and delivers a signal to its second output **36** when $t \leqq t_{max}$. Two indicator elements **37** and **38** of a fourth indicator device **39** are connected to the outputs **35** and **36** respectively, and react when a signal occurs at the respective outputs. The first output **35** of the third comparator **33** is connected to the erasing device **29**. As soon as a signal occurs at the first output **35**, the quenching device **29** is activated and the memory device **11** is quenced.

The mode of operation of the camera represented in the block wiring diagram in FIG. **1** is as follows:

The photographer must firstly determine his focal depth range. To this end, he focuses initially on a desired far point. For this purpose, he rotates the setting ring **3** until the far point is seen to be sharp in the measuring viewfinder **4**. A corresponding electrical signal occurs at the output of the Is value transmitter **10**. The photographer now actuates the memory device switch **12**, and the signal occurring at the output of the Is value transmiter **10** is received in the memory device as a memory device signal x_v'. The photographer now focuses in the same way on a desired near point. As soon as this point appears sharp in the measuring viewfinder **4**, the photographer presses the memory device switch **13**, and the signal occurring at the output of the Is value transmitter **10** is received in the memory device **11** as a memory device signal x_h'.

The first calculator **14** ascertains in accordance with equation (1) the desired stop figure $k_{desired}$, which the photographer can read off on the stop figure scale **22** of the second indicator device **21**. If the desired stop figure $k_{desired}$ ascertained by the calculator **14** is larger than the settable maximum stop figure of the objective, the indicator element **27** lights up and shows the photographer that the desired focal depth range cannot be obtained. Simultaneously, the erasing device **29** which erases the memory device **11** is activated, as the stored signals are zeroed. The photographer is obliged to determine his focal depth range again, that is to say, to reduce it. If the desired stop figure ascertained can be set on the camera

objective, the indicator element **28** of the third indicator device **26** lights up, and an OK signal is given to the photographer.

After the focal depth range has been determined, the photographer now has to set the necessary exact distance. This distance $x'_{desired}$ is ascertained by the second calculator **15** and conveyed to the first comparator **16**. The photographer now has to rotate the setting ring **3** until the two indicator elements **18** and **20** in the first indicator device **17** are erased and the indicator element **19** lights up. The two indicator elements **18** and **20** thereby give him, by appropriate illumination, an instruction as to whether he must move the setting ring in the direction of a larger or smaller distance.

If the camera is a manual camera, or if the camera operates manually by switching off the automatics which are usually provided, the photographer must adjust the stop figure $k_{desired}$ read off on the second indicator device on the stop figure setter of the camera, introduce a corresponding exposure time, and can therefore take the exposure. If the camera, as in the exemplified embodiment of FIG. **1**, is an exposure time automatic device, and if the automatics are switched on, the second indicator device **21** serves merely as additional information for the photographer. From the measured object brightness, the controlled film sensitivity, and the desired stop figure $k_{desired}$ which is ascertained by the first calculator **14**, the control circuit **30** ascertains the exposure time t in known manner. This exposure time t is compared in the third comparator **33** with a voluntarily predetermined maximum exposure time, for example, 1/30 sec., as a figure for manual exposure. If the exposure time t is larger than the introduced longest exposure time t_{max}, the indicator element **37** of the fourth indicator device **39** lights up and signals to the photographer that in view of the existing object brightness, an adequately lighted exposure is impossible with the desired focal depth range. At the same time, the erasing device **29** which erases the memory device signals present in the memory device is activated. The photographer is once again obliged to determine the focal depth range anew, and likewise reduce it. On the other hand, if the indicator element **38** of the fourth indicator device lights up, all the marginal conditions for an optimal photographic exposure are fulfilled, and the indicator element **39** likewise gives the photographer an OK signal. If, therefore, the indicator elements **29**, **38** and **19** light up, and the other indicator elements are dark, the photographer can actuate the release.

In order to be able to obtain such a construction of the camera of the invention in a technologically very simple manner, the first calculator **14** and the second calculator **15** are combined, so that they do not calculate the desired stop figure and the desired distance in accordance with the exact equations (1) and (2), but according to permitted proximity formulae which are adequate for practical requirements. Therefore, the desired stop figure is determined in the calculator **14** in accordance with:

$$k = \frac{x_h' - x_v'}{2z'} \tag{3}$$

and in the calculator **15** the desired distance in accordance with:

$$x' = \frac{x_v' + x_h'}{2} \tag{4}$$

In this case, the additional input of the x'_{AP} value into the two calculators **14** and **15** is unnecessary.

FIG. **2** shows an embodiment of the invention in which the calculators **14** and **15** for the stop and distance calculations take on a simple technological form.

The Is value transmitter **10** is here constructed as an incremental path transmitter **40**, which is responsive to the shifting movement of the objective **2** during the distance setting, and delivers a number of impulses corresponding to the extent of the shifting to a reversible digital counter **41**, as for example, an up/down counter. When the objective **2** is moved in the opposite direction, the incremental path transmitter **40** creates impulses of opposite polarity.

The reversible digital counter **41** is constructed as a forward/backward binary counter, such as is sold, for example, by Texas Instruments Model No. SN 74169. The two inputs for positive and negative counting impulses of the counter **41** are connected to the two outputs of the incremental path transmitter **40**. The reset input of the counter **41** is connected via the memory device switch **12** to a plus potential. The outputs of the digital counter **41** are connected to the inputs of a binary memeory device **42**. Such a memory device is likewise in normal commercial use and may be, for example, distributed by Texas Instruments Model No. SN 7475. The latch-enable input of the memory device **42** is connected via the second memory device swtich **13** to plus potential. Furthermore, a digital analog converter **43** is provided, whose digital inputs are connected to the corresponding outputs of the memory device **42**. Such a digital analog converter is similarly in normal commercial use and is, for example, sold by Hybrid Systems as an 8 bit digital analog converter Model No. DAC 371-8. To the analog output of the digital analog converter **43** is connected a resistance **44**, which is preferably adjustably constructed. Digital analog converter **43** and resistance **44** form the first calculator **14**, whose inputs are the digital inputs of the digital analog converter **43** and whose output is the free connection of the resistance **44**. The z' value, and therefore the permitted diameter of the circle of divergence in the film plane, is set with the resistance **44**. In addition, a scale **45** which is calibrated in diameter dimensions of the permitted circle of divergence can be provided on the resistance **44**.

The second indicator device **21**, as in FIG. **1**, is formed by a galvanometer which is connected to the output of the calculator **14** or to the resistance **44**. The second comparator **23** is a comparator **46**, whose non-inverting input is connected to the output of the calculator **14** or of the resistance. The inverting input of the comparator **46** is connected to a potential divider **47**, by which the maximum stop figure k_G of the respective objective **2** is set. For this purpose, there is fixed to the adjustable resistance **48** of the potential divider **47**, a scale **49** which is calibrated in stop figures. At the output of the comparator **46** is located a preferably optical indicator element **50**, which corresponds in mode of operation to the indicator element **27** in FIG. **1**. This indicator element **50** is connected to plus potential and lights up when the signal at the non-inverting input of the comparator **46** is larger than at the inverting input,

which means that the desired stop figure ascertained by the calculator **14** is larger than the largest settable stop figure of the objective.

As a result of the approximate determination of the desired distance in accordance with the approximate equation (4), the second calculator **15** and the comparator **16** can be combined into one unit and realized by a single structural element, that is to say, through a binary comparator **51**. Such a binary comparator is known and distributed by Texas Instruments as Model No. SN 7485. The binary comparator **51** has two input series, which are marked with A_1 to A_4 or B_1 to B_4. All the inputs A_1 to A_4 are connected to the outputs A to D of the binary counter **41**. Of the four inputs B_1 to B_4 of the binary comparator **51**, the first bit input B_1 is connected to the second bit output B of the memory device **42**, the second bit input B_2 is connected to the third bit output C, the third bit input B_3 to the fourth bit output Dof the memory device **42**, and the fourth bit input B_4 is connected to zero potential. The exemplified embodiment in FIG. **2** is fabricated from 4 bit modules. Naturally, a finer graduation of the distance measurement can be achieved by a multi-stage forward/backward binary counter **41**. If the binary counter **41** is an n staged counter with corresponding n bit outputs, the binary memory device **42** and the binary comparator **51** generally is connected such that the n bit inputs A_1 to A_n of the one input series are connected to the n bit outputs of the digital counter **41**, and such that the n-1 bit inputs B_1 to B_{n-1} of the second input series are each connected to the 2nd bit to n bit output of the binary memory device **42**, and that the n bit input B_n of the second input series is connected to zero potential. The binary comparator **51** has three outputs **52**, **53** and **54**, which are connected respectively to indicator elements **18**, **19** and **20** of the first indicator device **17**. At the first output **52** of the binary comparator **51** there occurs a signal as long as half the counter content of the binary counter **41** is larger than the memory device contents of the binary memory device **42**. A signal occurs at the second output **53** of the binary comparator **51** if the memory device contents of the binary memory device **42** and half the counter content of the binary counter **41** are identical, and a signal occurs at the third output **54** of the binary comparator **51** when the memory device content of the binary memory device **42** is smaller than half the counter contents of the binary counter **41**. As soon as a signal occurs at the putput **52–54** of the binary comparator **51**, the respective indicator elements **18–20** respectively is energized.

The mode of operation of the exemplified embodiment of the camera according to the invention is as follows:

As described with reference to FIG. **1**, the photographer has to focus the objective **2** on the far point by operating the distance-setting ring, and then close the memory device switch **12** for a short period. The forward/backward binary counter **41** is thereby set in its initial position via the reset input. The photographer now focuses on the near point. A corresponding number of impulses is conveyed to the counter **41**. As the counter **41** is a forward/backward counter, impulses are in each case counted up or down as would occur, for example, with repeated overrunning of the objective near the focusing point as the operator adjusts the objective to the near point focus. If the near point is focused, the counter contains a binary number which corresponds to the difference between the near point and far point, that is

$$\Delta x' = x_h' - x_v'. \tag{5}$$

By closing the memory device switch **13** for a short while, the information $\Delta x'$ is stored in the binary memory device **42**.

The content of the binary memory device **42** is converted by the digital analog converter **43** into an analog signal. The signal which corresponds to the z' value is set at the resistance **44**, so that at the output of the first calculator **14** (i.e. at the output of the resistance **44**) there occurs an analog signal which satisfies the equation

$$k = \Delta x'/2z'. \tag{6}$$

This analog signal is indicated by the galvanometer **21** on the stop figure scale **22**, and simultaneously conveyed to the comparator **46**. If this signal is larger than the maximum possible stop figure on the objective, the indicator element **50** lights up and the photographer must make his focal depth range smaller, whereby the aforedescribed procedure is repeated. If the analog signal at the output of the resistance **44** is smaller than or equal to the largest possible stop figure of the objective, the indicator element **50** shows no signal and the photographer knows that he has selected an acceptable focal depth range. Now he must also set the necessary desired distance exactly, for which he actuates the stop-setting ring until the indicator element **19** lights up and the indicator elements **18** and **20** are quenced. In this procedure, the necessary desired distance is calculated by the binary comparator in accordance with the following equation:

$$x' = x_v' + (\Delta x'/2). \tag{7}$$

As a result of the aforedescribed connection of the input series of the binary comparator **51** to the outputs of the binary counter **41** and of the binary memory device **42**, the 1 to n bits of the binary counter **41** are compared with the 2 to n+1 bits of the binary memory device **42**, whereby the n+1 bits is predetermined by zero potential. It thereby occurs that the second output **53** of the binary memory device **51** gives a signal when the counter content **41** amounts to half the memory device **42** content, so that the equation (7) is satisfied if it is borne in mind that the x_v' value is represented by the initial or zero position of the binary counter **41**.

The stop figure value indicated in the galvanometer **21** can be set on the stop setter of the camera. A corresponding exposure time control circuit **30** can likewise be connected to the output of the calculator **14** or to the output of the resistance **44**, as in FIG. **1**. As the latter is known per se, an additional representation and description of the exposure time control circuit is unnecessary.

What is claimed is:

1. A photographic camera having an objective, a viewfinder coupled to said objective and comprising:

(a) means for converting the setting of said objective into electrical signal values, x'_{actual},

(b) memory storage means for storing said electrical signal values, said memory storage means storing a first signal value, x_v', corresponding to the objective setting associated with a far point desired to be photographed, and for storing a second signal

value, x_h', corresponding to the objective setting associated with a near point desired to be photographed, and

(c) calculator means connected to said memory storage means for automatically calculating a desired stop figure, $k_{desired}$, and a desired distance-setting value, $x'_{desired}$, associated with said first and second signal values.

2. A photographic camera as recited in claim 1 further comprising means for indicating the desired stop figure, $k_{desired}$.

3. A photographic camera as recited in claim 1 further comprising first comparator means connected to said converting means and said calculator means for comparing the desired distance-setting value $x'_{desired}$ with the actual objective setting value, x'_{actual}, and means for indicating the equivalent of same.

4. A photographic camera as recited in claim 3 wherein said calculator means comprises a first calculator for calculating the desired stop figure, $k_{desired}$, and a second calculator for calculating the desired distance setting value $x'_{desired}$.

5. A photographic camera as recited in claim 4 further comprising means for indicating the desired stop figure, $k_{desired}$, said indicating means connected to said first calculator.

6. A photographic camera as recited in claim 5 further comprising second comparator means connected to said first calculator for comparing the desired stop figure $k_{desired}$ with a reference value corresponding to the largest stop figure for the camera objective, k_G, and means for providing an indication when $k_{desired} > k_G$.

7. A photographic camera as recited in claim 6 further comprising means for erasing said first and second signal values.

8. A photographic camera as recited in claim 7 wherein said erasing means is connected to said first calculator for erasing said first and second signal values, said erasing means operable when $k_{desired}$ is greater than k_G.

9. A photographic camera as recited in claim 6 further comprising means for providing an indication when $k_{desired} \leqq k_G$.

10. A photographic camera as recited in claim 1 further comprising a brightness control circuit connected to said calculator means for automatically determining exposure time, t, in response to film sensitivity, object brightness and the desired stop figure, $k_{desired}$.

11. A photographic camera as recited in claim 10 further comprising a comparator for comparing said exposure time, t, to a predetermined maximum exposure time, t_{max}, and means for indicating when $t > t_{max}$.

12. A photographic camera as recited in claim 11 further comprising means for indicating when $t \leqq t_{max}$.

13. A photographic camera as recited in claim 10 further comprising means for erasing said stored electrical signal values when $t > t_{max}$.

14. A photographic camera as recited in claim 1 wherein said means for converting the setting of the objective into electrical signal values comprises an incremental path transmitter.

15. A photographic camera as recited in claim 14 wherein said incremental path transmitter provides digital signals, and said camera further comprises a reversible digital counter providing digital signals to said memory storage device in response to said digital signals from said incremental path transmitter.

16. A photographic camera as recited in claim 14 wherein said calculator means comprises a digital-to-analog converter connected to said memory storage means and a variable resistor means connected to an output of said digital-to-analog converter.

[57] **ABSTRACT**

A pancratic camera objective of varifocal ratio close to 5:1, and with a relative aperture varying between 1:1.2 in a wide-angle position and 1:1.5 in a telephoto position, has a pair of axially shiftable negative components bracketed by a pair of substantially fixed positive components. Its negative third component is more widely separated from its positive fourth component in the wide-angle position than in the telephoto position.

CAMERA OBJECTIVE OF VARIABLE FOCAL LENGTH

FIELD OF THE INVENTION

My present invention relates to a pancratic camera objective of the general type described in commonly owned U.S. Pat. No. 4,087,160, including a varifocal forward lens group and a fixed-focus rear lens group centered on a common optical axis, the forward lens group consisting of a substantially axially fixed positive first component, axially shiftable negative second and third components, and an axially fixed fourth component. The first three components form a lens assembly of dispersive character; the third component approaches the fourth component more closely in a telephoto position of maximum overall focal length f_{max} than in a wide-angle position of minimum focal length f_{min} while having an inversion point at an intermediate position of overall focal length f_{med}.

BACKGROUND OF THE INVENTION

The prior patent referred to above discloses two specific embodiments, one of them with a varifocal ratio f_{max}/f_{min} approximately equal to 8, the other with a varifocal ratio of about 10. In the wide-angle position of the objective, its relative aperture is 1:1.2 according to the first embodiment and 1:1.8 according to the second one; the first system, accordingly, falls in the so-called XL (=existing light) class permitting—in a cinematographic camera—the taking of indoor motion pictures without additional illumination. The effective area of the third (negative) component of an objective as described in that patent is restricted to provide full illumination of the fourth (positive) component by axially incident light rays in the wide-angle position but less than full illumination in the telephoto position, thereby enabling a reduction in the lens diameters of the front component.

OBJECT OF THE INVENTION

The object of my present invention is to provide an objective of the general type described above which is of simpler construction, does not necessarily require a restriction of the effective area of the third component and has a relative aperture similar to that of the first embodiment disclosed in the prior patent, i.e. about 1:1.2 in the wide-angle position, while still affording a large varifocal ratio of approximately 5:1.

SUMMARY OF THE INVENTION

I realize this object, pursuant to my present invention, with a pancratic objective of only seven lens members (one of them a doublet) in its varifocal forward group, i.e. with a first component consisting of three singlets, having parameters substantially as given hereinafter.

BRIEF DESCRIPTION OF THE DRAWING

My invention will now be described in detail with reference to the accompanying drawing the sole FIGURE of which diagrammatically illustrates my improved pancratic objective.

SPECIFIC DESCRIPTION

In the drawing I have shown the wide-angle position of a pancratic objective according to my invention, including a varifocal forward lens group with components **1–4** and a rear lens group **5**. The substantially

stationary positive component **1** (which may be limitedly shiftable for focusing purposes) comprises a front lens in the form of a negative meniscus L_1 with radii r_1, r_2 and thickness d_1, two positive lenses L_2 (radii r_3, r_4 and thickness d_2) and L_3 (radii r_5, r_6 and thickness d_3) which intervening air spaces s_1 and s_2. A variable air space s_3 separates lens L_3 from the axially shiftable component **2** consisting of a singlet L_4 in the form of a negative meniscus (radii r_7, r_8 and thickness d_4) separated by an air space s_4 from a doublet consisting of lenses L_5 (radii r_9, r_{10} and thickness d_5) and L_6 (radii r_{10}, r_{11} and thickness d_6). Another variable air space s_5 lies between component **2** and component **3** which consists of a single lens L_7 in the form of a negative meniscus with radii r_{12}, r_{13} and thickness d_7. A third variable air space s_6 lies between component **3** and axially fixed component **4** which in this instance consists of two air-spaced biconvex lenses L_8 (radii r_{14}, r_{15} and thickness d_8) and L_9 (radii r_{16}, r_{17} and thickness d_9), the intervening air space having been designated s_7. The light path between components **3** and **4** is restricted by a mounting **6** for lens L_7, acting as an ancillary diaphragm.

A reflex prism P of thickness d_p, whose planar faces have been designated r_p' and r_p'', is separated by an air space s_8 from lens L_9 and by a diaphragm space $s_d'+s_d''$ from component **5**, the latter space containing an iris diaphragm **7**. Component **5** consists of five air-spaced singlets, namely a biconvex lens L_{10} (radii r_{18}, r_{19} and thickness d_{10}), a positive meniscus L_{11} (radii r_{20}, r_{21} and thickness d_{11}), a biconcave lens L_{12} (radii r_{22}, r_{23} and thickness d_{12}), a planoconvex lens L_{13} (radii r_{24}, r_{25} and thickness d_{13}) and another positive meniscus L_{14} (radii r_{26}, r_{27} and thickness d_{14}); the intervening air spaces have been designated s_9, s_{10}, s_{11} and s_{12}. The image plane of the objective has been shown at **8**.

In the following table I have given representative numerical values for the parameters r_1–r_{27}, d_1–d_{14} and s_1–s_{12} of the illustrated optical system, based upon a mean overall focal length $f_{med}=1$ in the extreme left-hand position of component **3**. The table also gives the refractive indices n_d and the Abbé numbers ν_d of the various lenses.

The objective conforming to the foregoing table has a minimum focal length $f_{min}=0.666$, a median focal length $f_{med}=1$ and a maximum focal length $f_{max}=2.863$. Its relative aperture is 1:1.2 in the illustrated wide-angle position and 1:1.5 in the telephoto position at the opposite end of its varifocal range.

I claim:

1. In a camera objective of variable focal length including a varifocal foward lens group and a fixed-focus rear lens group centered on a common optical axis, said forward lens group consisting of a substantially axially fixed positive first component, an axially shiftable negative second component, an axially shiftable negative third component and an axially fixed fourth component, said second and third components being displaceable between a wide-angle position of minimum overall focal length and a telephoto position of maximum overall focal length with maintenance of an invarient image plane behind said rear lens group, said third component approaching said fourth component more closely in said telephoto position than in said wide-angle position, the combination of said first, second and third components being of dispersive character,

the improvement wherein said first component consists of lenses L_1, L_2 and L_3, said second component consists of lenses L_4, L_5 and L_6, said third component consists of a lens L_7 and said fourth component consists of lenses L_8 and L_9, said lenses having radii of curvature r_1–r_{17}, axial thicknesses d_1–d_9 and axial spacings s_1–s_7 whose numerical values, based on a numerical value of unity for an intermediate overall focal length, together with their refractive indices n_d and Abbé numbers ν_d are substantially as given in the following table:

				n_d	ν_d

[57] **ABSTRACT**

A semi-wide angle objective lens in accordance with the present invention comprises five groups of six lens elements including a front group and a rear group in which the front group has a first group which includes a single positive meniscus lens L_1 with its convex surface directed toward the object side, a second group which includes a single negative meniscus lens L_2 with its convex surface directed toward the object side, and a third group which includes a single positive meniscus lens L_3 with its convex surface directed toward the object side; and in which the rear group has a fourth group which includes both a negative lens L_4 with its front concave surface having a large curvature directed toward the object side and a positive lens L_5 with its rear convex surface having a large curvature directed toward an image side with the fourth group lenses cemented together or arranged with an extremely small air space therebetween, and a fifth group which includes a positive lens L_6 characterized in that each of the following conditions is fulfilled:

$$1.4\,f < |f_2| < 2.0\,f \quad (1)$$

$$0.23\,f < r_4 < 0.33\,f \quad (2)$$

$$0.03\,f < d_4 < 0.08\,f \quad (3)$$

$$0.8 < r_4/r_5 < 1.0 \quad (4)$$

where,

f is the composite focal length of the entire lens system,

f_2 is the focal length of the lens L_2 of the second group ($f_2 < 0$),

r_4 is the radius of curvature of the rear surface of the lens L_2 of the second group,

d_4 is the axial air space between the lens L_2 of the second group and the lens L_3 of the third group, and

r_5 is the radius of curvature of the front surface of the lens L_3 of the third group.

SEMI-WIDE ANGLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

(1) Field of the Invention

This invention relates to an improved semiwide angle objective lens for use with single lens reflex cameras.

(2) Description of the Prior Art

In recent years, there has been an increasing trend towards compact size single lens reflex cameras and, along with this trend a requirement has developed for more compact and wider angle interchangeable lens. The shortest focal length of a standard lens for a 135 mm film format single lens reflex camera has been commonly chosen at 50 mm. However, lens shutter cameras have lenses with approximately equal to 40 mm are very popular. Thus, for SLR cameras, a semi-wide angle objective lens having a value of about f=40 mm has become a standard lens.

A desirable semi-wide angle objective lens having a compact size would have a preferred value of f=40 mm, an F number of F 2 to F 1.8 and a simple lens configuration of six lens elements or so. It has been extremely difficult to apply prior art lenses (e.g., Gaussian type six element lenses) for this purpose and keep the lens back focal length large enough for a single lens reflex camera and also provide a field angle up to about 56°.

The reason why it was so difficult is that keeping the back focal length f_B long requires a smaller setting of the positive power of the front group, resulting in an increased positive power of the rear group making it very difficult to correct residual aberrations with the positive lenses of the rear group.

Another reason for the above mentioned difficulty is that the requirement for a large aperture ranging from F 2 to F 1.8 results in a decreased power of refraction at each lens surface, which leads to difficulty correcting the curvature of the sagittal image surface, making it impossible to maintain a wide angle of view.

Further, even if an attempt is made to obtain a semi-wide angle objective lens by utilizing a lens system of a so-called retrofocus type e.g. a Gauss type or modified Tessar type in which a negative lens is added to the front lens element, the total length of the lens system is increased, or the front lens element is increased in size and the lens is no longer compact.

Because of the reasons mentioned above, it has been extremely difficult to provide a six lens element semi-wide angle objective lens of simple configuration having a large aperture and a compact size.

BRIEF SUMMARY OF THE INVENTION

It is an overall object of the present invention to provide a new and useful semi-wide angle objective lens for use with single lens reflex cameras.

It is further principal object of the present invention to provide a lens system for an extremely compact semi-wide angle objective lens having a simple configuration of five groups of six lens elements in which the back focal length f_B has a value of 0.85 times of the composite focal length f, an angle of view of 56°, an aperture range from F 2 to F 1.8 and in which all aberrations are well corrected.

The above and other objects of the present invention will be apparent from the following detailed description of a preferred embodiment of the present invention taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

The above description as well as further objects, features, and advantages of the present invention will be more fully understood by reference to the following description of a presently preferred but nonethless illustrative embodiment in accordance with the present invention, when taken in connection with the accompanying drawing, wherein

FIGS. 1A and 1B show a basic structural view of a semi-wide angle lens in accordance with the present invention with FIG. 1A showing an arrangement in which two lens elements in the fourth group are cemented together and with FIG. 1B showing an arrangement in which two lens elements in a similar fourth group are arranged with an extremely small air space being left therebetween.

FIGS. 2A, 2B, 2C, and 2D show, as labeled, the coma, spherical aberration, astigmatism, and distortion curves for a first embodiment having the basic construction shown in FIG. 1A;

FIGS. 3A, 3B, 3C, and 3D show, as labeled, the coma, spherical aberration, astigmatism, and distortion curves for a second embodiment having the basic construction shown in FIG. 1A;

FIGS. 4A, 4B, 4C, and 4D show, as labeled, the coma, spherical aberration, astigmatism, and distortion aberration curves for a third embodiment having the basic construction shown in FIG. 1A.

In each of these figures, the solid line in the spherical aberration curve shows the spherical aberration when d=line (a wave length: 587.56 mμ) is applied and the dotted line shows the spherical aberration when g-line (a wave length: 435.84 mμ) is applied. The solid line in the astigmatism shows a sagittal and the dotted line shows a meridional.

FIGS. 5A, 5B, 5C and 5D show, as labeled, the coma, spherical aberration, astigmatism, and distortion curves for a fourth embodiment having the basic construction shown in FIG. 1B; and

FIGS. 6 6B, 6C, and 6D show, as labeled, the coma spherical aberration, astigmatism, and distortion curves for a fifth embodiment in accordance with the basic construction shown in FIG. 1B.

In FIG. 1A,

L_1, L_2, L_3, . . . L_6: designates the lenses counted in sequence from the object side

r_1, r_2, r_3, . . . r_{11}: designates the radius of curvature of the lens surfaces measured in sequence from the object side,

d_1, d_3, d_5, d_7, d_8, d_{10}: designates the axial thickness of the lenses measured in sequence from the object side;

d_2, d_4, d_6, d_9: designates the axial air space between the lenses measured in sequence from the object side;

and in FIG. 1(B),

L_1, L_2, L_3, . . . L_6: designates the lenses counted in sequence from the object side

r_1, r_2, r_3, . . . r_{12}: designates the radius of curvature of the lenses surface measured in sequence from the object side

d_1, d_3, d_5, d_7, d_9, d_{11}: designates the axial thickness of the lens measured in sequence from the object side, and

d_2, d_4, d_6, d_8, d_{10}: designates the axial air space between the lenses measured in sequence from the object side

The solid line in the spherical aberration shows the spherical aberration when d-line (a wave length: 587.56 mμ) is applied and the dotted line shows the spherical aberration when g-line (a wave length: 435.84 mμ) is applied. The solid line in the astigmatism shows a sagittal and the dotted line shows a meridional.

DESCRIPTION OF THE PREFERRED EMBODIMENT

As apparent from the new type of lens shown in FIG. 1 A and B in which the arrangement of the front group of the Gauss type lens of five groups of six lens elements is changed by changing the arrangement of a positive lens, a positive lens and a negative lens to an arrangement of a positive lens, a negative lens and a positive lens, the present invention enables the provision of a lens system for an extremely compact and useful semi-wide angle lens having a back focal length f_B of about 0.85 times as that of a composite focal length f, an angle of view of 56°, and an aperture of F 2 to F 1.8 in which all aberrations are well corrected. A simple, common lens configuration of five groups of six lens elements, which has various problems when used as an interchangeable lens for single lens reflex cameras, may be improved upon by providing a lens system comprising five groups of six lens elements including a front group a rear group in which a first group includes a single positive meniscus lens L_1 having its convex surface directed toward a object side, the second group includes a single negative meniscus lens L_2 having its convex surface directed toward the object side, and a third group includes a single positive meniscus lens L_3 with its convex surface having a large curvature directed toward the object side and in which the rear group includes the fourth group which includes both a negative lens L_4 with its front concave surface having a large curvature directed toward the object side and a positive lens L_5 with its rear convex surface having a large curvature being directed toward the image side with the fourth group lenses cemented together or arranged with an extremely small air space therebetween and a fifth group includes a positive lens L_6 in which each of the following conditions are fulfilled.

$$1.4f < |f_2| < 2.0\ f \quad (1)$$

where,

f is the composite focal length of the entire lens system,

f_2 is the focal length of the lens L_2 of the second group;

$$0.23\ f < r_4 < 0.33\ f \quad (2)$$

where, r_4 is the radius of curvature of the rear surface of the lens L_2 of the second group;

$$0.03\ f < d_4 < 0.08\ f \quad (3)$$

where, d_4 is the axial air space between the lens L_2 of the second group and the lens L_3 of the third group; and

$$0.8 < r_4/r_5 < 1.0 \quad (4)$$

where, r_5 is the radius of curvature of the front surface of the lens L_3 of the third group

A technical background of the present invention and the meaning of several conditions are described in more detail as follows.

A new type of the lens in accordance with the present invention is made by replacing the arrangement of prior art Gauss-type lenses, which include five groups of six lens elements of which the front group includes a positive lens, a positive lens, and a negative lens, with an arrangement of a positive lens, a negative lens and a positive lens.

As mentioned in the description of the prior art, a semi-wide angle objective lens with the back focal length long enough for an interchangeable lens and with an aperture large enough for a standard lens is very difficult to provide with the prior art Gauss type or Tessar-type lens configurations.

To avoid the problems mentioned earlier, it is necessary to provide a lens which has a suitably large positive power in the front group as the prior art Gauss type lenses making a large aperture possible and which also has a suitably large emerging paraxial ray height at the end surface of the front group the prior art Tessar type lenses making a long back focal length possible; the new type of lens of the present invention satisfies these properties.

Namely, the suitably large power in the front group is made possible in the lens of the present invention by using the two positive lenses, one of which is located in the first position of the lens system, and one negative lens similar to the prior art Gauss-type lenses; thus keeping the power of the front group large and comparable to that of the Gauss-type lenses.

On the other hand, by changing the arrangement of the lenses in the front group from that of the Gauss-type lenses, which is a positive lens, a positive lens, and a negative lens, to the arrangement of a positive lens, a negative lens, and a positive lens, the type of lens of the present invention enables the attaining of a long back focal length.

Namely, the forward arrangement of the negative lens in the front group makes the emerging paraxial ray height at the end surface of the front group comparable to that of a Tessar type lens, and thus makes it possible for the total lens to have a long back focal length.

In view the arrangement described, major means for realizing a compact lens system having a superior aberration correction is expressed under the following conditions

$$1.4\ f < f_2 < 2.0\ f \quad (1)$$

$$0.23\ f < r_4 < 0.33\ f \quad (2)$$

$$0.03\ f < d_4 < 0.08\ f \quad (3)$$

$$0.8 < r_4/r_3 < 1.0 \quad (4)$$

Equation (1) shows a condition in which the negative lens arranged as the lens L_2 of the second group has a relatively large divergence action making it possible to obtain a required back focal length f_B without decreasing the composite power of the lenses of the front group when the single focal length is in the range indicated above.

Equation (2) shows a condition in which a substantially large radius of curvature r_4 of the lens surface of the meniscus lens L_2 of the second group directed toward the image side is provided, and a center of the curvature is approached toward the center of the lens in order to prevent a sagittal image surface from being curved, and then a space between the lens L_2 of the

second group and the lens L_3 of the third group is made small as indicated in the equation (3) to keep the size compact and also to keep the effect described below of a radius of curvature r_5 at the object side of the lens L_3 of the third group in reference to the equation (4). That is, these equations show the conditions to decrease the aberrations generated by the forward positioned negative lens, which aberrations are larger than those of the prior art arrangement of a positive lens, a negative lens and a negative lens, and thus provide a fast lens.

The reason for the above mentioned setting of the limitation values of each of the conditional equations are described as follows.

Negative power of the lens L_2 of the second group exceeding the lower limit of the equation (1) will necessarily increase the positive power of the lens L_3 of the third group and thus cause generation of an excessive aberration of each of the surfaces, making it impossible to provide a fast lens. In turn, negative power of the lens L_2 of the second group exceeding the upper limit of the equation (1) will decrease the diversive refractive power of the lens L_2 of the second group and thus it is impossible to obtain the required back focal length f_B.

Exceeding the lower limit of the equation (2) will make the negative refractive power excessive at the rear surface of the lens L_2 of the second group, and thus it will become impossible to correct the spherical aberration and coma, and further make it impossible to provide a fast lens. Conversely, exceeding the upper limit of the equation (2) will result in the center of curvature of the rear surface of the lens L_2 being moved farther away from the center of the total lens system decreasing the effect of correction of the sagittal image surface.

When the axial air space d_4 between the lens L_2 of the second group and the lens L_3 of the third group is small and exceeds the lower limit of equation (3), a positive refractive power at the front surface of lens L_3 decreases in reference to the equation (4), and then it becomes impossible to provide correction of the higher order spherical aberrations which may be generated in the negative lens L_2. To the contrary, when the axial air space d_4 exceeds the upper limit, a positive refractive power at the front surface of said lens L_3 increases, and thus it causes not only the tendency for the image surface to curve towards object side, but also the increase in size of the lens.

Equation (4) provides the relationship between the radii of curvature r_4 and r_5 with respect to a range of the axial air space d_4 given by the equation (3). When the value of r_4/r_5 exceeds the lower limit, it will cause an excessive negative refractive power in the front group, and, in a manner similar to the case in which the lower limit of the equation (3) is exceeded, and it is not possible to correct the spherical aberration and, further, it becomes impossible to provide a fast lens. When the upper limit is exceeded, it tends to increase the curvature of the image surface in the same manner as when the upper limit of the equation (3) is exceeded.

That is, under each of the conditions of the equations (1), (2), (3) and (4), it becomes possible to have the front group of the lens system satisfying the properties discussed earlier.

Thus, it is not necessary to have a large positive power in the rear group and thus the simple configuration of the prior art of only two positive lenses may be provided making it possible to correct aberrations easily while keeping the size of the lens compact and keeping the back focal length f_B sufficiently long enough. Further, in order to effect the correction of the aberration, it is preferable to provide the following conditions for the lenses of the rear group;

$$1.8 < n_6 \tag{5}$$

$$20 < \nu_5 - \nu_4 \tag{6}$$

where, n_6 is the refractive index of the glass of the lens L_6 of the fifth group with respect to d-line, ν_4 and ν_5 are Abbe numbers given by d-line of the component glass of the lenses L_4 and L_5 of the fourth group.

In order to keep the positive power born by the two positive lenses of the rear group as large as possible even if a positive power of the front group is made to be a relatively large value and a positive power of the rear group is not too high by fulfilling each of the above described conditions and further to keep a large aperture lens of the present invention, it is preferable to maintain the refractive indicies n of the two positive lenses as large as possible. However, it is required that the refractive index of the lens L_4 is large, the refractive index of the lens L_5 small, ν of the lens L_4 small, and the refractive index of the lens L_5 large in order to provide correction for the sagittal image surface in the fourth group and correction for the chromatic aberration and thus it is preferable to have a refractive index of n_6 as large as possible.

When it is less than the limit of the equation (5), it is impossible to provide proper corrections for the spherical aberration, distortion etc. in the lenses of the rear group. Along with this effect, the condition shown in the equation (6) is an essential condition of achromatism in the lenses L_4 and L_5 of the fourth group under such condition as a powerful achromatism in the lens L_6 of the fifth group may not be obtained and thus it becomes impossible to provide a chromatic correction in the rear group when it is less than the limitation.

Practical embodiments of the present invention will now be described herebelow.

Seidel's aberrations show the value when the distance of the object side is set to an infinite point and a diaphragm is set to a position of 0.092 rearward of the sixth lens surface, and the symbols in the table are as follows.

S: spherical aberration
C: coma
A: astigmatism
P: Petzval's condition
D: distortion
Σ: sum of each of the aberrations

What is claimed is:

1. A semi wide angle objective lens constituting of five groups of six lens elements formed a front group having the first group of a positive meniscus single lens L_1 with its convex surface directed toward the object side, the second group of a negative meniscus single lens L_2 with its convex surface directed toward the object side and the third group of a positive meniscus single lens L_3 with its convex surface directed toward the object side, and forming a rear group having the fourth group of a negative lens L_4 with its concave surface having a large curvature directed toward the object side and of a positive lens L_5 with its convex surface having a large curvature directed toward an image side which are arranged with a mutual contact condition therebetween, and the fifth group of a positive lens L_6 characterized in that each of the following conditions, i.e.

$$1.69f < |f_2| < 1.79f \quad (1)$$

$$0.27f < r_4 < 0.29f \quad (2)$$

$$0.045f < d_4 < 0.054f \quad (3)$$

$$0.94 < r_4/r_5 < 0.096 \quad (4)$$

where,

f: the composite focal length of the entire lens system

f_2: the single focal length of the lens L_2 of the second group

r_4: the radius of curvature of the rear surface of the lens L_2 of the second group

d_4: the axial air space between the lens L_2 of the second group and lens L_3 of the third group

r_5: the radius of curvature of the front surface of the lens L_3 of the third group

is fulfilled.

2. Semi wide angle objective lens for fulfilling the condition as set forth in claim 1 constructed according to the constructional data given herebelow:

f = 1 F 1.8	2ω = 56°	f_B = 0.8464	
r_1 = 0.9951	d_1 = 0.0725	n_1 = 1.71300	ν_1 = 53.9
r_2 = 3.9769	d_2 = 0.0024		
r_3 = 0.4274	d_3 = 0.0483	n_2 = 1.58144	ν_2 = 40.7
r_4 = 0.2873	d_4 = 0.0531		
r_5 = 0.3052	d_5 = 0.0966	n_3 = 1.67003	ν_3 = 47.3
r_6 = 0.3126	d_6 = 0.2029		

-continued

f = 1 F 1.8	2ω = 56°	f_B = 0.8464	
r_7 = −0.3341	d_7 = 0.0217	n_4 = 1.75520	ν_4 = 27.5
r_8 = 38.9089	d_8 = 0.1329	n_5 = 1.67790	ν_5 = 55.3
r_9 = −0.3966	d_9 = 0.0024		
r_{10} = 11.2319	d_{10} = 0.0725	n_6 = 1.88300	ν_6 = 40.8
r_{11} = −0.9167			

where,

$r_1,r_2, \ldots r_{11}$: the radius of curvature of the lens measured in sequence from the object side

$d_1,d_3,d_5,d_7,d_8,d_{10}$: the axial thickness of the lens measured in sequence from the object side

d_2,d_4,d_6,d_9: the axial air space between the lenses measured in sequence from the object side

$n_1,n_2, \ldots n_6$: the refractive index of the optical glass of the lens with respect to the d-line measured in sequence from the object side

$\nu_1,\nu_2, \ldots \nu_6$: Abbe number of the optical glass of the lens measured with respect to d-line in sequence from the object side.

3. Semi wide angle objective lens for fulfilling the condition as set forth in claim 1 constructed according to the constructional data given herebelow:

f = 1 F 1.84	2ω = 56°	f_B = 0.8443	
r_1 = 0.9963	d_1 = 0.0724	n_1 = 1.71300	ν_1 = 53.9
r_2 = 3.9165	d_2 = 0.0024		
r_3 = 0.4165	d_3 = 0.0458	n_2 = 1.58144	ν_2 = 40.7

r_5 = 0.3015	d_5 = 0.0965	n_3 = 1.67003	ν_3 = 47.3
r_6 = 0.3057	d_6 = 0.1978		
r_7 = −0.3287	d_7 = 0.0210	n_4 = 1.76182	ν_4 = 26.6
r_8 = 8.4698	d_8 = 0.1303	n_5 = 1.71300	ν_5 = 53.9
r_9 = −0.3998	d_9 = 0.0024		
r_{10} = 11.3076	d_{10} = 0.0724	n_6 = 1.83400	ν_6 = 37.2
r_{11} = −0.8810			

where,

$r_1,r_2, \ldots r_{11}$: the radius of curvature of the lens measured in sequence from the object side

$d_1,d_3,d_5,d_7,d_8,d_{10}$: the axial thickness of the lens measured in sequence from the object side

d_2,d_4,d_6,d_9: the axial air space between the lenses measured in sequence from the object side

$n_1,n_2, \ldots n_6$: the refractive index of the optical glass of the lens with respect to the d-line measured in sequence from the object side

$\nu_1,\nu_2, \ldots \nu_6$: Abbe number of the optical glass of a lens measured with respect to d-line in sequence from the object side.

4. Semi wide angle objective lens for fulfilling the condition as set forth in claim 1 constructed according to the constructional data given herebelow:

f = 1 F 2	2ω = 56°	f_B = 0.8518	
r_1 = 0.9272	d_1 = 0.0689	n_1 = 1.71300	ν_1 = 53.9
r_2 = 3.3721	d_2 = 0.0024		
r_3 = 0.4119	d_3 = 0.0447	n_2 = 1.58144	ν_2 = 40.7
r_4 = 0.2803	d_4 = 0.0456		
r_5 = 0.2950	d_5 = 0.0864	n_3 = 1.67003	ν_3 = 47.3
r_6 = 0.3038	d_6 = 0.1816		
r_7 = −0.3076	d_7 = 0.0194	n_4 = 1.71736	ν_4 = 29.5
r_8 = 2.4272	d_8 = 0.1214	n_5 = 1.69680	ν_5 = 55.5
r_9 = −0.3800	d_9 = 0.0024		
r_{10} = −24.2718	d_{10} = 0.0631	n_6 = 1.83400	ν_6 = 37.2
r_{11} = −0.8295			

where,

$r_1,r_2, \ldots r_{11}$: the radius of curvature of the lens measured in sequence from the object side

$d_1,d_3,d_5,d_7,d_8,d_{10}$: the axial thickness of the lens measured in sequence from the object side

d_2,d_4,d_6,d_9: the axial air space between the lenses measured in sequence from the object side

$n_1,n_2, \ldots n_6$: the refractive index of the optical glass of the lens with respect to the d-line measured in sequence from the object side

$\nu_1,\nu_2, \ldots \nu_6$: Abbe number of the optical glass of the lens measured with respect to d-line in sequence from the object side.

5. Semi wide angle objective lens for fulfilling the condition as set forth in claim 1 constructed according to the constructional data given herebelow:

f = 1 F 1.84	2ω = 56°	f_B = 0.8434	
r_1 = 0.9841	d_1 = 0.0700	n_1 = 1.71300	ν_1 = 53.9

r_8 = 11.5942	d_8 = 0.0024		
r_9 = 24.1546	d_9 = 0.1292	n_5 = 1.71300	ν_5 = 53.9
r_{10} = −0.3871	d_{10} = 0.0024		
r_{11} = 5.6763	d_{11} = 0.0628	n_6 = 1.83400	ν_6 = 37.2
r_{12} = −1.0360			

where,

$r_1,r_2, \ldots r_{12}$: the radius of curvature of the lens measured in sequence from the object side

$d_1,d_3,d_5,d_7,d_9,d_{11}$: the axial thickness of the lens measured in sequence from the object side

d_2,d_4,d_6,d_8,d_{10}: the axial air space between the lenses measured in sequence from the object side

$n_1,n_2, \ldots n_6$: the refractive index of the optical glass of the lens with respect to the d-line measured in sequence from the object side

$\nu_1,\nu_2, \ldots \nu_6$: Abbe number of the optical glass of the lens measured with respect to d-line in sequence from the object side.

6. Semi wide angle objective lens for fulfilling the condition as set forth in claim 1 constructed according to the constructional data given herebelow:

f =0 1 F 2	2ω = 56°	f_B = 0.8538	
r_1 = 0.9814	d_1 = 0.0685	n_1 = 1.71300	ν_1 = 53.9
r_2 = 3.7090	d_2 = 0.0024		
r_3 = 0.4053	d_3 = 0.0434	n_2 = 1.58144	ν_2 = 40.7
r_4 = 0.2796	d_4 = 0.0454		
r_5 = 0.2961	d_5 = 0.0869	n_3 = 1.67003	ν_3 = 47.3
r_6 = 0.3076	d_6 = 0.1834		
r_7 = −0.3132	d_7 = 0.0193	n_4 = 1.72825	ν_4 = 28.5
r_8 = 4.0871	d_8 = 0.0014		
r_9 = 4.4515	d_9 = 0.1219	n_5 = 1.69680	ν_5 = 55.5
r_{10} = −0.3747	d_{10} = 0.0024		
r_{11} = 16.6489	d_{11} = 0.0639	n_6 = 1.83400	ν_6 = 37.2
r_{12} = −0.9391			

where,

$r_1,r_2, \ldots r_{12}$: the radius of curvature of the lens measured in sequence from the object side

$d_1,d_3,d_5,d_7,d_9,d_{11}$: the axial thickness of the lens measured in sequence from the object side

d_2,d_4,d_6,d_8,d_{10}: the axial air space between the lenses measured in sequence from the object side

$n_1, n_2, \ldots n_6$: the refractive index of the optical glass of the lens with respect to the d-line measured in sequence from the object side

$\nu_1, \nu_2, \ldots \nu_6$: Abbe number of the optical glass of the lens measured with respect to d-line in sequence from the object side.

7. A semi wide angle objective lens constituting of five groups of six lens elements forming a front group having the first group of a positive meniscus single lens L_1 with its convex surface directed toward the object side, the second group of a negative meniscus single lens L_2 with its convex surface directed toward the object side and the third group of a positive meniscus single lens L_3 with its convex surface directed toward the object side, and forming a rear group having the fourth group of a negative lens L_4 with its concave surface having a large curvature directed toward the object side and of a positive lens L_5 with its convex surface having a large curvature directed toward an image side which are arranged with an extremely small air space therebetween, and the fifth group of a positive lens L_6 characterized in that each of the following conditions, i.e.

$$1.69f < |f_2| < 1.79f \quad (1)$$

$$0.27f < r_4 < 0.29f \quad (2)$$

[57] **ABSTRACT**

In a closeup focusing mechanism for objectives of long focal length, a tube carried between the objective housing and a camera mounting means telescopes into and out of the objective housing. The camera mounting means carries an axially extending rod externally of the tube which is guided in a guide carried by the objective housing. Thus the tube does not rotate relative to the housing.

CLOSEUP FOCUSING MECHANISM FOR AN OBJECTIVE OF LONG FOCAL LENGTH

BACKGROUND OF THE INVENTION

The invention concerns a camera closeup focusing mechanism for objectives of long focal length, comprising a tube between the objective housing and a mounting means for the camera, as well as anti-rotation means.

Telephoto objectives, objectives of long focal length, as a rule have focusing ranges of infinity to about 7 meters. However it is often desirable, when photographing birds and similar subjects, to be able to focus sharply at a distance of from two to three meters. This is achieved by inserting a closeup focusing mechanism between the objective housing and the mounting means for the camera.

The design of a closeup focusing mechanism in the form of a tube is already known. There is a certain minimum inner diameter which the tube must have, and should exceed, depending on the format and dimensions of the objective, in order to avoid underexposure of the border regions of the photograph.

At the same time the outer diameter of the tube imposes a limit on the dimensions of the objective and/or its fine-focusing mechanism. If the outer diameter of the tube is increased, all the dimensions of the objective must be modified. It is clear that the outer diameter of the tube is limited by these conditions

Known closeup focusing mechanisms use a tube which has the maximum possible thickness taking into account the above conditions. Grooves are machined into this tube in order to supply the required guiding means between the camera on the one side and the telephoto objective on the other.

Such guides or guide grooves are necessary in order to have means of transmitting rotational forces between the camera and the objective. This is a factor, for example, when the camera is being turned between vertical and horizontal formats, or in the attaching of the objective to the camera.

Cameras currently used for long-focal-length objectives, in particular, have substantial size and weight, typically with, for example, motorized film transports, etc. Also the weight of the telephoto objective itself is relatively high. The tube thus must form a connection between relatively heavy parts.

Since however the tube wall should be kept as thin as possible, the guide grooves in the tube must be kept small. The guides, grooves and the like are therefore subject to relatively high stresses. If the transmission and accommodation of these stresses is unsatisfactory, the guides can be overloaded, and there is danger of sudden or rapid wear. The useful life of the tube with guides therefore tends to be less than that of other parts of the camera or the telephoto objective.

An object of the present invention is to provide a closeup focusing mechanism for objectives with long focal lengths, which mechanism has a relatively high load-carrying capability and does not develop appreciable evidence of wear after long use. A further object of the invention is to provide a device which does not require an increase in the dimensions of the telephoto objective, particularly its diameter; but rather, such a closeup focusing mechanism should be usable with available telephoto objectives.

SUMMARY OF THE INVENTION

The present invention provides a closeup focusing mechanism for long-focal-length objectives, comprising a tube between the objective housing and the mounting means for the camera, which tube can be pushed or slid into and pulled out of the objective housing with prevention of rotation between the camera mounting means and the objective housing.

In accordance with the invention, it is proposed that the tube be manufactured from thin walled material, and that external to the tube there be a guide rod attached to the camera mounting means, which rod works in concert with a guide on the objective housing.

The invention employs a relatively thin walled tube but in an arrangement whereby it need not sustain any rotational stresses. It is therefore unnecessary to have grooves or other guide means on this tube. It is sufficient for the tube to be guided telescopically to ensure that the optical axis of the camera is directed in the direction of the optical axis of the telephoto objective. The forces involved in directing these parts can be transmitted by such a relatively thin walled tube substantially without damage or wear phenomena developing. One need only supply certain necessary elements, e.g., features of the camera mounting, or detent means, so as to prevent the tube from being pulled out of the objective housing. There is no particular problem in accommodating these parts with a thin walled tube of the type proposed. The invention thereby achieves a relatively large inner diameter for light beam passage without the diameter of the objective being increased.

The guide rod can be mounted so as not to affect the other parts of the objective, etc. The rod can for example be attached to the camera mount or mounting ring and work together with a guide on the objective housing. One guide rod suffices, since rotation is prevented by the combination of guide rod on one side and the tube on the other. The guide rod and guide are simple elements which can be manufactured at modest cost.

In its fixed position the guide rod is capable of bearing the entire stress of holding the assembly in place, thus substantially relieving the stress on the tube and its own telescoping guides, which contributes greatly to the operating life of the assembly.

It is further advantageous for the fixing of the guide rod to be effected by means of a set screw in the guide.

There is a wide choice of location of the guide rod. However, it is advantageous for the rod to be located in the angular section neighboring the attachment location of the holding grip or operating grip to the objective housing. In this way the guide rod fits into the outer contour of the telephoto objective and does not take up a great deal of additional space, which can become important when the apparatus is being carried or shipped. It is also important during use, where there are no projecting parts to interfere with manipulation.

It is further proposed that the set screw be on one side of the grip and the guide rod on the other, which yields a compact design.

BRIEF DESCRIPTION OF DRAWINGS

FIG. 1 is an elevation showing the rear part of a long-focal-length objective with a closeup focusing mechanism according to the invention;

FIG. 2 is a partial cross section of the above type of objective and closeup focusing mechanism;

FIG. 3 is a bottom view of the rear part of the objective of FIG. 1;

FIG. 4 shows the adjoining part of the objective of FIG. 3; and

FIG. 5 is a rear view of the objective of FIG. 1.

DESCRIPTION OF PREFERRED EMBODIMENT

The objective shown in the drawings is a piece which is constructed unitarily with objective housing 5. Another objective part attaches on at the front end 9 (see FIG. 4) of this first objective part, via bayonet mount 10, when the objective is in the operating mode. This front part of the objective is not shown further.

The associated camera is also omitted from the drawings. This camera can be attached, for example, on mounting ring 11, which is held by nut 12 to camera mount 3. The film plane of the camera is signified by 13 in FIG. 2.

The part of the objective shown in the drawing comprises basically the objective housing 5 which is rigidly connected to the grip 8. The tube 15 is moved in objective housing 5 for fine focusing by means of the movable part 14 of the grip. Tube 15 is supported in objective housing 5 by means of, for example, bearing 16. The guide tube 17 for tube 1 is attached at the rear end area of objective housing 5. A suitable coating 18 is provided on the inside of said guide tube 17 in order to ensure that tube 1 is easily slidable in guide tube 17.

The outer end of tube 1 supports the camera mount 3 and may be permanently joined to these parts. There may also be compartment 19 for filters or similar devices.

FIG. 2 shows the position in which tube 1 is fully slid into the objective housing 5. FIGS. 1 and 3 show a position where the tube is partly pulled out. A detent ring 20 is provided on the inner end of tube 1 to prevent undesired pulling out of said tube from the guide tube 17. At the maximum pulled-out position, detent 20 contacts the inner end 21 of guide tube 17.

A guide rod 2 is attached in a boss 22 on the camera mount 3. This guide rod is guided in guide 4 which is attached to guide tube 17. The arrangement places the guide rod in angular region 7 relative to grip 8 as attached to objective housing 5. A set screw 6, which is located on the other side of grip 8, is partially enclosed in part 23. It clamps by tightly engaging guide rod 2 in guide 4, at the desired extended position of tube 1. As seen clearly in FIG. 3, there is also an adjusting device 24 for fixing the fine-focusing setting of the objective.

What is claimed is:

1. A closeup focusing mechanism for a long-focal-length objective comprising an objective housing, means for mounting the objective to a camera, a tube between the objective housing and the camera mounting means, the tube being slidable into and out of the objective housing, a guide rod attached to the camera mounting means and extending towards the objective housing externally of the tube, and a guide for said rod on the objective housing.

2. A closeup focusing mechanism according to claim 1 including a set screw for fixing the guide rod in the guide.

3. A closeup focusing mechanism according to claim 2 and including an operating grip associated with said housing, said set screw being located on one side of said grip and said guide rod and guide being located on the other side of said grip.

4. A closeup focusing mechanism according to claim 1 or claim 2 including an operating grip associated with said housing and the guide rod being positioned adjacent the junction between said housing and said grip.

WIDE ANGLE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a wide angle objective lens system for use in a camera having a range finder, and more particularly to a wide angle objective lens system of a type in which a lens component of positive refractive power is sandwiched in between a pair of outer lens components of negative refractive power.

2. Description of the Prior Art

Various wide angle objective lens systems of a type having a positive lens component sandwiched in between a pair of outer negative lens component have been suggested in the prior art such as that disclosed in the U.S. Pat. Nos. 3,132,199, 3,591,257 and 3,601,473.

There is still a demand in the prior art to provide a high quality wide angle objective lens system that can be economically manufactured. More particularly there is a demand to provide these features on a wide angle objective lens system having a compact size.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a wide angle objective lens system of a type having a positive lens component sandwiched in between a pair of outer negative lens components in a compact size.

Another object of the present invention is to provide a wide angle objective lens system of the above mentioned type with an aperture ratio about 1/2.8, a field angle of about 76 degrees and a back focal distance of about 60 to 70 percent of the focal length of the system.

A still another object of the present invention is to provide an improved wide angle objective lens system for use in a camera having a range finder.

A further object of the present invention is to provide an improved wide angle objective lens system of the above mentioned type wherein the aberrations have been sufficiently corrected for commercial use.

The wide angle objective lens system of the present invention is of five-group, seven-element comprising, consecutively from the object to the image side, a first lens group consisting of a negative meniscus single lens convex to the object side, a second lens group consisting of a positive doublet having a cemented surface concave to the object side, a third lens group consisting of a negative meniscus single lens concave to the object side, a fourth lens group consisting of a positive doublet, and a fifth lens group consisting of a negative meniscus single lens concave to the object side, the system fulfilling the following conditions:

$0.70 < \phi_5/\phi_1 < 1.35$,

$0.15f < d_2 < 0.55f$,

$0.13 < N_2 - N_3 < 0.24$, and

$1.5f < r_5$.

The features of the present invention which are believed to be novel are set forth with particularity in the appended claims. The present invention, both as to its organization and manner of operation, together with further objects and advantages thereof, may best be understood by reference to the following description, taken in conjunction with the accompanying drawings.

DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic cross-sectional view of a first embodiment of the present invention;

FIGS. **2***a*, **2***b* and **2***c* are respectively graphical plots of the abberations of the first embodiment;

FIG. **3** is a schematic cross-sectional view of a second embodiment of the present invention;

FIGS. **4***a*, **4***b* and **4***c* are graphical plots of the abberations of the second embodiment;

FIG. **5** is a schematic cross-sectional view of a third embodiment of the present invention;

FIGS. **6***a*, **6***b* and **6***c* are graphical plots of the aberrations of the third embodiment;

FIG. **7** is a schematical cross-sectional view of the fourth embodiment of the present invention; and

FIGS. **8***a*, **8***b* and **8***c* are graphical plots of the aberrations of the fourth embodiment.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical art to make and use the invention and sets forth the best modes contemplated by the inventor of carrying out his invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention have been defined herein specifically to provide a wide angle objective lens system of a type having a positive component sandwiched in between a pair of outer negative components in a compact size.

The present invention represents the parameters of a compromise balance of acceptable aberrations in wide angle objective lens system for utilization with a 35 mm camera having a range finder.

In the accompanying drawings which supplement the following tables, the lenses in accordance with the present invention are illustrated diagrammatically. As usual, in conventional lens diagrams, light is assumed to travel from left to right. The individual lens groups are designated by the letter L with a subscript number corresponding to the consecutive numbers of the lens groups from image to object side. The radii of curvature of the lenses are indicated by r, with a subscript corresponding to consecutive numbers of the lens elements. The axial distances, d, along the optical axis are set forth both in the tables and in the drawings and include both the axial spacings between the lens elements and the thickness of the lens elements. Finally, the refractive index, N, and Abbe number, ν, are provided in each of the tables. Since the specific lens parameters are provided herein to meet the requirements of a full disclosure adequate to convey the present invention to a lens designer, they should not be construed as limiting to any specific lens design as set forth in an individual embodiment.

Four specific embodiments of the present invention are disclosed respectively in FIGS. **1**, **3**, **5**, and **7**. Each of these wide angle objective lens systems is of five-group, seven-element comprising, consecutively from the object of the image side, a first lens group L_1 consisting of a negative meniscus single lens convex to the object side, a second lens group L_2 consisting of a positive doublet having a cemented surface r_4 concave to the object side, a third lens group L_3 consisting of a negative meniscus single lens concave to the object side, a fourth lens group L_4 consisting of a positive doublet,

and a fifth lens group L_5 consisting of a negative meniscus single lens concave to the object side.

The wide angle objective lens system fulfills the following conditions:

(1) $0.70<\phi_5/\phi_1<1.35$;

(2) $0.15f<d_2<0.55f$;

(3) $0.13<N_2-N_3<0.24$;

(4) $1.5f<r_5$

wherein ϕ_1 represents a refractive power of the first lens group; ϕ_5 represents a refractive power of the fifth lens group; d_2 represents an axial distance between the first and second lens groups; f represents the focal length of the whole lens system; N_2 and N_3 represent refractive indices of the object side and image side lens elements in the doublet of the second lens group, respectively; and r_5 represents a radius of curvature of the image side surface of the doublet of the second lens group.

The above mentioned condition (1) relates to a pair of outer lens groups L_1 and L_5 each having a negative refractive power, and defines a ratio of refractive power of the fifth lens group L_5 to that of first lens group L_1 for minimizing the various aberrations which would be increased when a wide angle lens system having a positive component sandwiched in between a pair of outer negative components is desired to be compact. In case that the ratio, ϕ_5/ϕ_1 increases beyond the upper limit, the field curvature may be difficult to be corrected because of an inevitably increased Petzval Sum although the desired compactness of the system would be attained. On the contrary, a bulkiness of the system may undesirably result if a well balanced aberration correction is sought with the ratio, ϕ_5/ϕ_1 below the lower limit.

Condition (2) is for balancing the corrections of astigmatism and coma. The value of d_2 below 0.55f is favorable to the compactness of the system desired. However, the balance of aberration correction may be broken and a necessary back focal distance of the system may be impossible to be attained in case d_2 is less than 0.15f.

Condition (3) means that the refractive power of the cemented surface r_4 in the second lens group L_2 is positive. This condition is for cancelling aberrations which are generated at the first lens group L_1 and for decreasing the Petzval Sum to improve the field curvature. If (N_2-N_3) excessively increases beyond the upper limit, the correction of spherical aberration may be insufficient although it would be possible to decrease the Petzval Sum. On the other hand, the correction of distortion and negative coma may be insufficient and the spherical aberration may be excessively corrected.

Condition (4) is for correcting spherical aberration and balancing corrections of astigmatism and coma, and has a relation to the third lens group L_3. If condition (4) is violated, astigmatism may be negatively biased to deteriorate the field curvature. To recover the desirable field curvature, the third lens group L_3 may be required to have an excessive negative refractive power, which results in an additional generation of spherical aberration. Thus, it may be difficult to increase an aperture ratio.

The following Tables 1 to 4 show the first to fourth embodiments of the present invention, respectively.

In the above tables the spherical aberration, sine condition, astigmatism and distortion are plotted for each of the four embodiments in respectively FIGS. **2**, **4**, **6**, and **8**.

By adhering to the parameters and design considerations set forth in the above specification, a lens designer in the optical field is capable of providing a wide angle objective lens system. While the parameters of the present invention can be found in the above examples, the examples should not be considered limiting but rather illustrative of the advantages of the present invention. Accordingly, the parameters of the present invention should be measured solely from the following claims.

What is claimed is:

1. A wide angle objective lens system of five-group, seven-elements comprising, consecutively from the object to the image side:

a first lens group consisting of a negative meniscus single lens convex to the object side;

a second lens group consisting of a positive doublet having a cemented surface concave to the object side;

a third lens group consisting of a negative meniscus single lens concave to the object side;

a fourth lens group consisting of a positive doublet; and

a fifth lens group consisting of a negative meniscus single lens concave to the object side.

2. The invention of claim **1**, wherein the wide angle objective lens system fulfills the following conditions:

$0.70 < \phi_5/\phi_1 < 1.35$;

$0.15f < d_2 < 0.55f$;

$0.13 < N_2\text{-}N_3 < 0.24$;

$1.5f < r_5$

wherein:

ϕ_1 represents a refractive power of the first lens group;

ϕ_5 represents a refractive power of the fifth lens group;

d_2 represents an axial distance between the first and second lens groups;

f represents the focal length of the whole lens system;

N_2 and N_3 represent refractive indices of the object side and image side lens elements in the doublet of the second lens group, respectively; and

r_5 represents a radius of curvature of the image side surface of the doublet of the second lens group.

3. A wide angle objective lens system comprising the following design parameters;

	f = 100.0 F_{no} = 2.8 2ω = 76°			
	Radius of Curvature	Axial Distance	Refractive Index	Abbe Number
	r_1 = 157.331

7. A compact wide angle objective lens system comprising, consecutively from the object to the image side of the lens system;

a first negative lens;

a first positive doublet;

a second negative lens;

a second positive doublet, and

a third negative lens, wherein the wide angle objective lens system fulfills the following conditions:

$0.70 < \phi_5/\phi_1 < 1.35$;

$0.15f < d_2 < 0.55f$;

$0.13 < N_2 - N_3 < 0.24$;

$1.5f < r_5$

wherein:

$\phi 1$ represents a refractive power of the first negative lens;

$\phi 5$ represents a refractive power of the third negative lens;

d_2 represents an axial distance between the first lens and the first doublet;

f represents the focal length of the whole lens system;

N_2 and N_3 represent the refractive indices of the object side and image side lens elements in the first doublet respectively; and

r_5 represents a radius of curvature of the image side surface of the first doublet.

[57] **ABSTRACT**

A retrofocus wide angle objective having an angle of view of at least 82° with a relative aperture of 1:2.8 and whose back focal distance is made longer than 1.4 times the focal length of the entire system. The objective comprises, from front to rear, a first lens of positive power in a forwardly convex meniscus form, a second negative meniscus lens, a third positive lens, a fourth negative lens, a fifth biconvex lens, a diaphragm, a sixth biconvex lens, a seventh biconcave lens, and eighth and ninth positive lenses. In such retrofocus objective with the positive meniscus lens arranged at the front, while the angle of view is maintained increased, the lens system is reduced in dimensions and is properly corrected in particular for distortion and astigmatism.

RETROFOCUS TYPE WIDE-ANGLE OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to retrofocus type photographic objectives, and more particularly to a compact retrofocus objective having a wide angular field coverage and a longer back focal distance than 1.4 times the focal length thereof.

Recent developments in interchangeable objectives for use in 35 m/m single lens reflex cameras are directed to compact designs, and this tendency is especially pronounced in the wide angle lens art. Because it allows a sufficiently long back focal distance, the retrofocus type has been widely accepted in designing such wide angle objectives. The employment of the retrofocus type, however, gives rise to many difficult problems of aberrational correction because of the asymmetrical lens arrangement.

Of the various aberrations, the distortion which is introduced by the divergent front lens group constitutes a most important subject for correction. According to the generally accepted proposal, a positive component is arranged in the front group of the lens system. With such construction and arrangement of the front lens group, however, the off-axial rays of light are strongly refracted by that positive component. Hence the other aberrations tend to be increased and the diameter of the front member must be increased to secure the equivalent angular field coverage.

As the dimensions of this type wide angle objective are reduced, therefore, these problems are made more difficult to solve, resulting in a less standard of correction of the aberrations. A high standard of aberrational correction has so far been realized by employing especial optical glasses in making the various lens elements. This leads to an increase in the production cost of objectives.

Attempts have been made to provide a compact retrofocus wide angle objective which has overcome the above mentioned drawbacks and which is well corrected for the various aberrations as in U.S. patent application Ser. No. 892,422 (Filed Mar. 31, 1978) assigned to the assignee of the present invention. Of the examples of the lens systems described therein, the fourth example nears the construction of the lens of the present invention. The lens in this example has an angle of view of 75°, and f-number of 1:2.0. The present invention provides a retrofocus type lens having a larger angle of view than that of the above mentioned cited example, while nevertheless maintaining the length of the entire lens system at minimum, and achieving good correction of the aberrations.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a retrofocus type lens of reduced size and a large angle of view.

A second object of the present invention is to provide a retrofocus type lens having a back focal distance equal to or longer than 1.4 times the focal length thereof.

A third object of the present invention is to provide a retrofocus type lens which is well corrected for the various aberrations particularly distortion and astigmatism or lateral chromatic aberration simultaneously.

It is also an object of the present invention to prevent the image quality to be decreased when focusing is performed to suit for nearer objects.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a diagram of a first example of a specific compact retrofocus wide angle objective according to the present invention.

FIG. **2** is a diagram showing a second example of the present invention.

FIG. **3** is a diagram showing a third example of the present invention.

FIGS. **4A** to **4D** are graphic representations of the spherical aberration, astigmatism, distortion and lateral chromatic aberration of the lens of FIG. **1** with object at infinity.

FIGS. **5A** to **5D** and **6A** to **6D** are similar representations of the lenses of FIGS. **2** and **3** respectively.

FIGS. **7A** to **7C**, **8A** to **8C** and **9A** to **9C** are graphic representations of the spherical aberration, astigmatism and distortion of the lenses of FIGS. **1** to **3** respectively when focused at an object distance corresponding to a magnification of 1/10.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

In FIGS. **1** to **3** the lenses are identified by their dimensions D_x. FIGS. **1** to **3**, show an embodiment of a compact retrofocus wide angle objective according to the present invention including, from front to rear, a first lens D_1 of positive power in a forwardly convex meniscus form, a second negative meniscus lens D_3 of rearward concavity, a third positive lens D_5 and a fourth negative lens D_7, the image side curvature (radius R_6) of the third lens and the object side curvature (radius R_8) of the fourth lens being of the same sign and the combined refractive power of these four lenses being negative. The objective further includes a fifth biconvex lens D_9 having a strong front curvature R_9, that is, a smaller absolute value of the radius of curvature of the front surface than that of the radius R_{10} of curvature of the rear surface, a diaphragm, a sixth biconvex lens D_{11} having a strong rear curvature (radius R_{12}), a seventh biconcave lens D_{13} having a strong front curvature (radius R_{13}), and eighth and ninth positive lenses D_{15} and D_{17}. In the preferred embodiment of the present invention, the front surface of the third positive lens is convex toward the front, the rear surface of the fourth negative lens is concave toward the rear, and the eighth and ninth lenses are positive meniscus lenses of forward concavity. By employing the arrangement of the positive, negative, positive and negative lenses in this order from the front in combination with the above defined lens configurations, it is made possible to achieve simultaneous good correction of distortion and astigmatism which was considered in the prior art to be difficult to perform in good balance. Further, the location of the diaphragm in a space between the central or fifth lens D_9 and the sixth lens D_{11} is advantageously utilized to achieve the compactness of the lens system.

The objective of the present invention is characterized by fulfilling the following relationships:

$$0.5F \leqq |F_I| \leqq 0.75F,\ F_I < 0 \quad (1)$$

$$2.5F \leqq |F_{II}| \leqq 4.5F,\ F_{II} < 0 \quad (2)$$

$$0.29 \leqq (D9 + D11)/L \leqq 0.42 \quad (3)$$

$$\left| \frac{1}{R12} - \frac{1}{R13} \right| \leqq \frac{0.13}{F} \quad (4)$$

-continued

$0.02F \leqq D12 \leqq 0.1F$ (5)

$48 \leqq (\nu1, \nu4, \nu6) \leqq 63$ (6)

$30 \leqq (\nu2, \nu3) \leqq 41; 26 \leqq \nu5 \leqq 32$ (7)

wherein F is the focal length of the entire system; F_I is the composite focal length of the first four lenses; F_{II} is the composite focal length of the first five lenses; L is the total length of the lens system measured from the front surface of the first lens to the rear surface of the ninth lens; D9 is the axial thickness of the fifth lens; D11 is the axial thickness of the sixth lens; R12 is the radius of curvature of the rear surface of the sixth lens; R13 is the radius of curvature of the front surface of the seventh lens; D12 is the axial air separation between the sixth and seventh lenses; and $\nu1$, $\nu2$, $\nu3$, $\nu4$, $\nu5$ and $\nu6$ are the Abbe numbers of the first, second, third, fourth, fifth and sixth lenses respectively.

The fulfillment of the inequality (1) insures that a sufficiently long back focal length for adaptation to a single lens reflex camera is provided while the diameter of the front member of the lens system is maintained at minimum. In comparison with the conventional objective described in the aforesaid U.S. patent application Ser. No. 892,422, the absolute value of the composite focal length of the first four lenses is defined as shifted toward smaller values. This is because the objective of the present invention is provided with a larger angular field coverage of at least 82° than that of the conventional one, namely, 75°, and in order to provide such a large angular field coverage, it is necessary to increase the divergence of the first four lenses. But it is to be noted here that as $|F_I|$ is decreased, there is a higher possibility of producing higher order spherical aberration. On this account, according to the present invention, the F-number of the objective is increased from the cited reference so as to afford optimum aberrational correction. Moreover, the good correction of the aberrations for the marginal rays (rays at the large angle with optical axis), is facilitated by making use of a forwardly concave positive meniscus lens as a ninth component, since this lens form has no rapid refracting effect on the marginal rays. When the upper limit of the inequality (1) is exceeded, it is difficult to provide a sufficient back focal distance and to maintain the diameter of the front member at a minimum. When the lower limit is exceeded, extremely large higher order spherical aberration is produced. In the specific lens systems to be described later, the back focal length is made longer than 1.4 times the focal length.

The relationship (2) represents the focal length of a front lens group of all lens elements on the object side of the diaphragm. This focal length is required to be negative for the compactness of the lens system. As the angle of inclination of an oblique ray passing through an opening of the diaphragm aperture with the optical axis is smaller than that of incidence of that ray on the first surface of the lens system, the height of incidence of the most marginal ray (at the maximum angle with optical axis) on the first surface may correspondingly be decreased. Therefore, the diameter of the first member can be reduced along with those of the other four members in the front group. When the upper limit is exceeded, though the diameter of the front member may be decreased, the diameters of the following members must be increased to so large extent that the good correction of the aberrations particularly spherical aberration and coma is difficult to perform. Conversely when the lower limit is exceeded, the desired degree of compactness can not be assured so that the diameter of the front member and the physical length of the objective are simultaneously increased.

The relationship (3) represents a good compromise between the physical length of the objective and the diameter of the front member while still permitting distortion and astigmatism to be highly corrected. When the upper limit is exceeded, though the diameter of the front member may be reduced, the physical length of the objective becomes very long with increase in battel type distortion. When the lower limit is exceeded, the diameter of the front member is extremely increased with increase in higher order aberrations for the off-axial rays, and it becomes difficult to achieve simultaneous good correction of distortion and astigmatism.

The relationships (4) and (5) represent the form of an air lens between the sixth and seventh lenses which introduces higher-order aberrations into the system so that the spherical aberration and lateral aberration in the sagittal plane for the marginal rays at the full open aperture can be well compensated for. In other words, since the surfaces R12 and R13 are configured in almost concentric relation to the diaphragm, the meridional ray in the marginal zone is little susceptible to refraction, while the axial ray and the sagittal ray in the marginal zone are largely affected to compensate for the spherical aberration in an under-corrected sense at increasing rates as the size of diaphragm aperture is increased, and for the lateral aberration for the marginal rays in the sagittal plane in an under-corrected sense. When the values of $(1/R12 - 1/R13)$ and D12 are smaller than $-0.13/F$ and $0.02F$, respectively, the air lens hardly produces higher-order aberrations which compensate for the spherical aberration and for the lateral aberration for the marginal rays in the sagittal plane at the full open aperture toward moderate under-correction thereof. When the values of $(1/R12 - 1/R13)$ and D12 are larger than $0.13/F$ and $0.1F$ respectively, secondary and tertiary spherical aberrations are largely produced to result in extremely large under-correction of spherical aberration from the neighborhood of the optical axis. In addition thereto, the back focal distance becomes too short to cause mechanical interference between the objective lens and a tiltable mirror of the camera associated therewith.

The relationships (6) and (7) are the conditions for very good correction of lateral chromatic aberration, longitudinal chromatic aberration and chromatic spherical aberration. In other words, the first and second members are made up of glasses having Abbe numbers adjusted so as to contribute to under-corrected lateral chromatic aberrations with magnitudes as equal to each other as possible for the rays of inclination angles ranging from an intermediate angular field coverage to the maximum possible coverage at a short wave length, for example, that of g-line, while the third to sixth members are made up of glasses having Abbe numbers adjusted to contribute to over-corrected lateral chromatic aberrations (for g-line). As a result, the under-corrected residual of lateral chromatic aberration from the first and second members is cancelled out by the over-corrected one from the third to the sixth members.

The fourth member is made up of a glass having an Abbe number adjusted so as to produce as small longitudinal chromatic aberration and chromatic spherical aberration as possible, and the residual of such aberra-

tions introduced by the fourth member into the system is compensated for by adjusting the Abbe numbers of the third and fifth members.

Such selection of the glasses of the third, fourth and fifth members for adaptation to good simultaneous correction of lateral and longitudinal chromatic aberration and chromatic spherical aberration will lead to an occurrence of two different ideal values of Abbe number for each member. However these values do not deviate from each other so much as to be incapable of fulfilling the requirements (6) and (7), since a glass of low dispersion may be selected for employment in at least the positive first, negative fourth and positive lenses, and a glass of high dispersion in at least the negative second, positive third and positive fifth lenses. When the lower limit of the inequality (6) and the upper limit of the inequality (7) are simultaneously exceeded, it is no longer possible to achieve good correction of all lateral chromatic aberration, longitudinal chromatic aberration and chromatic spherical aberration. If the longitudinal chromatic aberration and chromatic spherical aberration are well corrected, the lateral chromatic aberration for g-line is under-corrected at the intermediate angles of view field, and is over-corrected at the largest angle. When the upper limit of (6) is exceeded, or when the lower limit of (7) is exceeded, the lateral chromatic aberration is well corrected, but instead the longitudinal chromatic aberration for g-line is extremely over-corrected, and the chromatic spherical aberration for g-line is extremely over-corrected in the neighborhood of the full open aperture. It is noted here that the glasses whose Abbe numbers fall in the ranges set forth in (6) and (7) are inexpensive and feasible for manufacturing techniques so that the production cost can be reduced.

In order to insure that the thus corrected aberrations are stabilized over the focusing range, it is desired to move the lens system as a whole toward the front as focusing is effected down to shorter object distances, while the axial air separation between the third and fourth members is decreased simultaneously and to fulfill the following requirements:

$$1.9F < |F_{III}| < 12F,\ F_{III} < 0 \quad (8)$$

$$1 < H7 < 1.2 \quad (9)$$

where R_{III} is the composite focal length of the first to third lenses, and H7 is the height of incidence on the front surface (R7) of the fourth lens of a paraxial ray which entered the system at an incident angle of zero (parallel to the optical axis) and at a height of 1 with object at infinity provided that the focal length of the entire system is 1.

As focusing is effected to suit shorter object distances, the forward axial movement of the lens system causes a tendency of producing extremely over-corrected astigmatism to appear. As is known in the art, such astigmatism can be compensated for by decreasing the axial air separation between the third and fourth members in synchronism with the forward axial movement of the entire lens system.

If such focusing provision is made without setting forth any condition, however, there will be a high possibility of deteriorating the other aberrations and particularly spherical aberration. The fulfillment of the requirements (8) and (9) insures that the astigmatism is maintained at a minimum without causing any large increase in the other aberrations.

With the first four lenses constituting a divergent group, as the diverging action of the fourth lens is prevented from becoming extremely strong, it is preferable to impart a negative power into the group of at least first three lenses. When the lower limit of (8) is exceeded, the spherical aberration becomes extremely over-corrected in close-up positions, and the astigmatism is varied considerably during focusing. Conversely when the upper limit is exceeded, the divergent refractive power of the fourth lens becomes too strong to increase the complexity of aberrational problem. Since the 3rd-order spherical aberration is proportional to the fourth power of incident height H, when H7 is larger than 1.2, extremely over-corrected spherical aberration is resulted in close up positions. When H7 is smaller than 1, the divergent refractive power of the fourth lens becomes too strong to unable the good correction of the aberrations by any simple method likewise as in the above.

Three examples of specific lens systems represented in FIGS. **1** to **3** can be constructed in accordance with the numerical data given in the following tables for the radii of curvature, **R1** to **R18**, the axial thickness and air separations, **D1** to **D17**, along with the indices of refraction, **N1** to **N9** and the Abbe numbers, ν**1** to ν**9** of the various lens elements. The minus values of the radii, R, indicate surfaces concave to the front. Each of the lens systems has a relative aperture of 1:2.8 and an angular field coverage of 82.9°.

What is claimed is:

1. A retrofocus type wide angle objective lens comprising, from front to rear, a first positive meniscus lens of forward convexity, a second negative meniscus lens of rearward concavity, a third positive lens, a fourth negative lens, the rear surface of said third positive lens and the front surface of said fourth negative lens having curvatures of the same sign, a fifth bi-convex lens with its front surface having a stronger curvature, a diaphragm, a sixth biconvex lens with its rear surface having a stronger curvature, a seventh biconcave lens with its front surface having a stronger curvature, and eighth and ninth positive meniscus lenses of foward concavity, said objective satisfying the following conditions:

$$0.5F \leqq |F_I| \leqq 0.75F,\ F_I<0 \quad (1)$$

$$2.5F \leqq |F_{II}| \leqq 4.5F,\ F_{II}<0 \quad (2)$$

$$0.29 \leqq (D9+D11)/L \leqq 0.42 \quad (3)$$

$$|1/R12-1/R13| \leqq 0.13/F \quad (4)$$

$$0.02F \leqq D12 \leqq 0.1F \quad (5)$$

wherein F is the focal length of the entire system; F_I is the composite focal length of the first to fourth lenses; F_{II} is the composite focal length of the first to fifth lenses; L is the length of the lens system from the front surface of the first lens to the rear surface of the ninth lens; **D9** is the axial thickness of the fifth lens; **D11** is the axial thickness of the sixth lens; **R12** is the radius of curvature of the rear surface of the sixth lens; **R13** is the radius of curvature of the front surface of the seventh lens; and **D12** is the axial air separation between the sixth and seventh lenses.

2. A retrofocus type wide angle objective lens according to claim **1**, satisfying the following conditions:

$$48 \leqq \nu 1 \leqq 63;\ 48 \leqq \nu 4 \leqq 63;\ 48 \leqq \nu 6 \leqq 63 \quad (6)$$

$$30 \leqq \nu 2 \leqq 41;\ 30 \leqq \nu 3 \leqq 41;\ 26 \leqq \nu 5 \leqq 32 \quad (7)$$

wherein $\nu 1$, $\nu 2$, $\nu 3$, $\nu 4$, $\nu 5$ and $\nu 6$ are the Abbe numbers of the first, second, third, fourth, fifth and sixth lenses respectively.

3. A retrofocus type wide angle objective lens according to claim **1**, wherein as focusing is effected down from infinity to shorter object distances, the lens system is moved forward as a whole, while the axial air separation between said third and said fourth lenses is simultaneously decreased, and satisfying the following conditions:

$$F_{III}<0,\ 1.9F \leqq |F_{III}| \leqq 12F \quad (8)$$

$$1 \leqq H7 \leqq 1.2 \quad (9)$$

wherein F_{III} is the composite focal length of the first to third lenses; and H7 is the height of incidence on the front surface of said fourth lens of a paraxial ray which entered the system at an incident angle of zero and at an incident height of 1 with object at infinity for the focal length of the entire system normalized to 1.

[57] **ABSTRACT**

A front component of a varifocal camera objective, axially shiftable for focusing purposes, is provided with a lens mount held by an axially extending guide rod which is slidably received in an inner annular flange and an end wall of a lens barrel. The guide rod has a rear extremity provided with male threads engaged by a drive nut held captive in the end wall, the nut being provided with outer gear teeth meshing on the one hand with a pinion, driven by a reversible electric motor via a slipping clutch, and on the other hand with a toothed wheel on the shaft of a milled setting wheel which projects from the camera housing. An ancillary rod, parallel to the driven guide rod but shorter than the latter, slides only in the annular flange and has its rear end gripped by a bracing ring also engaging the driven guide rod to form a cage.

FOCUSING MECHANISM FOR CAMERA OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a photographic or cinematographic camera whose objective includes one or more lenses that are axially shiftable for focusing purposes.

BACKGROUND OF THE INVENTION

Conventional cameras with focusable objectives are provided with an outer, axially fixed setting ring rotatably mounted on a lens barrel and provided with female threads engaging male threads of an inner guide ring which is held against rotation and is rigid with a lens mount supporting the shiftable lens or lenses, the latter usually constituting a front component of the objective. The two rings are centered on the objective axis and are therefore of a rather large diameter, resulting in considerable friction along their threaded contact surfaces. Moreover, the manual adjustment of a setting ring located forwardly of the camera body is inconvenient while automatic focusing with such an assembly is rather difficult.

In commonly owned U.S. Pat. No. 3,482,500 there has been disclosed a control mechanism for manual and automatic focusing in which a lens mount is supported by several axially extending guide rods, one of these rods having threads engaged by a nut which is integral with the shiftable lens mount. It has also been proposed to provide a shiftable lens support with an axially extending rack engaged by a rotatable worm; see German Pat. No. 1,101,801.

OBJECTS OF THE INVENTION

An object of my present invention is to provide a manually and/or automatically operable focusing mechanism for a photographic or cinematographic camera (this also includes television cameras) which has a reduced frictional resistance and can therefore be adjusted with little expenditure of energy.

Another object is to simplify the manipulation of such a focusing mechanism by allowing the positioning of a manually operable setting member on the camera body proper.

SUMMARY OF THE INVENTION

In accordance with my present invention, a guide rod fastened to a shiftable lens mount is slidably but nonrotatably held in stationary bearing means inside a lens barrel and extends rearwardly from that lens mount parallel to the optical axis of the objective, terminating in a threaded rear extremity within the camera housing which is engaged by a captive drive nut held in that housing against axial displacement. The nut is provided with external gear teeth in mesh with gear means forming part of the focusing mechanism. Advantageously, the gear means include a toothed wheel coaxial with a manually rotatable setting wheel projecting from the housing, the two wheels being positively coupled with each other and centered on an axis parallel to that of the objective, and further include a motor-driven pinion. The coupling between the pinion and its motor preferably comprises a slipping clutch to allow for manual setting without a decoupling of the motor; the slipping clutch also lets the motor continue its rotation when the lens mount is arrested in one of its limiting positions by a stop rigid with the two wheels.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing the sole FIGURE of which illustrates, somewhat diagrammatically and in axial section, a motion-picture camera with a varifocal objective focusable by a mechanism according to my invention.

SPECIFIC DESCRIPTION

The camera shown in the drawing comprises a varifocal or zoom-type objective, generally designated **1**, and a camera body, generally designated **2**. The objective **1** is provided with a lens barrel **26** which projects from the camera housing **27** and is centered on an optical axis **0**. Also centered on this axis are several lens members constituting a positively refracting front component **3**, two negatively refracting intermediate components **4, 5** and a stationary rear component **6**; the latter, disposed outside lens barrel **26** within housing **27**, consists of a plurality of lenses not illustrated individually.

As is well known per se, an axial shifting of the second component **4** changes the focal length of lens assembly **3 - 6** and must be accompanied by a compensatory displacement of the third component **5** in order to keep the image plane of the objective coincident with the sensitive surface of a film **7**. The concurrent shifting of components **4** and **5** is brought about by the rotation of a sleeve **29**, provided for this purpose with a knob **30**, which has camming grooves **24, 25** engaged by respective pins that pass through an axially extending slot **28** of the lens barrel **26** and are rigid with their respective lens mounts **31, 32**. The lens mounts are slidably supported by axially extending guide rods not shown.

Front component **3**, here shown as a compound lens, is provided with a lens mount **8** which is axially movable independently of lens mounts **31, 32** for focusing the objective upon an object to be photographed, either manully or automatically under the control of a conventional distance finder. Lens mount **8** is cantilevered on an axially extending guide rod **9** which is slidably and nonrotatably received in an inner annular flange **18** of lens barrel **26** as well as in a bearing block **19** forming part of a rear wall **20**. The extremity of guide rod **9** projecting rearwardly beyond the bearing block **19**, located within camera housing **27**, carries male threads **10** matingly engaged by a captive nut **11** which is held against axial displacement by the block **19** and by an extension **20'** of end wall **20**.

Nut **11** carries external gear teeth in mesh with a toothed wheel **12**, of larger diameter, which is rigid with a milled setting wheel **13** rotatable about a shaft **31** whose axis parallels the optical axis **0**. Setting wheel **13**, whose diameter—like that of wheel **12**—is considerably smaller than that of lens barrel **26**, partly projects through a lateral slot of camera housing **27** and carries a rearwardly facing distance scale **14** easily observable by the user. The manual rotation of wheels **12** and **13** is limited to less than a full revolution by a stud **22** projecting axially therefrom so as to come to rest on the periphery of end wall **20** in an infinity position and in a closeup position; the latter setting corresponds to a position of component **3** and lens mount **8** shown in dot-dash lines.

A reversible electric motor **16**, energizable (e.g. as described in commonly owned U.S. Pat. No. 3,165,044) from a nonillustrated power supply, is connected via a

slipping clutch **17** with the shaft of a pinion **15** also meshing with the gear teeth of nut **11**. The automatic displacement of nut **11** and lens mount **8** by motor **16**, under the control of the aforementioned distance finder for example, can thus be overridden by manipulation of setting ring **13** even if motor **16** is of the self-locking (e.g. stepping) type.

In order to hold the lens mount **8** against rotation, and to prevent jamming or canting, I provide that lens mount with an ancillary guide rod **21** also slidable in flange **18** but terminating short of end wall **20**. The two parallel rods **9** and **21** are fixedly interconnected, inside lens barrel **26**, by a bracing ring **23** fastened to the rear end of rod **21** by a screw **33** and frictionally fitted onto an intermediate portion of the driven guide rod **9**. It will be observed that ring **23** lies between the cam tracks **24** and **25** of components **4** and **5** so as not to interfere with their displacement by sleeve **29**. Such a precaution, however, will not be necessary if the shifting of these components for zooming purposes is controlled by a camming sleeve of smaller diameter lodged inside ring **23**. In either case, lens mount **8** forms with the two diametrically opposite rods **9** and **21** as well as ring **23** a rigid cage insuring precise axial movement of component **3** upon rotation of drive nut **7**.

The relocation of the manual focusing means **13**, **14** from the vicinity of the front end of the objective, pursuant to conventional practice, to a position on the camera housing **27**, according to my invention, leaves that front end free for the emplacement of various attachments such as supplemental lenses, filters or lens hoods without interfering with incident light rays.

With pinion **15** of smaller diameter than nut **11**, a favorable transmission ratio exists between motor **16** and guide rod **9** so that the frictional resistance encountered by the motor is small, its energy consumption is low and precise focusing is possible, e.g. under the control of an electronic comparator measuring contrasts between adjacent image points against a locally generated reference parameter. Other known distance meters usable for automatic focusing control operate with emitters of infrared radiation or radar pulses and corresponding receivers on the camera.

It will be apparent that more than a single component of an objective—possibly the entire lens assembly thereof—can be axially shifted for focusing purposes by the mechanism according to my invention.

I claim:

1. In a camera provided with a housing and an objective projecting forwardly from said housing, said objective including a lens barrel centered on an optical axis and a plurality of lenses in said lens barrel, at least one of said lenses being provided with an axially shiftable lens mount,

the combination therewith of:

stationary bearing means in said lens barrel;

a guide rod slidably and nonrotatably held in said bearing means, said guide rod being fastened to said lens mount and extending rearwardly therefrom parallel to said optical axis while terminating in a threaded rear extremity within said housing;

a rotatable captive drive nut matingly engaging said extremity, said nut being provided with external gear teeth and being held against axial displacement in said housing;

focusing means for rotating said nut to shift said lens mount along with said lenses, said focusing means including a setting wheel on an ancillary shaft parallel to said optical axis, said setting wheel projecting from said housing for manual rotation; and

a spur gear on said ancillary shaft rigid with said setting wheel and in mesh with the gear teeth of said nut.

2. The combination defined in claim **1** wherein said focusing means further comprises a reversible motor and a pinion coupled with said motor via a slipping clutch, said pinion meshing with said gear teeth.

3. The combination defined in claim **2**, further comprising stop means rigid with said setting wheel for limiting the rotation thereof to less than a full revolution.

4. The combination defined in claim **1** or **2**, further comprising an ancillary rod parallel to said guide rod and shorter than the latter, said bearing means including an internal annular flange on said lens barrel close to said lens mount, said ancillary rod being slidably guided in said flange.

5. The combination defined in claim **4**, further comprising annular bracing means centered on said optical axis rigidly connecting the rear end of said ancillar rod with an intermediate portion of said guide rod.

6. The combination defined in claim **5** wherein said one of said lenses is part of a front component of the objective, said lenses further formina a pair of additional components axially shiftable independently of said front component to vary the focal length of the objective, said annular bracing means being disposed between the paths of displacement of said additional components.

[57] **ABSTRACT**

An objective of a photographic or cinematographic camera has an adjustable four-component front lens group and a fixed rear lens group. Axial displacement of the movable second and third components of the front group establishes a normal varifocal range in which the overall focal length varies between a minimum value f_{min} and a maximum value f_{max} having a ratio of 1:6. In the presence of a front attachment with a negatively refracting additional lens member, further shifting of the two movable components establishes an extended wide-angle range with focal lengths smaller than f_{min}; similarly, in the presence of a front attachment with a positively refracting additional lens member the two movable components are shiftable to establish an extended telephoto range with focal lengths greater than f_{max}. Between the normal and wide-angle ranges the third component is also shiftable, without attachment, to focus in a macro range.

OPTICAL OBJECTIVE WITH EXTENDED VARIFOCAL RANGE

FIELD OF THE INVENTION

Our present invention relates to an optical objective with adjustable overall focal length, comprising a lens assembly with two axially shiftable components which can be concurrently but independently displaced by manual or automatic control means between a lower and an upper limit of a varifocal range.

BACKGROUND OF THE INVENTION

Conventional varifocal objectives of this type can be fitted with various attachments to extend their ratio of maximum and minimum overall focal lengths, either beyond the wide-angle end or beyond the telephoto end of their normal operating range. Such an extension of the normal range can also be effected by an exchange or an interposition of lens members, e.g. with the aid of a revolving carrier or turret. These attachments are, generally, somewhat unhandy, especially when it is desired to shift the operating range toward the shorter focal lengths since the resulting increase in the object-side field angle requires lenses of larger diameter at the front of the objective. Thus, a conventional wide-angle attachment includes a large negative front lens followed by several lenses or lens combinations air-spaced therefrom. The effect of such an attachment is to multiply the numerical values of the overall focal length in the various positions of the shiftable components by a factor smaller than unity, with the law of relative displacement of these components remaining unchanged; on the telephoto side the multiplication factor has a value greater than unity.

OBJECT OF THE INVENTION

The object of our present invention is to provide simple, inexpensive and easily manipulable means for extending the normal operating range of such a varifocal objective beyond its wide-angle and/or its telephoto limit.

SUMMARY OF THE INVENTION

We realize this object, pursuant to our present invention, by the provision of supplemental lens means positionable in front of the varifocal lens assembly whenever that assembly arrives at a limit of its normal range, the associated control means being operable to establish an adjoining ancillary range by axially displacing both shiftable components of the assembly in the presence of the supplemental lens means to increase the ratio of maximum and minimum overal focal lengths while maintaining the same fixed image plane throughout the normal range and the ancillary range or ranges.

Generally, the normal operating range will be separated from each ancillary range, established in accordance with our invention, by an intervening range in which the image plane is not stationary and which is of no further interest as far as the range extension is concerned, except at the wide-angle end where that intervening range may be used to focus the lens assembly upon nearby objects in a so-called macro range.

Advantageously, the camming sleeve serving for the axial displacement of the two shiftable components of our improved lens assembly has guide tracks (e.g. grooves) of which the first one—controlling the movement of the object-side shiftable component—has a constant slope within the normal operating range, as is usual in varifocal objectives. In the ancillary range or ranges according to our invention, the same guide track preferably also has a constant slope which, however, is different from its slope in the normal range and may in fact be of opposite sign. The law of motion of the image-side shiftable component, serving to maintain the constancy of the image plane, is therefore also different in the several ranges.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 is a developed view of the guide tracks of two axially shiftable components of a varifocal objective according to our invention;

FIG. 2 is a diagram similar to that of FIG. 1, illustrating a modification; and

FIG. 3 is an axial sectional view of the upper half of an objective conforming to the diagram of FIG. 1.

SPECIFIC DESCRIPTION

Reference will first be made to FIG. 3 in which we have shown a largely conventional objective of a photographic or cinematographic camera with a lens assembly including a varifocal front group I and a fixed-focus rear group or relay component R. Front group I consists of four components here shown for the sake of simplicity as single lenses L_1, L_2, L_3 and L_4. This lens group is of the general type described in commonly owned U.S. Pat. No. 3,451,743, with two axially shiftable components L_2 and L_3 of negative and positive refractivity, respectively; the first or front component L_1 is of positive refractivity whereas the fourth component L_4 is negatively refracting.

Front group I is mounted in a camera housing **20** centered on the optical axis of the objective, a sleeve **21** being rotatable about that axis to displace the second and third components L_2, L_3 whose lens mounts **32** and **33** carry balls **22** and **23** engaging in camming grooves S_1, S_2 of a cylindrical sheet **31** secured to that sleeve. Lens mounts **32** and **33** are slidably guided on axially extending rods **24** (only one shown); see commonly owned U.S. Pat. No. 3,931,629 for further details. A ring **26** threadedly engages the housing **20** at **25** and holds the front lens L_1 which is thus limitedly axially shiftable for focusing the objective in the normal varifocal range. Rear group R, consisting of a positive lens L_5, a negative lens L_6 and another positive lens L_7, is seated in a lens mount **30** rigid with housing **20**.

Focusing ring **26** has a flange **27** threadedly accommodating either of two attachments **28**, **29** which carry supplemental lenses L_{10} and L_{11} of negative and positive refractivity, respectively. These attachments are alternatively emplaceable on ring **26**, in line with lens assembly L_1–L_7, when the shiftable components L_2 and L_3 of group I have arrived at a respective end of a normal operating range N as shown in FIG. 1. In the embodiment represented there, the overall focal length F of the objective changes from a minimum value of 8 mm at the wide-angle end of range N to a maximum value of 48 mm at the telephoto end of that range, thus providing a varifocal ratio $F_{max}:F_{min}=6:1$.

An image plane BE remains constant throughout range N. At the wide-angle end of F=8 mm, however, component L_3 may be further displaced while compo-

nent L_2 remains stationary to bring about a sharp reduction in the overall focal length concurrently with a shifting of the image plane whereby the objective is focusable upon nearby objects as is well known per se. This so-called macro range has been designated M and is characterized by a shift of component L_3 toward the left, i.e. to the object side of the system; in principle, macro focusing is also possible by a shift of component L_2 while holding component L_3 stationary.

The guide track S_2 of component L_3 is so shaped that component L_3, upon further rotation of the control sleeve **21** of FIG. **3**, is shifted partly back to the right after reaching the extreme macro position. At this point, which represents one of the boundaries of an adjoining wide-angle range W, the negative supplemental lens L_{10} is placed in front of component L_1 to realign the image plane BE with the position it had in the normal range N. Lens L_{10} may have a power of about -10 to -20 diopters corresponding to an individual focal length of -50 to -100 mm.

It will be understood that the addition of this negative supplemental lens L_{10} results in a slight increase of the overall focal length from the low value, substantially less than 8 mm, it assumed on account of the forward shift of component L_3. The new focal length at the end of the extended wide-angle range W is 4.5 mm and represents the lowest value attainable with this system for focusing upon infinity. Further rotation of camming sleeve **21** moves the two lenses L_2 and L_3 toward each other to increase the focal length until it again reaches the value $F=8$ mm it had at the wide-angle end of the normal varifocal range N.

At the opposite end of that varifocal range, i.e. in a position of $F=48$ mm, further rotation of the camming sleeve separates the two shiftable lenses L_2 and L_3 within an intervening range of instability of image plane BE (the progressively increasing overall focal length) until they reach a position where the addition of the positively refracting supplemental lens L_{11} re-establishes the value of $F=48$ mm while restoring the image plane to its normal position. From that point on the tracks S_1, S_2 again diverge, letting the lenses L_2 and L_3 separate in an extended telephoto range T whose other boundary represents an overall focal length $F=70$ mm.

Thus, the overall focal length F is continuously variable from a lowest value of 4.5 mm to a highest value of 70 mm which corresponds to an extended varifocal ratio of about 15.5:1.

Lens L_{11} may have a power of about 0.5 to 5 diopters corresponding to an individual focal length of 200 to 2,000 mm. The maximum stroke of lens L_2 is about 65 mm, that of lens L_3 being about 37 mm.

Naturally, the bulge in track S_2 establishing an extreme macro position can be omitted if focusing in the macro range is not required. It is evidently also possible to displace the lenses L_2 and L_3 from the extreme macro position directly into the position shown at the top of FIG. **1** in which $F=8$ mm in the presence of lens L_{10}, the additional range from 8 mm to 4.5 mm being then traversed upon further rotation of sleeve **21** as indicated in dot-dash lines.

FIG. **2** shows a modified objective with components L_1', L_2', L_3', L_4', R' and supplemental lenses L_{10}', L_{11}'. In this system the two shiftable components L_2', L_3' of the varifocal group I' are both negative while the stationary (or substantially stationary) components L_1' and L_4' are positive, e.g. as shown in commonly owned U.S. Pat. No. 3,273,457, 3,442,573 or 3,457,003. Guide tracks S_1' and S_2' are shaped generally similarly to tracks S_1 and S_2 of FIG. **1**. The maximum strokes of components L_2' and L_3' are about 60 and 32 mm, respectively. Again, an extreme macro position beyond the wide-angle end of the normal range N could be skipped, with or without inversion of the extended range W as described above.

The displacement of the shiftable components in the manner illustrated in FIGS. **1** and **2** could also be brought about automatically with digital control, e.g. as described in commonly owned U.S. Pat. No. 4,008,951. The law of displacement may be prerecorded on a data carrier such as a glass rod or a perforated tape. With manual control, the various operating ranges N, W and T could be indicated to the user by distinctive coloring, for example; a control member such as sleeve **21** could be indexable at the boundaries of these several ranges, e.g. by means of a ball check, to alert the user to the need for emplacing or removing a supplemental lens.

The supplemental lenses L_{10}, L_{11} or L_{10}', L_{11}' may be given an aspherical curvature for improved optical performance.

Whereas focusing upon objects at distances closer than infinity is accomplished in the normal range N by the axial displacement of front lens L_1 or L_1', such focusing can be carried out in the two extended ranges W and T by a shifting of either or both components L_2, L_3 or L_2', L_3' in a manner moving the image plane BE out of its normal position.

We claim:

1. In an optical objective of adjustable overall focal length, with a lens assembly including two axially shiftable components and control means coupled with said shiftable components for concurrently displacing same to vary said overall focal length between a lower value and an upper value defining a wide-angle end and a telephoto end of a normal varifocal range,

the combination therewith of supplemental lens means positionable in front of said lens assembly upon arrival at a limit of said normal range, said control means being operable to establish an adjoining ancillary range by axially displacing both said shiftable components in the presence of said supplemental lens means to increase the ratio of maximum and minimum overall focal lengths beyond the ratio of said upper and lower values, with maintenance of a fixed image plane throughout both said normal range and said ancillary range;

said supplemental lens means including negative lens means and positive lens means alternatively positionable in front of said lens assembly at said wide-angle end and at said telephoto end, respectively, said shiftable components being concurrently displaceable by said control means to establish an ancillary wide-angle range in the presence of said negative lens means and an ancillary telephoto range in the presence of said positive lens means.

2. The combination defined in claim **1** wherein at least one of said shiftable components is displaceable by said control means in a zone between said normal range and said wide range ancillary range to focus said lens assembly upon objects in a macro range.

3. The combination defined in claim **1** wherein said lens assembly includes a variable four-component front group and a fixed rear group, said shiftable components being a second and a third component of said front group.

4. The combination defined in claim 3 wherein said front group includes a first component shiftable independently of said second and third components, further comprising focusing means coupled with said first component for displacing same.

5. The combination defined in claim 3 wherein said control means comprises a camming sleeve with guide tracks for said second and third components, the guide track for said second component having a constant slope in said normal range and a different constant slope in said ancillary telephoto range.

6. The combination defined in claim 5 wherein the guide track for said second component has slopes of opposite sign in said normal and ancillary wide-angle ranges and has infinite slope in an intervening range.

7. In an optical objective of adjustable overall focal length, comprising a lens assembly which includes a fixed rear group and a variable four-component front group with axially shiftable second and third components, said assembly being provided with control means coupled with said shiftable components for concurrently displacing same to vary said overall focal length between a lower value and an upper value defining a wide-angle end and a telephoto end of a normal varifocal range,

the combination therewith of supplemental lens means positionable in front of said lens assembly upon arrival at a limit of said normal range, said control means being operable to establish an adjoining ancillary range by axially displacing both said shiftable components in the presence of said supplemental lens means to increase the ratio of maximum and minimum overall focal lengths beyond the ratio of said upper and lower values, with maintenance of a fixed image plane throughout both said normal range and said ancillary range;

said control means comprising a camming sleeve with guide tracks for said second and third components, the guide track for said second component having constant slopes of the same sign but different magnitudes in said normal and ancillary ranges and having a slope of opposite sign in an intervening range.

8. The combination defined in claim 7 wherein said ancillary range is separated by said intervening range from the telephoto end of said normal range.

[57] **ABSTRACT**

A retrofocus type lens having an angle of view at least 75° and F number 1:2.0. The lens includes a first lens group of a divergent type, a second lens group of a convergent type and a third lens group of a convergent type. The first lens group includes in the order stated a positive meniscus lens, a negative meniscus lens, a positive meniscus lens and a negative meniscus lens. The second lens group includes a positive lens which is either a single lens or consists of a positive lens and a negative lens cemented to each other and with a front convex face directed toward an object to be photographed. The third lens group includes a positive lens having a rear convex face directed toward an image of the object, a biconcave lens with its front surface radius smaller than its rear surface radius, a positive meniscus lens with a convex surface facing the image and a positive lens. The biconcave lens and the positive meniscus lens are respectively replaceable with cemented doublet lenses. The lens system is characterized in that the first lens group includes meniscus lenses arranged in the order of positive, negative, positive and negative lenses, and particularly in that the third positive meniscus lens serves effectively to correct chromatic distortion aberration and chromatic coma aberration.

RETROFOCUS TYPE WIDE-ANGLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

This invention relates to a large-aperture, wide-angle photographic lens and particularly to a lens system having a short total length.

A strong desire on the part of users of single lens reflex cameras has recently prompted attempts to construct wide-angle or ultra-wide-angle lenses which are more compact and yet have larger apertures than hitherto available Wide-angle lenses for single lens reflex cameras generally utilize a so called retrofocus arrangement. A characteristic of this type of photographic lens is that the symmetry of the lens is impaired when the lens permits a long back focal distance. This makes it difficult to correct aberrations in such lenses. The difficulty tends to increase as the lens construction incorporates a wider angle of view, a larger aperture and a smaller size.

The most difficult problem in reducing the size of a retrofocus type wide-angle lens lies in correcting the distortion in the divergent lens group at the object end of the lens. Such aberration can be effectively corrected by including a positive lens in the divergent lens group. The typical lens arrangements in such a divergent lens group include the following two: In one lens arrangement, a negative lens is disposed at the object end of the lens arrangement and a positive lens positioned behind the negative lens. In the other lens arrangement, a positive lens is disposed in one position and a negative lens arranged behind the positive lens. Because the incident height and the incident angle of light rays relative to the optical axis of the positive lens that acts to correct distortion are great, the corrective action can be made more effectively with a positive lens disposed on the object end. Hence the positive lens disposed at the object end avoids one problem, namely that the total length can not be shortened for effective correction of aberration. However, such a lens arrangement has the following disadvantages: The rays of light outside of an optical axis are excessively bent by the positive lens at the object end. This tends to increase astigmatism, comatic aberration, chromatic distortion aberration or chromatic coma aberration. Moreover, because it is necessary to increase the diameter of the first lens in view of the excessive inward bending of the rays of light, the front lens diameter tends to become greater than other lenses of the same angle of view.

An example of a retrofocus type lens with a positive lens disposed at the object end is disclosed in U.S. Pat. No. 3,877,795. Such a known lens arrangement, however, requires a plurality of negative meniscus lenses behind a positive meniscus lens. Further, the positive lens to be disposed next to the negative meniscus lenses is either a biconvex lens or a positive meniscus lens directing its convexed face toward an image of the object being photographed.

SUMMARY OF THE INVENTION

It is an object of this invention to provide a retrofocus type lens system having a wider angie of view with a larger aperture.

It is another object of this invention to provide a retrofocus type lens system which prevents the diameter of a lens on the object end of the lens system from increasing and which corrects various aberrations in spite of the shortness of its total length.

In accordance with this invention, a retrofocus type lens comprises a negative first lens group at the object end thereof, a positive second lens group and a positive third lens group. From the object end, the first lens group is composed of a positive meniscus lens with a convex surface facing the object to be photographed, then a negative meniscus lens with a convex surface facing the object, then a positive meniscus lens with a convex surface directed toward the object and then a negative meniscus lens with a convex face to the object. The second lens group is either composed of a positive cemented doublet lens consisting of a positive lens and a negative lens or is composed of a positive single lens. The third lens group is composed of seven lenses in the order of a positive lens having a face of a greater curvature on the object side, either a positive-and-negative cemented biconcave lens having a face of a greater curvature directed to an image of the object being photographed or a single biconcave lens, and either a positive-and-negative cemented positive meniscus lens having a convex face on the image end or a single positive meniscus lens and a positive lens. A diaphragm is disposed between the second and third lens groups.

According to a feature of the invention the first lens group is composed of a positive lens, a negative lens, another positive lens and another negative lens, each of these lenses being a single lens and each of them being in a meniscus shape with a convex surface of each facing the object end of the lens system. The first lens group is particularly characterized by the employment of a meniscus lens as the positive lens arranged third from the front to ensure effective correction of chromatic distortion aberration and chromatic coma aberration. It is another feature of the invention that, in the third lens group, an air lens is interposed in between the positive first lens and the biconcave second lens. The air lens has a negative meniscus shape with a convex surface facing an image of the object being photographed to ensure effective correction of spherical aberration and various aberrations that take place outside of the optical axis. The whole lens system may be either composed of single lenses only, as hereinafter will be shown as embodiment example in FIG. 7, or may be formed using cemented doublet lenses as will also be shown as other examples.

The above and further objects and novel features of the invention will more fully appear from the following detailed description taken in connection with the accompanying drawings in which:

BRIEF DESCRIPTION OF THE DRAWING

FIG. 7 is a sectional view showing a lens system representing embodiment Example 4 of the invention.

FIGS. 8A–8D are illustrations showing various aberrations of Example 4.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

The lens arrangement of the invention as already described in the foregoing permits increase in lens aperture and reduction in lens size. For improved performance, however, it is preferable to add the following conditions to the lens arrangement already described:

(1) $0.8f < |fI| < 1.5f$—provided that $fI < 0$
(2) $1.5f < |fI, II| < 6.0f$—provided that FI, II, < 0
(3) $f1 > f3$
(4) $|f2| > |f4|$—provided that $f2 < 0$ and $f4 < 0$
(5) $\nu 1 > \nu 3$
(6) $0.32f < DII < 0.72f$

In the above conditions,

f: Focal length of the total lens system
FI: Focal length of the first lens group
FI, II: Focal length of the first and second lens groups
f1: Focal length of the positive meniscus lens of the first lens group.
f2: Focal length of the negative meniscus lens of the first lens group disposed in the 2nd place from the front of the first lens group.
f3: Focal length of the positive meniscus lens of the first lens group disposed in 3rd place from the front of the first lens group
f4: Focal length of the negative meniscus lens of the first lens group disposed in 4th place from the front of the first lens group.
$\nu 1$: Abbe number of the positive meniscus lens of the first lens group disposed in 1st place in the first lens group
$\nu 3$: Abbe number of the positive meniscus lens of the first lens group disposed in 3rd place in the first lens group
DII: Lens thickness on the axis of the positive lens of the second lens group

Of the above conditions, the conditions (1) and (2) determine the allocation of the basic refracting power of the lens system of the present invention. The condition (1) is necessary for ensuring a sufficient long back focal length for a lens usable in a single lens reflex camera and is required for keeping the front lens diameter small. If the upper limit value of this formula $0.8f < |fI| < 1.5f$ is exceeded, it would be difficult to obtain a sufficiently long back focal length and to hold the front lens diameter to a small value. On the other hand, if the lower limit value is further lowered, the positive spherical aberration including the high aberration which takes place at the first lens group increases. This makes it difficult to have a large lens aperture.

Conditions (2) is required for keeping the front lens diameter small by making the refracting power of the lens portions from the first lens face to the diaphragm relatively strong and divergent. If the upper limit value of the condition $1.5f < |fI, II| < 6$ is exceeded, the front lens diameter tends to increase. On the other hand, if the lower limit value of the condition is not reached, the positive refracting power of the third lens group must be made stronger. The stronger positive refracting power results in an increase in the negative spherical aberration in the third lens group and this makes a large lens aperture difficult.

It is a novel feature of the present invention that the first lens group is composed of, as already mentioned in the foregoing, a positive lens, a negative lens, another positive lens and another negative lens each having a meniscus shape and, in addition to that, the conditions (3) and (4) are applied to the lens arrangement under the condition (1). In other words, the rays of light impinging upon the first lens group outside of the optical axis are refracted by each lens and their incident height is gradually lowered. The refracting power is arranged to increase as the incident height gradually decreases in such a manner as to correct distortion by naturally refracting the rays of light outside of the optical axis. This arrangement ensures satisfactory correction of the various aberrations which take place outside of the optical axis. Thus, with these conditions satisfied, improvement can be effectively attained in the correction of astigmatism and comatic aberration.

The condition (5) is required for lessening chromatic distoration aberration and chromatic coma distortion at the positive lenses disposed in the first lens group. The condition defines the Abbe number of the positive third lens from the front and at which the incident height incident angle of off-axial rays is smaller than those of the positive lens disposed in the first place. Because of the smaller Abbe number in condition (5), chromatic aberration on the optical axis and magnification chromatic aberration are corrected for improvement in the correction of chromatic distortion aberration and chromatic coma aberration. Also, because the positive third lens from the front is formed into a meniscus shape, chromatic distortion aberration and chromatic coma aberration occur to a relatively lesser degree at this lens even when a glass material of high dispersion (or a small Abbe number) is used for this lens.

In accordance with the condition (6), the lens thickness of the positive lens of the second lens group is made relatively thick. This arrangement makes it possible to satisfactorily correct curvature of field and astigmatism. If the lower limit value of the condition $0.32f < DII < 0.72f$ is not reached, the curvature of field and astigmatism increase while, if the upper limit value thereof is exceeded, the front lens diameter tends to increase. Therefore, deviation from this condition is not desirable.

Further, for higher performance of the lens system, it is preferable to impose the following conditions upon the third lens group:

(7) $0.75 < (Ra/Rb) < 0.95$
(8) $0.7f < |Ra| < 1.2f$—provided that $Ra < 0$, i.e. convex face is directed toward the object.
(9) $1.7 < \overline{NIII}$

In the above conditions

Ra: Radius of curvature of the face on the object side of the positive lens disposed in the 1st place in the third lens group
Rb: Radius of curvature of the face on the object side of the biconcave lens of the third lens group
NIII: Mean value of refractive indexes of the materials of all positive lenses included in the third lens group

It is a novel feature of the third lens group that, with lenses arranged in order of positive lens, negative lens, positive lens and another positive lens, the aforementioned conditions (7) and (8) are imposed upon an air lens interposed between the first positive lens and the negative lens next disposed in such a way as to give the air lens a positive refracting power. The air lens is formed into a relatively strong meniscus shape with its convexed side disposed toward the image end. This arrangement makes it possible to obtain satisfactory

conditions in terms of spherical aberration and various aberrations that take place outside of the optical axis.

The condition (7) defines a range of the ratios of radius of curvature of one side to the other of the air lens. If the lower limit value of the condition $0.75<(-Ra/Rb)<0.95$ not reach, the spherical aberration tends to be insufficiently corrected while the comatic aberration tends to be excessively corrected when the air lens is formed in a strong miniscus shape. On the other hand, if the upper limit value of the condition (7) is exceeded, the reverse tendency arises. In both cases, deviation from condition (7) makes it difficult to achieve a lens system with a large aperture.

Condition (8) is required so that the radius of curvature of the front of the air lens lies within the optimum range for correction of aberrations under the condition (7). If the lower limit value of the condition (8) $0.7f<|Ra|<1.2f$ is not exceeded, a negative high spherical aberration would take place in this part. This is not desirable. Then, if the upper limit value of this condition is exceeded, correction of comatic aberrations would become insufficient. Hence deviation from the condition (8) is disadvantageous for correction of curvature of field and astigmatism.

Condition (9) is required to make the refracting power of the positive lenses in the third lens group relatively high for reducing the spherical aberration and the curvature of field in the third lens group. Deviation from this condition is disadvantageous for satisfactory correction of spherical aberration and the curvature of field. Also, the value of $\overline{NIII}$ is normally less than 1.9. Examples of preferred embodiments the present invention are given in the following values. In Example 1, $f=24$, $F1=2.0$ and $\omega=42°$. In Example 2, $f=28$, $F1=2.0$ and $\omega=37.5°$. In Example 3, $f=24$, $F1=2.0$ and $\omega=42°$. In Example 4, $f=28$, $F1=2.0$ and $\omega=37.5°$. In these examples, the values are converted into $f=1$; R represents radius of curvature; D represents spacing between lenses; Nd represents a refractive index for a ray d; and νd represents an Abbe number for the ray d.

Moreoever, for the purpose of preventing degradation of images of nearby objects, the following examples of embodiments employ a method of correcting aberrations by expanding the distance between faces R6 and R7 when the whole lens system is drawn out forward for focusing on such objects.

What is claimed is:

1. A retrofocus type wide-angle objective lens comprising:

a divergent first lens group including in the indicated order a first positive meniscus lens having a convex face directed toward an object to be photographed, a second negative meniscus lens having a convex face directed toward the object, a third positive meniscus lens having a convex face directed toward the object and a fourth negative meniscus lens also having a convex face directed toward the object;

a convergent second lens group behind the first lens group and coaxial therewith and including a positive lens having a convex front lens face directed toward the object;

a convergent third lens group behind the second lens group and coaxial therewith and including in the indicated order a positive lens having a convex rear lens face directed toward an image of the object being photographed, a biconcave lens, a positive meniscus lens directing a convexed face to the image and a positive lens; and

a diaphragm disposed between the second and third lens groups.

2. A wide-angle objective lens according to claim 1, wherein the positive lens of said second lens group includes positive and negative lenses cemented to each other.

3. A wide-angle objective lens according to claim 1, wherein the biconcave lens of said third lens group includes positive and negative lenses cemented to each other.

4. A wide-angle objective lens according to claim 1, wherein the positive meniscus lens of said third lens group includes positive and negative lenses cemented to each other.

5. A lens as in claim 1, wherein the distance between the third positive meniscus lens and the fourth negative meniscus lens changes during focusing.

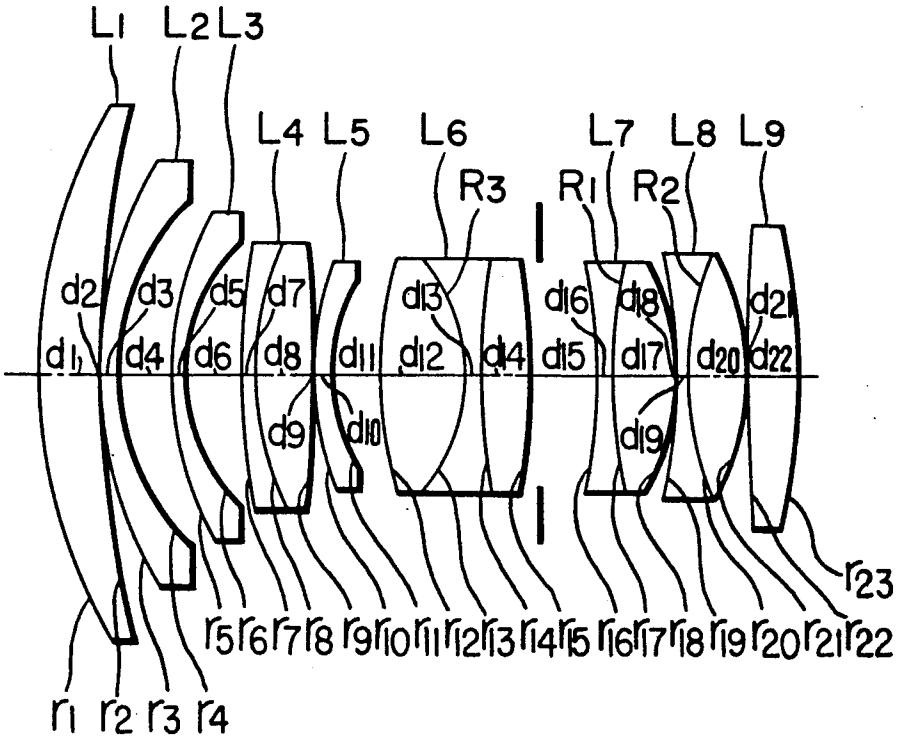

FIG. 1

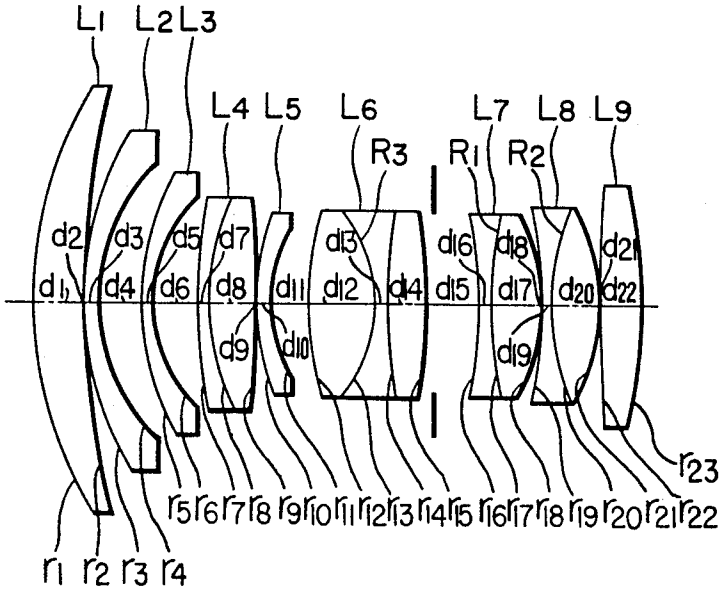

FIG. 2A

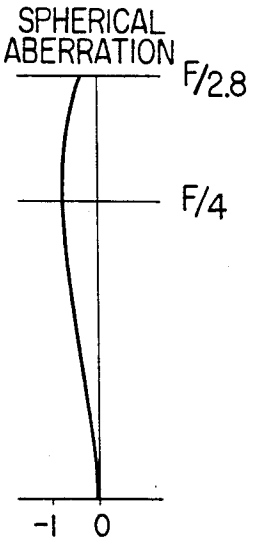

FIG. 2B

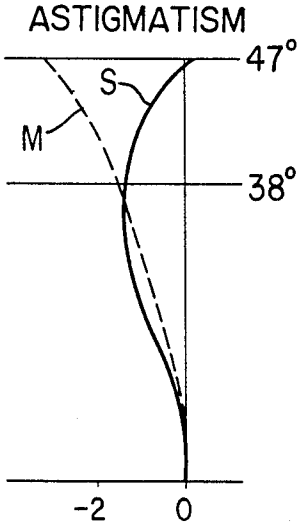

FIG. 2C

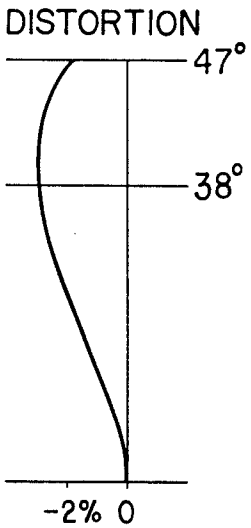

WIDE-ANGLE PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to an inverted telephoto lens type or a retrofocus type wide-angle photographic objective.

2. Description of the Prior Art

In single lens reflex cameras there is a demand for lenses of small size and of camera bodies which are compact. Nevertheless, it has also become desirable to increase the relative aperture while covering a wider angle of view in order to increase the versatility of the photographic objectives. The attainment of such lenses has been difficult because of the problems encountered in the correction of the aberrations.

SUMMARY OF THE INVENTION

The primary object of the present invention is to provide a wide-angle photographic objective which affords small size coupled with large relative aperture, wide angle of view and good correction of the aberrations.

The wide-angle photographic objective according to the present invention is small in size while having an angle of view of 94° and a relative aperture of 1:2.8. More particularly, for use as the objective for a 35 mm single lens reflex camera, the filter diameter of the forward lens may be even smaller, on the order of 52 mm.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 illustrates a lens construction according to the invention;

FIGS. 2A, 2B and 2C are graphs illustrating the spherical aberration, astigmatism and distortion of the third embodiment of the invention, the values of the various aberrations being for an objective where f=100 mm.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The wide-angle photographic objective as shown in FIG. 1 comprises nine components. In the order from the object side, the objective comprises a first component L1 which is a positive meniscus lens convex to the object side, a second component L2 which is a negative meniscus lens convex to the object side, a third component L3 which is a negative meniscus lens also convex to the object side, a fourth component L4 which is a positive lens, a fifth component L5 which is a negative meniscus lens convex to the object side, a sixth component L6 which is a positive lens, a seventh component L7 which is a meniscus lens convex to the image side and comprising a biconcave lens and a biconvex cemented together, an eighth component L8 which is a meniscus lens also convex to the image side and comprising a biconcave lens and a biconvex lens cemented together, and a ninth component L9 which is a positive lens. Adjacent components are disposed with a predetermined air space therebetween, and a diaphragm is disposed between the sixth component L6 and the seventh component L7. The significant features of the photographic objective of the invention reside in the lens components subsequent to the diaphragm, particularly the seventh component which is a meniscus lens convex to the image side and comprising a concave and a convex lens cemented together, and the eighth component which is a meniscus lens similar in construction to the seventh component.

In greater detail and in accordance with the preferred form of the invention, when the curvature radius of that surface of a certain one of the lens components which faces the object side is Rf and the curvature radius of that surface of the same component which faces the image side is Rr, the shape factor (SF), if introduced as a value representing the shape of such lens component, is defined as $SF=(R_r+R_f)/(R_r-R_f)$. For the seventh and the eighth component each comprising a concave and a convex lens cemented together, let SF_1 and SF_2 designate the shape values, respectively, let N_{1n} and N_{2n} designate the refractive indices of the glass materials of the concave lenses forming the respective two components, and let N_{1p} and N_{2p} designate the refractive indices of the glass materials of the biconvex lenses forming the respective two components. Also, let R_1 and R_2 designate the curvature radii of the cemented surfaces of the respective two lens components, and f the total focal length of the entire system.

Then, these significant features or conditions may be expressed as follows:

$$-5.0<SF_1<-2.5 \quad (1)$$

$$-3.5<SF_2<-1.3 \quad (2)$$

$$N_{1n}>N_{1p} \quad (3)$$

$$0.7f<R_1 \quad (4)$$

$$N_{2n}>N_{2p} \quad (5)$$

$$0.6f<R_2<2f \quad (6)$$

Usually, reduction in size of a lens system necessarily results in the aggravation of various aberrations. However, by adopting a lens construction which includes the above-described conditions in the portion subsequent to the diaphragm space, it is now possible to adequately correct the various aberrations created in the portion of the lens system disposed forwardly of the diaphragm and to arrange the forward lens group more compactly than has heretofore been accomplished.

Each of the aforementioned conditions will hereinafter be discussed in detail. Conditions (1) and (2) define the shapes of the seventh component L7 and the eighth component L8 each comprising a doublet. Outside the ranges of these conditions, coma will be aggravated to induce curvature of the image plane; also, unbalanced coma will result from the image height. If the upper limits of these conditions are exceeded, distortion will be under-corrected, and while this might be corrected by increasing the center thickness or the air space of a particular lens component without affecting the other aberrations, the result is loss of compactness for the lens system.

Conditions (3) and (4) define the refractive indices of the glass materials on the opposite sides of the cemented surface of the seventh component L7 and the radius of curvature of this cemented surface. Condition (3) is essential because to depart therefrom will cause coma to be aggravated. It is usually the tendency of a cemented surface that as the difference in its refractive index is greater, the curvature radius of the cemented surface is greater to make the aberrations easier to correct. If selection of a glass material having a great difference in

refractive index is allowed for the cemented surface of this component, it will be possible to provide a construction in which the curvature radius is infinitely great. On the other hand, if the difference in refractive index is small, the curvature radius of the cemented surface must be small.

Conditions (5) and (6) are similar in significance to conditions (3) and (4) but concerned with the eighth component L8 which comprises a doublet. Condition (5), like condition (3), also is essential in order that the cemented surface of this component may be effective. The above-described relationship between the cemented surface and the refractive indices holds true in this case as well. This component greatly affects coma and distortion in particular and plays an important role in the correction of these aberrations, imposing even stricter conditions than the seventh component. If the lower limit of condition (6) is exceeded, coma will be aggravated while distortion will be over-corrected. If the upper limit of this condition is exceeded, the symmetry of coma will be destroyed and distortion will be under-corrected. In any case, these aberrations may not be maintained well corrected by any other component.

By satisfying the above-described construction and conditions, there is achieved a wide-angle photographic objective having an angle of view of 94° and a relative aperture 1:2.8 and yet smaller in size than heretofore.

In a wide-angle photographic objective according to the present invention, it is further preferred that the following conditions be satisfied to enable the correction of aberrations in the entire system to be accomplished with greater ease. More specifically, the sixth component L6 is a triplet lens comprising, in the order from the object side, a positive lens, a negative lens and a positive lens. Preferably, the following conditions are satisfied:

$$N_{3p} > N_{3n} \quad (7)$$

$$-0.4f < R_3 < -0.8f \quad (8),$$

where N_{3p} represents the refractive index of the glass material forming the positive lens nearer the object side, N_{3n} the refractive index of the glass material forming the negative lens, and R_3 the curvature radius of the cemented surface of these two lenses.

Condition (7) is desirable to make the role of this component more effective, and condition (8) is particularly effective to correct spherical aberration and coma under the restriction of condition (7). Outside condition (8), spherical aberration cannot be maintained well and asymmetry of coma will be created. Of the two cemented surfaces of this component, the one between the positive lens nearer the image side and the negative lens is intended only for the correction of chromatic aberration and will be unnecessary if chromatic aberration can be sufficiently corrected by substituting a doublet for one of any other component.

The lens system of the invention enables the correction of aberration for close-up photography. This is accomplished by causing the lens groups behind the diaphragm to be moved as a unit in a direction to reduce the diaphragm space when the entire lens system is moved axially in accordance with a desired photographing magnification, thereby correcting for the curvature of the image plane during the short distance photography.

Numerical data of some embodiments of the present invention will be shown below, with the understanding that $r_1, r_2, r_3, \ldots, r_{23}$ represent the curvature radii of the successive lens surfaces in the order from the object side, $d_1, d_2, d_3, \ldots, d_{22}$ represent the center thicknesses or the air spaces between the respective lenses, $nd_1, nd_2, nd_3, \ldots, nd_{14}$ represent the refractive indices of the glass materials forming the respective lenses, and $\nu d_1, \nu d_2, \nu d_3, \ldots, \nu d_{14}$ represent the Abbe numbers of such glass materials.

The lens construction of each embodiment has been described previously and typically may be represented by the lens construction of the first embodiment which is shown in FIG. 1. To illustrate the aberrations in the wide-angle photographic objective of the present invention, FIGS. 2A, 2B and 2C illustrate the various aberrations for the third embodiment. It will be seen that the photographic objective of the present invention is small in size while having an angle of view of 94° and a relative aperture of 1:2.8 and yet maintains good conditions of aberrations.

It is believed that the advantages and improved results afforded by the wide angle photographic objectives of the invention will be apparent from the foregoing detailed description of preferred embodiments thereof. Various modifications and changes may be made without departing from the spirit and scope of the invention as sought to be defined in the following claims.

I claim:

1. A wide-angle photographic objective comprising, in the order from the object side:
- a first component which is a positive meniscus lens convex to the object side;
- a second component which is a negative meniscus lens convex to the object side;
- a third component which is a negative meniscus lens convex to the object side;
- a fourth component which is a positive lens;
- a fifth component which is a negative meniscus lens convex to the object side;
- a sixth component which is a positive lens;
- a seventh component which is a meniscus lens convex to the image side and comprising a biconcave lens and a biconvex lens cemented together;
- an eighth component which is a meniscus lens convex to the image side and comprising a biconcave lens and a biconvex lens cemented together; and

a ninth component which is a positive lens.

2. A wide-angle photographic objective according to claim 1, wherein said sixth component has at least one cemented surface of a positive and a negative lens, said cemented surface being convex to the image side.

3. A wide-angle photographicobjective according to claim 1, wherein the numerical values of the radii r_1 to r_{23} and of the thickness and separations d_1 to d_{22}, the refractive indices nd and the Abbe numbers νd of the respective components are substantially as follows:

Total focal length f=100mm Relative aperature 1:2.8
Angle of view $2\omega = 94°$

r_1=	170.588	d_1=	18.63	nd_1=1.60327	νd_1=60.7

r_{23}=	−177.897				

6. In a wide-angle photographic objective comprising a diaphragm, a front lens group positioned at the object side and a rear lens group positioned at the image side, the diaphragm being interposed between said lens groups, the improvement wherein the front lens group comprises a positive meniscus component having its surface convex to the object side, at least two negative meniscus lens components having their surfaces convex to the object side and at least one positive lens component, and wherein the rear lens group consists of, in the order from the object side, two meniscus lens components each having their surfaces convex to the image side and comprising a biconcave and a biconvex lens cemented together, and one position lens component.

7. A wide-angle photographic objective according to claim 6, wherein the front lens group comprises, in the order from the object side:

a first component which is a positive meniscus lens convex to the object side;

a second component which is a negative meniscus lens convex to the object side;
a third component which is a negative meniscus lens convex to the object side;
a fourth component which is a positive lens;
a fifth component which is a negative meniscus lens convex to the object side; and
a sixth component which is a positive lens.

8. A wide-angle photographic objective according to claim 7, wherein in the rear lens group said meniscus lens components each having their surfaces convex to the image side and comprising a biconcave lens and a biconvex lens cemented together constitute the seventh and eighth components; and the positive lens constitutes the ninth component.

[57] **ABSTRACT**

A viewfinder system of a photographic or cinematographic camera, provided with a varifocal objective, is illuminated by light deviators including a fully reflective mirror intercepting part of the light rays passing from the fourth to the final component of the objective. The mirror has a body of dark-stained glass, designed to prevent spurious reflections at the edges, and is coated on its front surface with a reflective layer produced by vapor deposition.

LIGHT-RAY DEVIATOR FOR CAMERA OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a photographic or cinematographic camera equipped with a viewfinder system of the type wherein some of the light rays traversing certain lens members of the main objective are deviated to an eyepiece of the finder.

BACKGROUND OF THE INVENTION

The deviation of some of the incident rays for viewfinding purposes can be carried out either by a semitransparent reflector intercepting the entire beam, as formed for example by a pair of cemented prisms, or by a small fully reflective mirror interposed in the path of only some of the rays. The latter solution is often preferred for economic reasons.

Conventional mirrors of the fully reflective type have lateral edges which, on being struck at a glancing angle by incident rays not directly intercepted, may give rise to objectionable reflections. To avoid this problem, it has been customary to blacken the mirror edges by coating them with a lacquer or the like.

OBJECT OF THE INVENTION

The object of my present invention is to provide an improved mirror for the purpose set forth which need not be subjected to such a blackening procedure.

SUMMARY OF THE INVENTION

I have found, in accordance with the present invention, that disturbing reflections from the lateral edges of an interposed mirror can be avoided if the body of that mirror is made of dark-stained glass. The front surface of this body, facing the incident rays, is covered by a fully reflective layer which may be applied thereto by vapor deposition, for example.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of the invention will now be described in detail with reference to the accompanying drawing the sole FIGURE of which diagrammatically shows a camera objective equipped with a viewfinder system according to my invention.

SPECIFIC DESCRIPTION

The objective shown in the drawing is of a conventional zoom type with a varifocal front group **1–4** and a fixed-focus rear or relay group **5** whose several lenses have not been illusrated individually. The varifocal group consists of a positive front component **1**, two negative and axially shiftable intermediate components **2, 3** and a stationary positive component **4**, all represented diagrammatically by single lenses. The optical axis of the objective has been indicated at **0**.

In accordance with my invention, a part of the incoming beam is diverted in a direction generally perpendicular to axis **0** by a reflector **6** comprising a prismatic body **7** of dark-stained glass coated with a reflecting layer **8** on its forward surface confronting the incident rays. Mirror **6**, which may be disposed just ahead of a nonillustrated iris diaphragm, is entirely located on one side of axis **0** so as to intercept only a fraction of the bundle of light rays originating at any point of an object to be photographed. The deflected rays pass through a finder objective **9** and are redirected into an axial position by another mirror **10** so as to traverse a pair of lenses **11, 12**, the latter constituting the eyepiece of the finder. It will be noted than an edge *7a* of mirror body **7** transverse to its reflecting front surface **8** is positioned to intercept some of the incident light rays. The dark color of the body and therefore of edge *7a* prevents the latter from reflecting any of these intercepted light rays.

My improved reflector **6** can be produced at low cost without giving rise to objectionable reflection phenomena within the objective **1–5**.

I claim:

1. In a camera provided with a multilens objective centered on an optical axis, a viewfinder eyepiece offset from said axis, and ray-deviating means for diverting to said eyepiece part of the light traversing said objective, the improvement wherein said ray-deviating means includes a fully reflecting mirror inserted between two lens members of said objective, said mirror having a body of nonreflective dark-stained glass covered with a reflective layer on a surface confronting the incident light rays, said body further having a lateral edge transverse to said surface positioned to intercept some of said light rays but prevented by the dark color of the body from reflecting the intercepted light rays.

2. The improvement defined in claim **1** wherein said mirror is entirely positioned on one side of said axis.

3. The improvement defined in claim **1** or **2** wherein said objective comprises a varifocal front group and a fixed-focus rear group, said mirror being disposed between said groups.

[57] **ABSTRACT**

In order to establish a predetermined position of focusing or focal-length adjustment for an optical objective, a mechanism for the axial shifting of one or more lens members has a lost-motion zone in its operating range in which a continuing displacement of a control element does not change the focal length and/or distance of the objective. The halting of the lens shift (or, possibly, a compensatory displacement of an otherwise stationary lens member) can be brought about mechanically, with the aid of suitably shaped cam tracks, or electromechanically, via analog or binary position sensors. Arrival of the adjusting mechanism in the lost-motion zone may be signaled to the user by a detent, by a change in frictional resistance, or by a visual or acoustical indicator.

ADJUSTING MECHANISM FOR OPTICAL OBJECTIVE WITH LOST-MOTION ZONE

FIELD OF THE INVENTION

Our present invention relates to a mechanism for adjusting an optical objective, for a camera or a projector, by shifting one or more lens members thereof along its optical axis to vary a parameter such as focusing distance or focal length.

BACKGROUND OF THE INVENTION

In conventional objectives, sharp focusing upon an object to be photographed is carried out by shifting or rotating a control element operatively coupled with a movable lens member whereby the latter is axially displaced. This lens member is often a front component of the objective, or part of such component, especially for focusing at normal distances between infinity and the so-called macro range generally defined as lying between the image-ratio limits of 1:10 and 1:1. To facilitate the taking of close-up pictures in this macro range, especially with a pancratic or varifocal objective having two fixed positive components and two movable negative components, one of these movable components (generally the second one) may be shifted while the other is held stationary; see, for example, commonly owned U.S. Pat. application Ser. No. 747,207 filed Dec. 3, 1976 by Walter Besenmatter et al, now U.S. Pat. No. 4,087,160.

With normal front-lens focusing, the usual distance scale engraved on a lens barrel will provide a sufficiently accurate reading inasmuch as—given a tolerable blur circle in the image plane—the objective will have a depth of field allowing minor positional deviations. With focusing in the macro range by the displacement of a more rearwardly located lens member, however, precise setting of that lens member becomes critical since the position of the object plane changes significantly even upon the slightest shifting of that member. To help the user find the proper setting for the taking of pictures in a predetermined object plane, e.g. for producing titles with an amateur motion-picture camera, it has heretofore been the practice to provide stops or detents (e.g. ball checks) indexing the control element in the correct position. The emplacement of the detent on the objective housing, however, involves unavoidable manufacturing tolerances which are difficult to compensate; such arrangements, therefore, are costly and of limited reliability.

Similar problems arise with conventional devices for indexing the shiftable components of a varifocal objective in a preselected position of focal-length adjustment.

OBJECT OF THE INVENTION

The object of our present invention, therefore, is to provide simple means for establishing a desired focusing or focal-length setting in an effortless manner and with a high degree of optical precision.

SUMMARY OF THE INVENTION

We realize this object, in accordance with our present invention, by operatively coupling one or more shiftable lens members with manual or automatic control means therefor via intermittently effective drive means holding the lens member or members stationary throughout at least one lost-motion zone which extends over a fraction of the range of adjustment of the control means.

There are several ways in which this temporary immobilization of a shiftable lens member can be achieved. One possibility is the physical decoupling of that lens member from its control element as it passes through the lost-motion zone; this, however, may allow the decoupled lens member to change its position spontaneously unless means are provided for holding it in place. Another solution would be the use of a special transmission, such as a crank drive or a Geneva gear. Where the shiftable lens member is displaced by an electric motor, its energizing circuit may be temporarily interrupted in response to a signal from an analog-type or digital position sensor, possibly with intervention of a microprocessor.

A particularly simple and advantageous mechanical solution utilizes a stationary or movable cam carrier, having at least one dwell of zero pitch (i.e., an edge portion parallel to the direction of motion), as part of the intermittently affective drive means. Such a cam carrier may be a slotted or grooved cylinder or plate of the type used in conventional varifocal objectives to shift the two movable components independently of each other. In that instance, the cam carrier according to our invention has a first and a second guide track engaged by respective cam followers rigid with the two movable components, these guide tracks having zero-pitch dwells concurrently engaged by their associated cam followers so that both components are held stationary simultaneously. The zero-pitch dwell of one guide track, generally the one for the first movable component, may be substantially longer than the corresponding dwell of the other guide track in order to define a focusing subrange adjoining a varifocal subrange, the zero-pitch dwell of the other guide track being engaged by its cam follower over only a fraction of that focusing subrange to define the lost-motion zone. In some instances we may provide more than one lost-motion zone in this subrange.

According to another feature of our invention, the arrival of the cam carrier in the lost-motion zone is indicated to the user by special position-sensing means preferably of the tactile type, such a coacting indexing formations on the cam carrier and on an adjoining surface (which could be part of the control element). Since the cam carrier may move relatively to the adjoining surface over considerable distance without changing the objective setting, a precise positioning of these indexing formations is no longer required. By the same token, a change in frictional resistance may signal that the desired focusing position (or focal-length setting) has been reached. Visual or audible indicators may also be used, especially with electromechanical control of the lens shift.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 diagrammatically shows a varifocal objective, of well-known type, adjustable in conformity with our invention;

FIG. 2 is a cross-sectional view of the objective, drawn to a larger scale and showing a control ring and a camming sleeve included in its adjusting mechanism;

FIG. 3 is a developed view of the camming sleeve and part of the control ring of FIG. 2;

FIG. 4 is a diagrammatic developed view of a modified adjusting mechanism;

FIGS. 5A and 5B are enlarged detail views of part of the mechanism of FIG. 4 in two different positions;

FIG. 6 is a side-elevational view (parts broken away) of a camera objective embodying our invention;

FIG. 7 is a view similar to FIG. 6, showing a modification;

FIG. 8 is an axial sectional view, drawn to a smaller scale, of a front atachment for the objective of FIG. 7;

FIGS. 9A and 9B show different images appearing in a viewfinder of the camera of FIG. 7 in certain operating positions;

FIG. 10 is a circuit diagram of an electromechanical system for adjusting an objective in accordance with our invention; and

FIG. 11 is a developed view of a modified camming sleeve for the objective of FIG. 1.

SPECIFIC DESCRIPTION

In FIG. 1 we have shown a pancratic objective, generally designated 1, with a varifocal front group consisting of four components I–IV, a component V constituted by a reflex prism P, a diaphragm D, and a fixed-focus rear group VI. The image plane of objective 1 is shown at M.

Front component I is axially fixed and positively refracting, consisting of three lens members L1/L2, L3 and L4. Component II is shiftable along optical axis O and consists of two lens members L5, L6/L7 held in a lens mount 2. Component III is a single lens L8 of negative refractivity held in an axially shiftable lens mount 3. Component IV is an axially fixed positively refracting lens L9. Rear group VI is composed of four single lenses L10, L11, L12 and L13.

For adjustment of the focal length, with maintenance of a constant image plane M, components II and III are separately shifted as is well known per se. With lens L8 in the position L'8 illustrated in dotted lines, the objective shown in FIG. 1 is at the wide-angle end of its varifocal range. A shift of lens L8 into the solid-line position focuses the objective onto nearby objects for the taking of close-ups.

Lens mounts 2 and 3 carry cam-follower pins 5 and 6 which, as shown in FIGS. 2 and 3, traverse respective guide slots 9 and 10 of a camming sleeve 4 rigid with the otherwise non-illustrated objective housing or lens barrel. The pins 5 and 6 further engage in respective slots 25 and 26 of a control ring 7, axially fixed but rotatable about axis 0, for entrainment thereby. Manual rotation of ring 7 is facilitated by a knurled periphery 8.

The guide track 9 for component II has a constant-slope section of angular extent α, defining a varifocal subrange, and an adjoining dwell of zero pitch, i.e. a section located in a plane transverse to the optical axis, of angular extent β defining a focusing subrange (at close-up distances). The guide track 10 for component III is of varying slope throughout the entire range $\alpha+\beta$, except for a short zero-pitch dwell of angular extent γ corresponding to a minor fraction of subrange β. Curve section γ defines a lost-motion zone since neither of these components moves during its engagement with pin 6, the other pin 5 simultaneously engaging the transverse section of curve 9. Thus, rotation of control ring 7 through the angle γ does not cause any change in either the focal length or the position of the object plane of objective 1. This situation is indicated to the user by the engagement of a ball check 11 on sleeve 4 in a notch 12 on ring 7; the angular position of the ball check, within an arc of length γ, is not critical since it does not affect the setting of the objective.

Whereas in FIGS. 2 and 3 the cam member 4 is stationary and the lens mounts 2, 3 rotate about axis 0 during adjustment, the reverse arrangement is possible as illustrated in FIG. 4. Here the two lens mounts are traversed by an axially extending guide rod 13, preventing their rotation, and are provided with extensions 14 and 15 carrying pins 16 and 17 engaging in respective slots 18 and 19 of a transversely shiftable cam plate 20. This plate, provided with a knurled control knob 27 to facilitate its displacement, has a pair of parallel guide slots 21 engaged by fixed pins 23 on the objective housing; any play in these slots is eliminated by the pressure of a ball check 22 and of a leaf spring 28 upon a longitudinal edge of plate 20, ball check 22 engaging in a notch of that edge in the illustrated position which represents the transition between varifocal subrange α and focusing subrange β. Plate 20 is also representative of the developed peripheral surface of an annular cam member, similar to ring 7 of FIGS. 2 and 3, centered on axis 0. Curve 19 has two mutually separated zero-pitch dwells at $\gamma 1$ and $\gamma 2$ within section γ.

Although plate 20 could be provided with two further notches engageable by ball check 22 in the two lost-motion positions, i.e., with pin 17 received in the transverse stretch $\gamma 1$ or $\gamma 2$ of curve 19, we have shown in FIGS. 5A and 5B an alternate way of signaling to the user the arrival of component III in a desired focusing position. Thus, either or both slots 21 may be lined with a friction layer 24 in contact with pin 23 anywhere except along stretch $\gamma 1$ or $\gamma 2$, as seen in FIG. 5A; the manual displacement of plate 20 by the user, therefore, encounters a significant resistance. In the two zero-pitch zones the layer 24 is omitted, as seen in FIG. 5B, so that shifting is noticeably easier (albeit ineffectual). The thickness of layer 24 is taken into account in the shaping of curve 19, the additional play being eliminated by the biasing elements 22 and 28; the precise locations of the gaps of layer 24, however, are not critical for the reason already explained.

In FIG. 6 we have shown a motion-picture camera equipped with a lens-adjusting mechanism according to our invention. The camera body, partly illustrated at 30, carries a lens housing with a rotatable front ring 31 which accommodates an attachment 32 comprising a dispersive lens 33 positionable in front of the varifocal objective 1. A camming sleeve 34 has grooves 38', 38'', with zero-pitch dwells again indicated at γ, engaged by respective follower pins 37', 37'' which are entrainable by horizontal slots in a non-illustrated extension of ring 31. A nonrotatable blocking sleeve 36 is axially slidable on camming sleeve 34 and has a ledge 36*a* which normally is held by a spring 39 against a fixed portion 31*a* of the lens housing, overlying the section γ of curve 38'' and preventing the displacement of the shiftable lens members into the lost-motion zone defined by that section within the focusing subrange β (cf. FIG. 3). A push rod 35 rigid with a lug 36*b* of sleeve 36, engaged by spring 39, projects in that normal position beyond front ring 31 so as to be repressible into its illustrated position by the attachment 32 upon emplacement thereof in line with objective 1. Lens 33 forms a virtual intermediate image of an object in a plane located forwardly (i.e., to the left) of that lens, e.g. in its focal plane if the object is situated at infinity. For an extreme wide-angle or panoramic effect, therefore, the objective 1 can be fo-

cused in its lost-motion position on that forward plane after section γ of curve 38'' has been uncovered by repression of the rod 35 which acts as a feeler for the presence of attachment 32.

FIG. 7 shows a similar arrangement in which, however, the interplay of a front attachment with a focusing control is reversed in that an emplacement of the attachment is possible only after a selector has been preset to permit focusing upon a predetermined object distance at close range. A slider 40, shiftable in a slot 48 of camera body 30, is connected by a linkage 41 with an axially displaceable blocking sleeve 42 having two axially and angularly staggered ledges 46 and 47. In a slider position designated NORMAL, designed for the taking of pictures beyond the macro range, ledge 46 cuts across cam groove 19 (here shown inverted with reference to FIG. 4) just above its dwell γ1 so as to allow focusing in only a part of the macro range. In another slider position, designated TITLE, ledge 46 unblocks the dwell γ1 yet ledge 47 still inhibits the shifting of the movable lens members into the position defined by dwell γ2. The latter position can be attained upon moving the slider 40 into a third position, designated PANORAMA, in which sleeve 42 is fully withdrawn from the path of a cam-follower pin 43 traversing the groove 19. A push rod 45, rigid with a lug 44 of sleeve 42, normally projects beyond front ring 31 so as to prevent the emplacement of any attachment thereon.

Besides the panoramic-lens attachment 32, shown emplaced in FIG. 7, another attachment 50 illustrated in FIG. 8 can be used with this camera. A comparison of the two attachments 32 and 50 (the latter being drawn to a much smaller scale) will show that attachment 50 has an axially extending neck 50*a* whose length substantially exceeds that of a corresponding neck 32*a* of attachment 32. Attachment 50, holding a title carrier 50*b*, can therefore be fitted into front ring 31 in the intermediate position of slider 40 in which the rod 45 projects farther to the left than in the extreme right-hand position of the slider, illustrated in FIG. 7. Thus, the intermediate slider position allows the filming of titles upon entrainment of pin 43 (by rotation of control ring 31) to dwell γ1 whereas the right-hand position permits the taking of panoramic views, with the aid of lens 33, upon further entrainment of the cam follower to dwell γ2.

The position of slider 40 can also be indicated directly to the user by a coupling of linkage 41 with a shutter 51, FIGS. 9A and 9B, located in the light path of a viewfinder of the camera 30. In the intermediate slider position, as shown in FIG. 9A, the shutter obstructs a legend reading PANORAMA but uncovers another legend reading TITLE. In the right-hand slider position, as shown in FIG. 9B, the reverse is the case. In the left-hand slider position labeled NORMAL in FIG. 7, both legends are obscured. The shutter 51 could be mechanically operated but might also be represented by a pair of electro-optical light-control elements such as Kerr cells.

We shall now describe, with reference to FIG. 10, an electromechanical system for establishing a number of lost-motion zones in a range of displacement of an axially shiftable lens mount 1*a* for a component of a focusable objective, e.g. its front member. Lens mount 1*a* is here shown provided with an extension which bears a rack 60 meshing with a pinion 61, the latter being coupled with a reversible electric motor 62 whose energizing circuit includes a pair of batteries 63, two limit switches 65', 65'', a reversing switch 64 and a break contact 66 of a relay 67. A resistance bridge 69 has one arm formed by a potentiometer 68 whose slider is coupled with pinion 61. One bridge diagonal is connected across power supply 63 whereas its other diagonal is connected across the inputs of a differential amplifier 70. From a balanced or nearly balanced state in one limiting position of lens mount 1*a*, bridge 69 is progressively unbalanced upon a shifting of the lens mount to the other end of the adjustment range so as to develop progressively higher voltages in the output of amplifier 70.

Four threshold circuits 71–74, such as Schmitt triggers, are connected in parallel across this amplifier output and work into respective one-shot pulse generators, such as monoflops, 75–78. These trigger stages are connected in parallel, via respective diodes 85–88, to the winding of relay 67 as well as to the base of a transistor 80 shunting the motor 62. Each monoflop, when in its off-normal condition, also energizes a respective visual indicator such as a light-emitting diode 81–84.

With switch 64 in either of its two operative positions, i.e., "forward" (F) or "reverse" (R), motor 62 drives the pinion 61 to change the position of the object plane of the objective within its macro range. At a first predetermined point in that range, the output voltage of amplifier 70 is sufficient to trip the Schmitt trigger 71 whereupon monoflop 75 generates a pulse which actuates the relay 67 to break the motor circuit; the simultaneous saturation of shunt transistor 80 effectively cuts off the motor 62 (and could also operate a nonillustrated brake). The duration of this pulse is long enough to allow the user to open the switch 64 if the system is to remain in that position for an extended period.

In an analogous manner, trigger stages 72, 73 and 74 successively go into action upon the attainment of progressively higher voltage thresholds by the output of amplifier 70. The particular threshold, and therefore the specific stop position, is inidicated to the user by the respective LED 81–84 which could be positioned in line with the viewfinder of the camera. Audible signals could also be produced, if desired, by sound generators in the outputs of monoflaps 75–78. The interruption of the lens shift, taking place while control switch 64 is held closed, may be considered a lost-motion operation.

The four stop positions established by trigger stages 71–74 could be so chosen that the first two lie in the macro range (e.g. at locations defined by the dwell γ1 and γ2 of FIGS. 4 and 7), the third one lies in an intermediate range (e.g. at a distance suitable for snapshots) and the fourth markings focusing at infinity. Furthermore, pinion 61 could be coupled with a control element such as ring 7 (FIGS. 2 and 3) or plate 30 (FIG. 4) to provide varifocal adjustment, as described above, with or without focusing control in the macro range. Also, a digital mode can be substituted for the analog mode of operation described above, with the use of a stepping motor to drive the pinion 61 and with replacement of Schmitt triggers 71–74 by binary pulse counters stepped by the source of driving pulses for that motor. In either instance the stop positions may be preprogrammed with the aid of servo drives for the establishment of selected voltage thresholds or pulse counts.

In FIG. 11 we have illustrated a modified camming member 4' (either a sleeve or a plate) with curves 9' and 10' engaged by respective cam-follower pins 5' and 6', these curves having zero-pitch dwells δ in an intermediate section of varifocal range α. The lost-motion zone defined by these dwells δ may represent a middle posi-

tion of the varifocal group I–IV (FIG. 1) in which the magnification ratio of that group has a value of unity.

The front component I (or its first lens member LI/L2) of a varifocal objective 1 as shown in FIG. 1, whose negative components are shiftable by means of cam drives as described with reference to FIGS. 1–7 and 11, could be conventionally adjustable for focusing at normal range. Such cam drives, however, could also be used (like the electromechanical drive system of FIG. 10) for the intermittent shifting of a front lens or component with stop positions indexed by lost-motion zones.

The position-feeling or emplacement-blocking mechanism of FIGS. 6 and 7 is not part of our invention, except in combination with attachments 32 and 50; such a mechanism has been disclosed and claimed in application Ser. No. 711,835 filed Aug. 5, 1976 by Kurt Bohm et al. and assigned to a company affiliated with the assignee of our present application, now U.S. Pat. No. 4,110,005.

We claim:

1. An optical system comprising:

a varifocal objective including lens means axially shiftable over a predetermined range of displacement including a first subrange for varying the focal length of the objective and a second subrange for varying the position of an object plane thereof;

control means adjustable over a predetermined operating range corresponding to said range of displacement; and

drive means operatively linking said control means with said lens means, said drive means positively connecting said control means with said lens means throughout said operating range except for at least one lost-motion zone coinciding with a predetermined position of said lens means in said second subrange in which said object plane lies at a certain close distance from the objective.

2. The system defined in claim 1 wherein said shiftable lens means comprises a first and a second component respectively displaceable by separate portions of said drive means, said portions being operative to immobilize said first component throughout said second subrange during axial shifting of said lost-motion zone.

3. The system defined in claim 1, further comprising position-sensing means coupled with said control means for indicating the arrival thereof at said lost-motion zone.

4. The system defined in claim 1 wherein said intermittently effective drive means comprises a cam carrier having at least one dwell of zero pitch.

5. The system defined in claim 4 wherein said shiftable lens means comprises a first and a second component, said cam carrier forming a first and a second guide track engaged by respective cam followers on said first and second components, said guide tracks having zero-pitch dwells concurrently engaged by their respective cam followers.

6. The system defined in claim 5 wherein the zero-pitch dwell of said first guide track defines a focusing subrange of said operating range corresponding to said second subrange and adjoining a varifocal subrange of said operating range corresponding to said first subrange, the zero-pitch dwell of said second guide track being engaged by its cam follower over only a fraction of said focusing subrange.

7. The system defined in claim 6 wherein the objective is part of a camera provided with an attachment positionable in front of said objective for the taking of pictures in a position of engagement of said cam followers with said zero-pitch dwells.

8. The system defined in claim 7 wherein the camera is provided with inhibiting means normally blocking a displacement of said control means into said focusing subrange, said inhibiting means being deactivable by said attachment upon emplacement thereof on said camera.

9. The system defined in claim 7 wherein the camera is provided with selector means for optionally blocking and unblocking a displacement of said control means into said focusing subrange, said selector means having an extension preventing the emplacement of said attachment on said camera in a blocking position.

10. The system defined in claim 9 wherein said second guide track has two zero-pitch dwells in a first and a second part of said focusing subrange, the camera being provided with a second attachment emplaceable thereon in said second part of said focusing subrange, said selector means having an intermediate position blocking access to only said second part of said focusing subrange while preventing emplacement of said second attachment only.

11. The system defined in claim 4, further comprising position-sensing means on said cam carrier and on an adjoining surface for indicating the arrival of said control means in said lost-motion zone.

12. The system defined in claim 11 wherein said position-sensing means comprises a pair of indexing formations on said cam carrier and on said adjoining surface.

13. The system defined in claim 11 wherein said position-sensing means comprises a pair of mating formations on said cam carrier and on said adjoining surface, one of said formations being a guide slot, the other of said formations being a projection received in said guide slot, the latter being provided with a friction layer engageable by said projection, said friction layer being omitted at a location corresponding to said lost-motion zone.

14. In an optical objective provided with axially shiftable lens means and with control means for varying an optical parameter of the objective, said control means being operatively coupled with said shiftable lens means for axially displacing same within a predetermined adjustment range,

the improvement wherein the coupling between said control means and said shiftable lens means comprises intermittently effective drive means holding said shiftable lens means stationary throughout at least one lost-motion zone extending over a fraction of said adjustment range, said drive means including a cam carrier having at least one dwell of zero pitch,

further comprising position-sensing means on said cam carrier and on an adjoining surface for indicating the arrival of said control means in said lost-motion zone, said position-sensing means including a pair of mating formations on said cam carrier and on said adjoining surface, one of said formations being a guide slot, the other of said formations being a projection received in said guide slot, the latter being provided with a friction layer engageable by said projection, said friction layer being omitted at a location corresponding to said lost-motion zone.

[57] **ABSTRACT**

The wide angle ophthalmoscopic system disclosed includes an objective lens group having a forward direction toward an eye to be examined and having at least one meniscus lens and a positive lens. The meniscus lens includes a front concave forward surface and constitutes substantially an aplanatic lens having an aplanatic point to be situated in the front part of an eye to be examined. A converging lens group in the system is positioned behind the objective lens group. An illuminating system has at least one light source and light transmitting arrangement for directing light in the forward direction. An observing optical system is optically aligned with the objective lens group for transmitting images formed by the objective lens group.

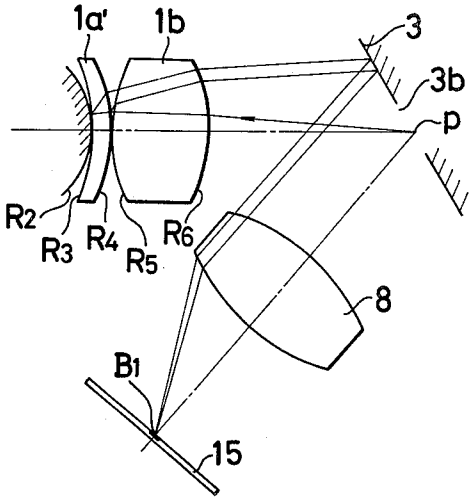

FIG.10

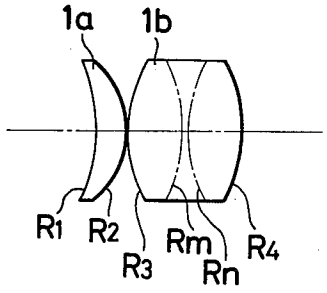

OPHTHALMOSCOPIC SYSTEM WITH A WIDE ANGLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

This invention relates to ophthalmoscopes and ophthalmoscopic cameras, and more particularly to improvements of an objective lens for use in such ophthalmoscope or ophthalmoscopic camera.

Most of the ophthalmoscopic cameras which have found wide acceptance are designed to have an objective lens comprised of a positive meniscus lens convex toward an eye to be examined with limitation of its view angle to about 30 degrees. To increase the image angle up to about 45 degrees, it is known to make use of a biconvex lens as the objective lens. It has also been proposed by the present applicant to construct the objective lens from a positive meniscus lens concave toward an eye to be examined and a positive meniscus lens concave toward an image thereof as described in U.S. Pat. No. 3,914,032.

With the objective lens having an increased view angle, it is desired to reduce astigmatism. Incorporation of an apertured mirror as arranged between the objective lens and an image forming lens to reflect the illuminating light rays from a light source in the direction of the optical axis of the eye leads to a further requirement of increasing the relative aperture of the objective lens, while still minimizing spherical aberration and coma thereof. As the objective lens is positioned in the path of the illuminating light rays, there is some possibility of producing disturbing light reflection due to the light rays reflected from the surfaces of the objective lens to the film plane.

SUMMARY OF THE INVENTION

The present invention has for its general object to provide an ophthalmoscopic system with an objective lens having an increased angle of view without causing production of unduly large aberrations. Whilst the conventional objective lens described in U.S. Pat. No. 3,914,032 has an angle of view not exceeding 45 degrees, two specific embodiments of the present invention to be described later are to provide for view angles of 60 degrees and 80 degrees. According to the present invention, the achievement of such a large increase in the angle of view is realized by designing at least one positive meniscus lens element of concavity toward an eye to be examined in the objective lens to aplanatic configuration, or likewise configuration to an aplanatic lens element. In this connection, it should be noted that the positive meniscus lens shown in U.S. Pat. No. 3,914,032 is designed not so much complicated but to the simple positive meniscus lens configuration known in the art.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic sectional view of one embodiment of an ophthalmoscopic system according to the present invention.

FIGS. **2** and **3** are plan views of an apertured illuminating mirror and a ring-shaped diaphragm usable in the system of FIG. **1**.

FIG. **4** is a fragmentary sectional view of the system of FIG. **1**.

FIG. **5** is a diagram of geometry considered in defining the location of a black spot for freedom from disturbing light reflections according to the prior art.

FIGS. **6** and **7** are similar views showing a method of eliminating the disturbing light reflections from the objective lens according to the present invention.

FIG. **8** is a fragmentary schematic sectional view of another embodiment of an ophthalmoscopic system according to the present invention.

FIG. **9** is a diagram of geometry considered in defining the location of a black spot for freedom from disturbing light reflections from the objective lens of FIG. **8**.

FIG. **10** is a block diagram of the objective lens of the present invention in which the biconvex lens comprises a plurality of elements cemented together.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIGS. **1** to **7** and first to FIG. **1**, there is shown one embodiment of an ophthalmoscopic system according to the present invention including an objective lens group **1** and an image-forming lens group **2** aligned along a common optical axis of an eye E so that an image of the ocular fundus Ef to be examined is either to be formed at a film plane **9** with a tiltable mirror **10** set in its non-viewing position, or to be viewed through a field lens **11**, a reflection mirror **12** and an eye-piece **13**, as the tiltable mirror **10** is set in the illustrated position.

Positioned in an air space between the objective lens group **1** and the image-forming lens group **2** is an illuminating mirror **3** inclined to the optical axis of the eye E and reflecting the illuminating light rays from an illuminating optical arrangement in the direction of the optical axis of the eye E. The illuminating mirror **3** contains a central aperture **3***b* for the passage of image forming rays, in known manner as shown in FIG. **2**, with the remaining area **3***a* being fully mirrored. The illuminating optical arrangement is disposed with its optical axis declined from the optical axis of the eye E and comprises a tungsten lamp **4** as a first light source extending transversely to the optical axis, a condenser lens **5**, a strobotube **6** as a second light source extending transversely to the optical axis, a ring-shaped diaphragm **7** positioned adjacent the strobotube **6** and in conjugate relation to the first light source or tungsten lamp **4** with respect to the condenser lens **5**, and a relay lens **8** arranged so that the ring-shaped diaphragm **7** is conjugate to the apertured illuminating mirror **3** with respect to the relay lens **8**. The details of the ring-shaped diaphragm are shown in FIG. **3**, wherein a central obscuring diaphragm element **7***a* and an apertured diaphragm element **7***c* are concentrically disposed on a single transparent substrate not shown with the resulting opening being of a ring-shape so that an outer annular zone of a pupil Ep of an iris Eq in the eye E is illuminated, as the apertured mirror **3** is almost conjugate to the pupil Ep with respect to the objective lens group **1**. Although the apertured mirror **3** serves as a diaphragm for the image forming rays, a diaphragm may be used as located at **3'**.

The objective lens group **1** comprises a positive meniscus lens **1***a* concave toward the eye E and a biconvex lens **1***b* which may be in the form of a singlet but preferably of a cemented triplet of achromatism. The image-forming lens group **2** comprises a plurality of singlets. According to the present invention, while the front surface R_1 of the positive meniscus lens **1***a* is a spherical

surface with its center of curvature being coincident with the center A of the pupil Ep (see FIG. 4), the rear surface R_2 is configured to an aplanatic surface relative to the center A of the pupil Ep. Letting S denote the axial separation between the pupil center A and a point at which the surface R_2 intersects the optical axis, and S' the axial separation between that point and an aplanatically conjugate point which is designated by B in FIG. 4, then we have $S'/S=n$, wherein n is the index of refraction of the material from which the positive meniscus lens is made. With this lens configuration, there is no spherical aberration and no coma from the front and rear surfaces R_1 and R_2 and also no astigmatism from the rear surface R_2, provided that the object point is located in coincidence with the pupil center A. To facilitate aberrational correction in the extended range of view angles, it is preferred that the rear surface R_4 of the biconvex lens **1***b* is made aspherical as known in the art. For a further increase in the view angle, the both surfaces of the biconvex lens **1***b* are formed to aspherical surfaces.

Another advantage deriving from the employment of the aplanatic lens **1***a* is that, as a ray of light l_1 emanating from the pupil center A is not subjected to refraction at the front surface R_1 and is refracted by the rear surface R_2 as if it emanate from the aplanatically conjugate point B, the angle of inclination of the incident light ray on the front surface R_3 of the biconvex lens can be gradually decreased.

As the objective lens group constitutes part of a photographic optical system with its diaphragm coinciding with the iris Eq, a light ray l_1 passing through the opening of the iris Eq at the center thereof becomes a principal light ray. And a bundle of light rays including ones l_1 and l_2 as marginal rays contributes as a part to the image forming rays which are projected by (image-forming) lens the group **2** onto the film plane **9**. In this case, the front surface R_1 does not produce any coma and astigmatism, because the diaphragm is located at the center of curvature of the front surface R_1. It will be understood from the above that a large increase in the view angle of the ophthalmoscopic system can be achieved by designing the positive meniscus lens **1***a* in the form of an aplanatic lens, or likewise lens having a similar function to that of the aplanatic lens, while nevertheless preserving a high level of aberrational correction over the extended range of view angles.

A specific example of the objective lens group having only one positive meniscus lens as shown in FIG. 4 with a view angle of 60 degrees may be constructed in accordance with the numerical data given in Table 1 below. In the table, the radii of curvature, R, and the axial thicknesses and separations, D, numbered consecutively from front to rear are given along with the corresponding indices of refraction for the spectral D line of sodium and the Abbe numbers for the various lens elements. The minum values of the radii, R, indicate surfaces concave toward front.

Table 1

f = 100 (mm)	2ω = 60° (view angle) F 1 : 1		
R_1 = −96.05			
	D_1 = 24.01	Nd = 1.617	Vd = 62.8
R_2 = −74.19			
	D_2 = 0.1		
R_3 = 124.87			
	D_3 = 124.87	Nd = 1.617	Vd = 62.8
R_4 = −124.87	(aspherical)		

As the objective lens group **1** is illuminated, some of the illuminating light rays are reflected from the lens surfaces in the group **1** to the central hole **3***b* of the illuminating mirror **3** which must be kept free from disturbing incident light as the hole **3***b* serves for the passage of image forming rays. It is known to eliminate disturbing light reflections on the surfaces R_3 and R_4 of the biconvex lens element in the group **1** by making use of a black spot B_1 arranged at a point between the light source and the relay lens **8** coaxially on the optical axis of the illuminating optical arrangement as shown in FIG. **5**. This is also disclosed in U.S. Patent application Ser. No. 658,874 now U.S. Pat. No. 4,098,549 assigned to the assignee of the present invention. The location and size of the black spot B_1 are defined as follows. A light ray emerging from a point P on the plane of the illuminating mirror **3** in the area of the hole **3***b* is either reflected from, or refracted by the rear surface R_4 of the biconvex lens **1***b* to the mirror **3**, or to the front surface R_3 respectively. The reflected ray from the mirror **3** is converged by the relay lens **8**, while the refracted ray after successive reflections from the front surface R_3 and from the mirror **3** is also converged by the same relay lens **8**. The convergence points for the reflected and refracted rays can be brought into coincidence with each other by suitable selection of the radii of curvature of the front and rear surfaces R_3 and R_4 and the axial thickness of the lens **1***b*. In practice, the black spot B_1 may be formed on a transparent plate **14**.

FIG. **6** shows a method of determining the location and size of an additional black spot B_2 for eliminating disturbing light reflections on the rear surface R_2 of the positive meniscus lens **1***a*. In this case, the black spot B_2 is conjugate to the hole **3***b* of the illuminating mirror **3** with respect to a particular optical arrangement consisting of the aplanatic surface R_2, the biconvex lens **1***b*, the reflecting surface **3***a* of the illuminating mirror **3** and the relay lens **8**, as an ideal light ray emerging from the point P is passed through the biconvex lens **1***b* to the aplanatic surface R_2, then reflected therefrom to the biconvex lens **1***b*, then goes after passage therethrough to the mirror surface **3***a* and is then reflected therefrom to the relay lens **8** by which it is converged to the black spot B_2 formed on a transparent plate **15**.

In the case of disturbing light reflections on the front surface R_1 of the positive meniscus lens **1***a*, there is no possibility of its entrance into the hole **3***b* of the illuminating mirror **3**, because, as has been explained in connection with FIGS. **1** and **2**, the center of curvature of the front surface R_1 coincides with the center of the eye-pupil, and the rear surface R_2 is made aplanatic for freedom from aberrations even at wide angles of view. When the front surface R_1 is regarded as a mirror surface, therefore, an ideal light ray emerging from an optional point, q, on the mirror **3** which is conjugate to the eye-pupil is converged to a point symmetrical to the point, q, with respect to the optical axis, as shown in FIG. **7**.

According to the present invention, therefore, the two black spots B_1 and B_2 on the respective transparent plates **14** and **15** are employed as arranged in an air space between the light source **4** and the relay lens **8** and extending transversely to the optical axis of the illuminating optical arrangement as shown in FIG. **4** for the purpose of eliminating disturbing light reflections on the objective lens group **1**.

FIG. **8** shows another embodiment of the present invention in which two positive meniscus lenses **1***a* and

1a' are employed as arranged nearer an eye to be examined than a biconvex lens 1b. These two positive meniscus lenses 1a and 1a' are so configured that the front surface R_1 of the front positive meniscus lens 1a has a center of curvature coincident with the center A of an eye-pupil, and the rear surface R_2 is aplanatic with its aplanatically conjugate point at B, and that the front surface R_3 of the second positive meniscus lens 1a' has a center of curvature coincident with the point B, and the rear surface R_4 is aplanatic with an aplanatically conjugate point to the point B being at C. In other words, the first and second positive meniscus lenses 1a and 1a' form an aplanatic broken-contact doublet to the center of the eye-pupil, so that there is no spherical aberration and no coma for the object point at the pupil center A. Further, the surfaces R_2 and R_4 produce no astigmatism. When this objective lens is used for photography, the surfaces R_1 and R_3 produce no coma and no astigmatism provided that the iris position corresponds to the diaphragm position.

A specific example of the objective lens corresponding to that shown in FIG. 8 may be constructed in accordance with the numerical data given in Table 2 below. The various symbols in the table have the meanings described in connection with Table 1.

Table 2

f = 100 (mm)	2ω = 80°	F 1 : 0.78	
R_1 = −83.54			
	D_1 = 22.28	Nd = 1.617	Vd = 62.8
R_2 = −65.39			
	D_2 = 0.1		
R_3 = −171.39			
	D_3 = 22.28	Nd = 1.617	Vd = 62.8
R_4 = −119.67			
	D_4 = 0.1		
R_5 = 150.38			
	D_5 = 150.38	Nd = 1.617	Vd = 62.8
R_6 = −150.38	(aspherical)		

The disturbing light reflections on the objective lens of FIG. 8 are also possible with two black spotted plates 14 and 15. In other words, those on the surfaces R_5 and R_6 of the biconvex lens 1b are eliminated by the method shown in FIG. 5, and those on the front surfaces R_1 and R_3 of the first and second positive meniscus lenses 1a and 1a' are removed for the reasons explained in connection with FIG. 7. The elimination of those on the rear surfaces R_2 and R_4 will next be explained by reference to FIG. 9.

For the surface R_4, situation is similar to that shown in FIG. 6. On the other hand, a light ray coming from the point P through the biconvex lens 1b and the second positive meniscus lens 1a' is reflected from the surface R_2 and therefrom directed through the second positive meniscus lens 1a' and the biconvex lens 1b to the mirror 3 by which it is reflected to the relay lens, finally reaching a convergence point. This point can be brought into coincidence with that for the surface R_4 at the black spot B_1 by suitable selection of either the axial thickness of the second positive meniscus lens 1a', or the axial air separation between the surfaces R_2 and R_3, or between the surfaces R_4 and R_5. The size of the black spot B_1 is dependent upon an image of the hole 3b formed on the plate 15 by a particular optical system between the illuminating mirror 3 and the black spotted plate 15 in the path of disturbing incident light. As a single black spot is adopted for elimination of reflexes from two separate reflecting surfaces, it is of course required that a larger size of black spot be selected from two different ones.

If the biconvex lens 1b is constructed in the form of a cemented triplet as shown in FIG. 10, disturbing light reflections on the cemented surfaces Rm and Rn must be taken into account. In this case, those on the surface Rm is simultaneously eliminated with those on the surface R_2 in a manner similar to that shown in connection with the surfaces R_3 and R_4 of FIG. 9. The surface Rn may be designed in relation to the surfaces R_3 and R_4 for elimination of reflection. The number of black spots necessary to eliminate disturbing light reflections is equal to that of the lens surfaces in the objective lens group 1 with exclusion of those shown in FIG. 7. As has been noted above, however, this number can be largely reduced not only by suitable selection of the lens thicknesses and/or axial air separations, but also by adjusting the size of each black spot to a somewhat larger level than the theoretical one.

It will be seen from the foregoing that the present invention provides an ophthalmoscopic system with a remarkably increased angle of view without causing production of unduly large aberrations over the extended view angle range. The positive lens located on the image side of the aplanatic lens is formed to biconvex configuration, thereby giving an additional advantage of increasing design flexibility for power distribution and aberrational correction, as both of the entrance and exit surfaces of the eye convex lens act in converging manner. A furthermore advantage of the invention is to facilitate elimination of disturbing light reflections.

What is claimed is:

1. An ophthalmoscopic system provided with a wide angle objective lens comprising;
   - an objective lens group opposed to a human eye and including at least one meniscus lens and positive lens, and said meniscus lens having a front surface concave to the human eye and being substantially an aplanatic lens having an aplanatic point, the aplanatic point being situated in the front part of the human eye;
   - a converging lens group positioned in rear of said objective lens group;
   - an illuminating system having at least one light source and light transmitting means, and the light emergent section of this system being directed toward the human eye; and
   - an observing optical system having said objective lens group and image transmitting means.

2. An ophthalmoscopic system as described in claim 1, wherein said objective lens group consists of a positive meniscus lens and a biconvex lens.

3. An ophthalmoscopic system as described in claim 1, wherein said objective lens group consists of two positive meniscus lenses and a biconvex lens.

4. An ophthalmoscopic system as described in claim 1, wherein said light transmitting means has reflecting means and a plurality of lenses, and said reflecting means is positioned between the human eye and said converging lens group.

5. An ophthalmoscopic system as described in claim 1, wherein said light transmitting means has a mirror and lens means, an aperture stop is arranged between the reflecting plane of the mirror and said converging lens group, and a light obscuring spot is arranged in conjugate relation to the aperture of said stop with respect to said positive lens, the aplanatic surface serv-

ing as a mirror surface, said positive lens, said reflecting plane and lens means.

6. An ophthalmoscopic system provided with a wide angle objective lens comprising;

at least one positive aplanatic meniscus lens concave to a human eye, a biconvex lens arranged adjacent and in rear of said positive meniscus lens, followed by an image forming lens group, and followed by a photographic film;

an apertured mirror arranged between said biconvex lens and said image forming group;

a relay lens and a light-impermeable spot between a photographic light source and the apertured mirror, said light-impermeable spot and the aperture opening of said apertured mirror as well as said biconvex lens being conjugate in respect of the rear surface of said positive aplanatic meniscus lens with said biconvex lens and the mirror portion of said apertured mirror and said relay lens.

7. A wide angle opthalmoscopic system for examining an eye comprising:

an objective lens group having a forward direction toward an eye to be examined, said group having at least one meniscus lens and a positive lens, said meniscus lens having a front concave forward surface, said meniscus lens being substantially an aplanatic lens having an aplanatic point to be situated in the front part of an eye to be examined;

a converging lens group positioned behind said objective lens group;

an illuminating system having at least one light source and light transmitting means for directing light in the forward direction; and

an observing optical system optically aligned with said objective lens group for transmitting images formed by said objective lens group.

8. A system as in claim 7, wherein said objective lens group consists of a positive meniscus lens and a biconvex lens.

9. A system as in claim 7, wherein said objective lens group consists of two positive meniscus lenses and a biconvex lens.

10. A system as in claim 7, wherein said light transmitting means includes reflecting means and a plurality of lenses, said reflecting means being positioned between the converging lens group and the objective lens group.

11. A system as in claim 7, wherein said light transmitting means has lens means and a mirror with a reflecting plane, an aperture stop between the reflecting plane of the mirror and said converging lens group, and a light obscuring spot in conjugate relation to the aperture of said stop with respect to said positive lens, said aplanatic surface serving as a mirror surface, said positive lens, said reflecting plane and said lens means.

[57] **ABSTRACT**

A wide angle objective lens with an angular field coverage of 76° and a relative aperture of 1:2.8, comprising seven members of which the first and second (counting from the front) are negative meniscuses of forward convexity, the third is positive with the front surface more strongly curved than the rear one and convex toward the front, the fourth is bi-convex, the fifth is bi-concave, and the sixth and seventh are positive meniscuses of rearward convexity. This lens is shortened in the longitudinal direction and the diameter of the first member is smaller. By the shortening of the dimensions of the lens, it is increasing in the halo due to the sagittal rays. In order to diminish the increased halo it is restricted optimumly the reduced air space between the second and fourth members which affects the incident height of the marginal ray on the fourth member.

COMPACT RETROFOCUS WIDE ANGLE OBJECTIVE

This invention relates to photographic objectives, and more particularly to a wide angle objective having a long back focus suited for use in a single lens reflex camera.

Wide angle objectives when in the retrofocus type, though being advantageous for an increase in the back focal length, tend to give rise to a very difficult aberrational problem for distortion, coma and particularly halo due to the sagittal rays because of the requirement of employing a strongly divergent lens members at the front part. To avoid a considerable drop in image quality, therefore, the conventional design features are that the suitable arrangement of the lens members that follow the front member is combined with the simultaneous elongation of the complete objective in the longitudinal direction to reduce the absolute amount of aberrations ascribable to the individual lens members, and that the number of lens members in the complete objective is increased to facilitate correction of aberrations.

A retrofocus wide angle objective lens which is well corrected for the various aberrations has been proposed in U.S. Pat. No. 4,046,459 assigned to the assignee of the present invention. With this lens when shortened by 10% in the longitudinal length and at the same time in the diameter of the front member, however, it has been found that the halo due to the sagittal rays becomes serious. The use of special and expensive glass materials in making the lens elements is effective to improve the image quality, but will lead to an increase in the production cost.

Accordingly, the present invention aims at affording optimum correction for the various aberrations including halo due to the sagittal rays by making the lens arrangement appropriately selected.

For this purpose, two negative meniscus lens members are arranged in the foremost section of the objective, and are spaced from each other by as close a distance as is needed to achieve a minimization of the size of the objective in the total length and in the diameter of the front members. In such compact objective, the two negative meniscus lens members tend to produce remarkable halo of the sagittal rays which can be balanced out by the suitable design of the following lens members.

FIG. 1 is cross-sectional view of a preferred embodiment of the present invention.

FIG. 2 is aberrations diagram of the lens of FIG. 1.

One example of a specific wide angle objective lens of the present invention is represented in the drawing with FIG. 1 showing a lens block diagram wherein the first and second negative meniscus lens members (counting from the front) are convex toward the front and followed by a third lens member of positive power, in this instance, of bi-convexity as near as plano-convexity, a fourth lens member of bi-convexity, a fifth lens member of bi-concavity, a sixth lens member of rearwardly convex meniscus form, and a seventh lens member of positive power, in this instance, of rearwardly convex meniscus form. A diaphragm is positioned in a space between the third and fourth lens members.

The data of the objective represented in FIG. 1 refer to a total focal length of 100, a relative aperture of 1:2.8 and an angular field of 76°, and are given in Table 1 for the radii of curvature, R, the axial thicknesses of the lens elements or the axial separations between the lens elements, D, along with the corresponding indices of refraction, Nd, for the spectral D line of sodium and the Abbe numbers, || d, for the lens elements.

[57] **ABSTRACT**

A varifocal camera objective is adjusted in its telephoto position, by an axial shift of one of its movable components or by the insertion of a negative lens member, to extend its overall focal length with consequent increase in its back-focal length, that increase being compensated by the emplacement of a supplemental positive lens member in first or second position. If the movement of the shiftable component is controlled by a cam track, the axial displacement thereof beyond the varifocal range may be normally blocked and may be unblocked only when a feeler detects the presence of the supplemental positive lens member. A similar feeler mechanism may be used to prevent the emplacement of an attachment bearing such a supplemental lens member unless the shiftable component is enabled to move into its off-normal position. A focal-length-increasing negative lens member may be carried on an eccentric disk for selective interposition into the path of incident light rays just ahead of a reflex prism. The supplemental positive lens member may have an aspherical surface approximating a paraboloid of revolution.

VARIFOCAL OBJECTIVE WITH FOCAL LENGTH ADJUSTMENT

FIELD OF THE INVENTION

My present invention relates to an optical objective including a positively refracting lens assembly, as used in photographic and cinematographic cameras, which is adapted to focus incident rays from remote objects upon a receiving surface (e.g. a sensitive film) in line with an image plane located rearwardly of that lens assembly.

BACKGROUND OF THE INVENTION

The usual photographic and cinematographic objective can be sharply focused upon objects in a normal range between infinity and a so-called macro range, the latter being generally defined as lying between the image-ratio limits of 1:10 and 1:1. In the case of varifocal or pancratic objectives, in which the image plane does not shift between a telephoto position and a wide-angle position brought about by the concurrent axial displacement of two movable components, focusing within the macro range can be achieved by axially shifting one of these movable components beyond the position occupied by it at the wide-angle end of the varifocal range; see, for example, U.S. Pat. No. 3,891,304. Moreover, as proposed in commonly owned application Ser. No. 711,835 filed by me jointly with two others on Aug. 5, 1976, now U.S. Pat. No. 4,110,005 the angle of view can be further increased with the aid of a front attachment to be emplaced on the optical axis, such an attachment being of compact design so that its presence does not significantly extend the overall physical length of the objective.

At the opposite or telephoto end of the varifocal range, however, no such simple attachments have heretofore been available for the purpose of further extending the overall focal length of the system to increase its image scale. In order to operate in such an extended telephoto range, telescope-type front attachments of considerable axial length had to be used. The presence of such a device not only complicates handling of the camera but also tends to destabilize same, thereby aggravating the risk of blurring which commonly exists to a greater or lesser extent in any objective of large focal length.

OBJECTS OF THE INVENTION

The general object of my present invention, accordingly, is to provide simple means for modifying an objective of standard optical quality to facilitate the taking of telephoto pictures with an image scale greater than that normally obtainable.

A more particular object is to provide means for adapting a convex varifocal or pancratic objective to the taking of such telephoto pictures.

SUMMARY OF THE INVENTION

In accordance with my present invention, a multilens optical objective is provided with focal-length-increasing means effective to enlarge the image scale thereof, with consequent rearward displacement of the image plane from its normal position in line with a receiving surface, and a positively refracting supplemental lens member which is emplaceable on the optical axis in line with the lens assembly of the objective for restoring the image plane to its normal position by shortening the back-focal length of the system.

There are two basic ways of increasing the focal length of such an objective, namely by the shifting of one of its lens members or by the interposition of a negatively refracting ancillary lens member in its ray path. With a pancratic objective including a varifocal lens group, either of these measures is preferably carried out in the telephoto position. Thus, by holding one of the shiftable components stationary and further displacing the other shiftable component, I can achieve the desired increase in overall focal length together with an unwanted increase in back-focal length which is to be compensated with the aid of the supplemental lens member of positive refractivity. Alternatively, however, the negatively refracting ancillary lens member may be introduced between certain elements of the lens assembly, preferably on the image side of both shiftable components, without further axial displacement.

In optical systems used with xerographic copying machines, in which an object plane and an image plane are separated by a fixed distance, it has already been proposed to change the image scale or magnification ratio by axially shifting a main lens group and selectively interposing a supplemental lens in the light path thereof; see, for example, U.S. Pat. No. 3,600,066. In the normal position of the main lens group, without any supplemental lens, that system has a magnification ratio of 1:1. In order to reduce this ratio, the main group is shifted with insertion of a supplemental lens whereby the overall focal length of the system is decreased. In contradistinction thereto, my present invention seeks to increase rather than to reduce the overall focal length of an objective.

According to a more particular feature of my invention, the supplemental lens member is to be emplaced either at the very front of the lens assembly or in second position, i.e. just behind a front component which may constitute one of the axially shiftable members of a varifocal lens group. In some instances, it will be desirable to provide this supplemental lens member with an aspherical surface for better correction of aberrations due to the shifting of another component beyond the telephoto position or the insertion of an ancillary negative lens member. Such an aspherical surface may approximate a paraboloid of rotation, as more fully described hereinafter; under less exacting conditions, however, that surface may conform to the paraboloid itself or even to its osculating sphere.

Since correct focusing in the extended telephoto range requires both the enlargement of the overall focal length and the emplacement of the supplemental positive lens member, means may be provided for preventing the inadvertent omission of one of these steps by the user which could result in the spoiling of a picture or even of an entire film. For this purpose, the mechanism designed to shift one of the movable components of the varifocal lens group beyond the telephoto position may be blocked in the absence of a front attachment carrying the supplemental lens member; alternatively, the emplacement of such a front attachment may be prevented unless the shiftable component is enabled to move into its off-normal position.

If the focal-length-increasing means includes a mechanism for interposing a negatively refracting lens member as described above, that mechanism advantageously comprises a disk-shaped lens carrier rotatable about an axis parallel to that of the objective and provided with

a plurality of peripherally spaced cutouts, one of these cutouts containing the ancillary lens member. A similar arrangement may be used for the selective emplacement of the positively refracting supplemental lens member, especially when that member is to be inserted in some intermediate position.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing in which:

FIGS. 1A, 1B and 1C diagrammatically illustrate one of the aspects of my present invention, involving the axial shifting of a lens member for focal-length-increasing purposes;

FIGS. 2A, 2B and 2C illustrate, in a similar diagrammatic way, another aspect of my invention involving the interposition of an ancillary lens member for the same purpose;

FIG. 2 shows a camera objective embodying the principles described with reference to FIGS. 1A–1C;

FIG. 4 shows a camera objective embodying the principles described with reference to FIGS. 2A–2C;

FIG. 5 shows another camera objective according to my invention, operable according to the principles of either FIGS. 1A–1C or FIGS. 2A–2C;

FIG. 6 shows a camera objective similar to that of FIG. 5, representing a modification;

FIG. 7 shows a cam member adapted to be used with the system of FIG. 3;

FIG. 8 is an elevational view of a camera equipped with such a system;

FIG. 9 is a cross-sectional view taken on the line IX—IX of FIG. 8;

FIG. 10 is a side-elevational view (parts broken away) of the front part of a camera equipped with an objective of the type shown in FIG. 3, including a removable front attachment;

FIG. 11 is an axial sectional view of an alternate attachment for the camera shown in FIG. 10;

FIG. 12 is a view similar to FIG. 10, illustrating a modification;

FIG. 13 is a side-elevational view of the front part of a camera equipped with an objective of the type shown in FIG. 4; and

FIG. 14 is a fragmentary cross-sectional view of the camera shown in FIG. 13, taken generally on line XIV—XIV thereof.

SPECIFIC DESCRIPTION

FIG. 1A diagrammatically illustrates a multilens objective, represented in simplified fashion by a positive lens 1 and a negative lens 3, focused on infinity. The incident parallel light rays converge on an image plane 2 which in a camera would lie at the sensitized surface of a film or plate. The optical axis has been indicated at 0.

In FIG. 1B the negative lens 3 has been shown axially shifted to the left, i.e. toward the object side of the system. This shift causes an increase in the overall focal length of the objective and, with it, of its back-focal length s defined as the distance between its last lens vortex—that of member 1—and its image plane. The latter, therefore, has shifted to the right by a distance z to a position 2'.

A supplemental positive lens 5 has been positioned in FIG. 1C forwardly of the lens assembly 1,3. The presence of lens 5 shortens the back-focal length s by the amount z, thus restoring the image plane to the position 2 of FIG. 1A, without reducing the overall focal length to its original value.

Although the shiftable member 3 of FIGS. 1A–1C is shown as a negatively refracting lens, there are also multilens systems—such as the one of FIG. 5 described hereinafter—in which a similar focal-length-increasing effect can be achieved by the leftward displacement of a positive lens member or component.

In FIG. 2A I have shown a similar multilens objective here represented simply by a single positive lens 1 again having an image plane 2. The addition of an ancillary lens 4, of negative refractivity, shifts that image plane to a more distant position 2', FIG. 2B, as the back-focal length s of the system increases to s+z along with its overall focal length. Here, too, the emplacement of a supplemental positive lens 5 in front of the basic objective 1 restores the image plane to its normal position 2 while preserving an increased overall focal length.

FIG. 3 depicts a complete camera objective according to my invention including a basic objective 100 and a supplemental, positive lens L_{100x} selectively emplaceable in front thereof. Objective 100 consists of a varifocal front group with components 7, 8, 9, 10 and a fixed-focus rear group 11. Front component 7, which is positively refracting and stationary except for focusing purposes, consists of three air-spaced positive lens members, namely a doublet L_{101}, L_{102} and two singlets L_{103}, L_{104}. The second, negatively refracting component is axially shiftable and consists of a negative singlet L_{105} air-spaced from a biconcave doublet L_{106}, L_{107}. The third, also axially shiftable component 9 consists of a single negative lens L_{108} here illustrated in two alternative positions, the one shown in dotted lines representing the conventional telephoto position while the other one (solid lines) indicates the extra shift given to this member for extending the telephoto range with simultaneously use of supplemental lens L_{100x}. Component 10, fixed and positively refracting, consists of two air-spaced biconvex lenses L_{109}, L_{110}. There follows an air space, occupied by a reflex prism P and a diaphragm D, separating the varifocal group 7–10 from the fixed-focus group 11; the latter consists of five air-spaced singlets, namely two positive lenses L_{111}, L_{112}, a negative lens L_{113} and two further positive lens L_{114}, L_{115}.

In Table A, below, I have given representative numerical values in linear units (e.g. millimeters) for the radii r of the lenses shown in FIG. 3 as well as their thicknesses and separations d, together with their refractive indices n_d and Abbé numbers ν_d. In the wide-angle position, the system has a minimum focal length $f_{min}=7$; its maximum focal length in the telephoto position, without lens L_{100x} and with lens L_{108} in its dotted-line position, is $f_{max}=56$. With lens L_{108} shifted to its full-line position and lens L_{100x} in place, that focal length changes to $f_{ext}=80$. The image plane 2 retains its position in all instances, with a back-focal length s=13.546. In this and the following tables, items pertaining to the extended telephoto position according to my invention have been placed in parentheses.

It will be noted that the air space between lenses L_{110} and L_{111}, accommodating the prism P and the diaphragm D, equals 11.439 units.

It may be mentioned that the emplacement of lens L_{100x} accompanied by an axial shift of lens L_{108} is also possible with the first variable air space (between lenses L_{104} and L_{105}) smaller than in the telephoto position, though the increase in overall focal length will then not be as great.

FIG. 4 illustrates the application of my invention to an objective **200** of the type disclosed in U.S. Pat. No. 3,937,562, comprising a shiftable positive component **12**, a shiftable negative component **13** and a fixed positive component **14** followed by a fixed-focus rear group

15. Components 12 consists of a negative lens L_{201} and two positive lenses L_{202}, L_{203}; component 13 is formed from a negative singlet L_{204} and a negative doublet L_{205}, L_{206} whereas component 14 is a single biconvex lens L_{207}. Rear group 15 is composed of a positive doublet L_{208},L_{209}, a negative singlet L_{210} and two positive singlets L_{211}, L_{212}. Prism P and diaphragm D are here inserted between components 13 and 14, this diagragm space also accommodating in the telephoto position an ancillary planoconcave lens L_{200y} whose interposition is accompanied by the placement of a supplemental, positive lens member L_{200x} in front of objective 200 whereby the overall focal length of the system is further increased without dislocation of image plane 2. Naturally, members L_{200x} and L_{200y} need not be single lenses, as shown; this also applies to member L_{100x} of the preceding embodiment and to analogous members of subsequent Figures.

In the following Table B I have given representative numerical values for the radii r, thicknesses and separations d, refractive indices n_d and Abbé numbers ν_d for the lenses shown in FIG. 4. The overall focal length of this system changes from $f_{min}=7.5$ to $f_{max}=22$ in the varifocal range and increases to $f_{ext}=34$ in the presence of lenses L_{200x} and L_{200y}. The system has a back-focal length s=9.298.

In this case the prism P and the diaphragm D lie in a variable air space separating components 13 and 14 of

the varifocal group, the length of this space changing from 28.760 for f_{min} to 15.230 for f_{max}.

The objective **300** of FIG. **5** is generally similar to that of FIG. **4**, except that its shiftable front component **19** is a biconcave singlet L_{301} and its likewise shiftable second component **20** consists of two positive singlets L_{302}, L_{303} while a fixed third component **21** is another biconcave singlet L_{304}. This varifocal group is separated from a fixed-focus group **22** by an air space containing prism P and diaphragm D. As before, a supplemental positive lens L_{300x} and an ancillary negative lens L_{300y} can be used to extend the overall focal length of the system beyond its varifocal range, the former being positioned in front of lens L_{301} while the latter is inserted between lens L_{304} and prism P in the diaphragm space. Group **22** consists of a positive singlet L_{305}, a negative singlet L_{306} and another positive singlet L_{307}.

Representative numerical values for radii r, thicknesses and separations d, refractive indices n_d and Abbe numbers ν_d are given in Table C, below, for a system whose overall focal length ranges from $f_{min}=10.6$ to $f_{max}=27.0$ without lenses L_{300x}, L_{300y}, the focal length increasing to $f_{ext}=37.0$ in the presence of these additional lenses.

Here the air space between the vertical and fixed-focus lens groups **19–21** and **22**, of length 14.300, accommodates the ancillary lens L_{300y} together with prism P and diaphragm D.

In a refinement of the system given in Table C, the front surface of lens L_{300x} is made aspherical according to the formula

$$x = \frac{y^2}{R(1+\sqrt{1-y^2/R^2})} - k \cdot y^4$$

where x is the distance of any point on that surface from a reference plane transverse to axis O passing through the left-hand vertex of the lens, y is the distance of the point from the axis, R is the radius of an osculating sphere and k is a constant on the order of $1/R^4$. Within an area centered on the axis for which $y<<R$ we can write $x \approx y^2/R$ which is the formula for a paraboloid of rotation. With $R=20$ (corresponding to the radius for the first lens surface given in Table C), k may have a value of $5.5 \cdot 10^{-6}$.

The objective **300** of FIG. **5** can also be adjusted to an extreme telephoto position by the technique described with reference to FIGS. **1A–1C**, without use of the ancillary lens L_{300y} but with a further axial shifting of component **20** toward the object side, i.e. to the left, accompanied by the emplacement of lens L_{300x}. In this instance, lens L_{301} is substantially stationary while lens L_{304} is shiftable. The parameters of such a system are

given in the following Table D; the overall focal length changes from $f_{min}=10.41$ to $f_{max}=29.16$ in the varifocal range and is increased to $f_{ext}=34.00$ by the adjustment according to my invention. The back-focal length is s=11.700.

In the foregoing table the last variable air space is measured between lens L_{304} and prism P. Since the position of the prism is not critical (in fact, it might be omitted), that space could also be measured between lenses L_{304} and L_{305} if the latter lens—like lens L_{207} in FIG. 4—is considered part of the varifocal group, i.e. 11.481 for f_{min} and 24.032 for f_{max} and f_{ext}.

In FIG. 6 I have shown the same objective **300** as in FIG. 5, with insertion of ancillary lens L_{300y} but with supplemental lens L_{300x} positioned between components **19** and **20** rather than forwardly thereof. The corresponding parameters are given in Table E, below, for a system whose overall focal length normally varies between $f_{min}=10.6$ and $f_{max}=26.9$ but can be increased to $f_{ext}=34.5$ by the addition of these extra lenses. In this instance, too, the optical properties in the extreme telephoto positions can be further improved by using an aspherical front surface for lens L_{300x} according to the formula given in connection with Table C, or at least a paraboloidal approximation thereof. Elements P, D and L_{305}–L_{307} have the same dimensions and spacings as in Table C, with a back-focal length s=12.906.

The axial shifting of the movable components of any of the aforedescribed objectives can be brought about in the well-known manner with the aid of rotatable or slidable cam members. FIG. 7 shows, in developed view, a camming sleeve **30** coaxial with a control ring **31**, the latter being provided with axially extending guide slots **34**, **34'** traversed by pins **35** and **36** which are rigid with the lens mounts for the shiftable components, e.g. those designated **8** and **9** in FIG. 3. Pins **35** and **36** also pass through respective camming slots **38** and **39** in sleeve **30** which bring about their independent axial displacement upon relative rotation of members **30** and **31**.

The camming slots **38** and **39** are seen to be divided into three sections corresponding to respective operating zones α, β and γ. Zone α represents the normal varifocal range in which slot **38** has a constant slope or pitch angle for a linear shifting of component **8**. In zones β and γ, the slot **38** has zero pitch so that no further displacement of component **8** occurs even though component **9** continues to move under the control of slot **39**. It will be noted that this slot is so shaped as to shift component **9** toward the right, i.e. from its dotted-line position to its full-line position as seen in FIG. **3**, upon rotation of ring **31** past the telephoto end of the varifocal range as indicated by an arrow A. A shift of component **9** in the opposite direction, i.e. toward the left, takes place in zone γ under the control of slot **39** as the ring **31** is rotated in a reverse sense past the wide-angle end of the varifocal range as indicated by an arrow B; this latter displacement serves for the focusing of the objective in the macro range as discussed above.

In FIG. 7 I have also schematically indicated the provision of retractable stops **29**, **29'** for blocking the transition frame from zone α to either of the other two zones under certain conditions, e.g. as more fully described hereinafter with reference to FIGS. **10–12**. Stops **29** and **29'** are shown to coact with a pin **37** on sleeve **30** extending into a guide slot **33** of ring **31**.

FIGS. **8** and **9** illustrate a motion-picture camera **40** of conventional construction equipped with an objective of the type shown in FIG. **3**, for example, whose focal length is adjustable within the normal varifocal limits as well as into an extended telephoto range in which the camera is to be fitted with a front attachment **42** carrying a supplemental lens member of positive refractivity. A manually operable handle **41** on control ring **31** (cf. FIG. 7) can be swung, upon the release of a nonillustrated detent, through a large arc corresponding to zone α and a smaller arc corresponding to zone β as seen in FIG. **9**; an opposite swing into the zone γ discussed with reference to FIG. 7 may also be allowed. Attachment **42**, holding for example the lens L_{100x} of FIG. **3**, has a lug **43** fitting into a groove **44** of the objective housing **45**. Another such groove **47**, differing in size and location from groove **44**, is engageable by a lug of a similar attachment carrying a negative lens to be used in the marco range upon shifting of component **9** to a position in zone γ, such an attachment having been illustrated in FIG. **11** discussed hereinafter. Thus, either type of attachment occupies a characteristic position when mounted on the objective housing.

Attachment **42** further has a projection **46** extending into the path of handle **41** to form an abutment which defines the correct position of component **9** for the particular supplemental lens carried by it. This insures a correct positioning of the image plane if the camera can be selectively fitted with a variety of telephoto attachments. The same applies, of course, to wide-angle attachments usable in the marco range.

FIG. **10** illustrates a camera **50** having a camming sleeve **51** with a slot **52** generally similar to the slot **39** of FIG. 7, the slot being again divided into three sections corresponding to respective zones α, β and γ. A nonrotatable blocking sleeve **54** is positively connected with a slide **59** which moves within a slot **56** between three positions respectively labeled "NORMAL," "TELE" and "MARCRO." In position "NORMAL," the objective can be used only within its varifocal range as the extremities of slot **52** are overlain by respective ledges **57** and **57'** of sleeve **54**, thus preventing the cam-follower pin **53** of component **9** (FIG. **3**) from moving

into either the extended telephoto zone β or the macro zone γ. In slider position "TELE" the lower part of slot **52** is uncovered, allowing operation in the extended telephoto zone, whereas in position "MACRO" the upper slot extremity is also accessible to facilitate the taking of closeups.

A push rod **62** rigid with sleeve **54** projects forwardly under pressure of a spring **58** which tends to hold the sleeve in its position "NORMAL," the rod **62** extending past the objective housing **61** as long as no attachment is mounted thereon.

If a telephoto attachment **60** with a positive lens **6** is secured to the objective housing, the presence of this attachment is sensed by the rod **62** which represses the sleeve **54** into its position "TELE" and indicates this fact to the user with the aid of slider **59**. Another attachment **63**, shown in FIG. **11**, carries a negative lens **64** for the taking of closeups; attachment **63** has a peripheral flange **63'** which partly embraces the objective housing **61** and represses the sensing rod **62** still further to the right, thus moving the slider **59** into the position "MACRO" and fully unblocking the camming slot **52**.

FIG. **12** shows a similar camera whose camming slot **52**, however, lacks the extension labeled γ in FIG. **10**. Slider **59**, accordingly, is manually shiftable only between positions "NORMAL" and "TELE" within a slot **71**, with selective blocking or unblocking of slot extension β. Sleeve **54** is indexable in position "NORMAL" or is urged into that position by a strong biasing spring (not shown) so that a push rod **70** rigid therewith prevents the emplacement of an attachment **60** on the objective housing **61** in that position. Thus, the user must first shift the sider **59** to the position "TELE" before the attachment can be used. In FIG. **12** the attachment **60** and the objective housing **61** are shown provided with complementary threads facilitating the emplacement of lens member **6** which may correspond to lens L_{100x} of FIG. **3**.

In FIGS. **13** and **14** I have shown a camera **80** in which an ancillary lens member **17**, which may be the lens L_{200y} of FIG. **4**, is interposable in the lens assembly of a varifocal objective whose housing **81** can be fitted with an attachment **60** or **63** as shown in FIGS. **10–12**. A control ring **31** on the objective housing is rotatable by a handle **82**.

The camera body has a lateral aperture through which a disk **83**, provided with knurled rim **89**, projects for manual rotation about a shaft **95** offset from the optical axis O. Disk **83** has four angularly equispaced circular cutouts **84–87** and is provided with as many peripheral notches **91** engageable by a detent **90** for releasable indexing in any position in which one of these cutouts is in line with the optical axis. Detent **90**, passing through a slot **92** in a partition **93** of the camera housing, may be biased by a nonillustrated spring into engagement with notches **91**. The camera is further provided with a viewfinder **94** and other conventional devices.

Besides the negatively refracting ancillary lens **17**, lodged in cutout **84**, there may also be provided a positively refracting ancillary lens **96** for interposition in the taking of closeups with the aid of a negative supplemental lens **64** as shown in FIG. **11**. Lens **96** is shown mounted in cutout **87** whereas cutout **85** holds a toroidal lens **88** for the taking of anamorphotic pictures. Cutout **86** is empty and is aligned with axis O during normal focusing in the varifocal range.

Although my invention has been particularly described in its application to varifocal or pancratic objectives, its teachings are also applicable to objectives of fixed focus. Aside from being useful in photography, the invention could be readily adapted to the enlargement of scenes viewed through a telescope. A device similar to slider **59** of FIG. **10**, indicating the adjustment of the objective to the extended telephoto range, may also serve to alert the user to the desirability of placing the camera on a tripod or other suitable support.

The position-feeling or emplacement-blocking mechanism of FIGS. **10** and **12** is of the general type disclosed and claimed, for use with wide-angle attachments, in the aforementioned copending application Ser. No. 711,835 now U.S. Pat. No. 4,110,005.

I claim:

1. In an optical objective including a positively refracting lens assembly centered on an optical axis and adapted to focus incident rays from remote objects upon a receiving surface in line with an image plane located rearwardly of said lens assembly, the combination therewith of focal-length-increasing means for enlarging the image scale of said lens assembly, with consequent rearward displacement of said image plane from a normal position, and a positively refracting supplemental lens member emplaceable on said axis in line with said lens assembly for restoring said image plane to said normal position thereof.

2. The combination defined in claim **1** wherein said focal-length-increasing means comprises an axially shiftable member of said lens assembly and mechanism for axially displacing said axially shiftable member.

3. The combination defined in claim **2** wherein said lens assembly includes a varifocal lens group with two axially shiftable components for selectively establishing a wide-angle position and a telephoto position between which said image plane remains fixed, said axially shiftable member being one of said components.

4. The combination defined in claim **3** wherein said supplemental lens member is emplaceable on the side of said axially shiftable member remote from said image plane.

5. The combination defined in claim **4** wherein the objective is part of a camera provided with an objective housing, said supplemental lens member being part of a front attachment emplaceable on said objective housing.

6. The combination defined in claim **5** wherein the camera is provided with inhibiting means normally blocking a displacement of said one of said components by said mechanism beyond said telephoto position, said inhibiting means being deactivable by said attachment upon emplacement thereof on said objective housing.

7. The combination defined in claim **5** wherein the camera is provided with selector means for optionally blocking and unblocking a displacement of said one of said components by said mechanism beyond said telephoto position, said selector means having an extension preventing the emplacement of said attachment on said camera in a blocking position.

8. The combination defined in claim **5** wherein said supplemental lens member L_{100x} and the lenses L_{101}–L_{110} of said varifocal lens group have radii of curvature r, axial thickness and separations d, refractive indices n_d and Abbé numbers ν_d substantially as given in the following table:

	−13.0			

13. The combination defined in claim 1 wherein said focal-length-increasing means comprises an ancillary negatively refracting lens member interposable in said lens assembly, on the image side of said supplemental lens member, and mechanism for selectively interposing said ancillary lens member.

14. The combination defined in claim 13 wherein said lens assembly includes a varifocal lens group with two axially shiftable components for selectively establishing a wide-angle position and a telephoto position between which said image plane remains fixed, said ancillary lens member being insertable by said mechanism in said telephoto position on the image side of said shiftable components.

15. The combination defined in claim 14 wherein said mechanism comprises a lens carrier rotatable about an axis parallel to said optical axis.

16. The combination defined in claim 15 wherein said lens carrier is a disk with a plurality of peripherally spaced cutouts, one of said cutouts being provided with said ancillary lens member.

17. The combination defined in claim 16, further comprising indexing means for arresting said disk in a position of alignment of any of said apertures with said lens assembly.

18. The combination defined in claim 14 wherein said supplemental lens member is emplaceable on the object side of said shiftable components.

19. The combination defined in claim 18 wherein said supplemental lens member has an aspherical surface approximating a paraboloid of rotation.

20. The combination defined in claim 19 wherein said aspherical surface is defined by the formula

$$x = \frac{y^2}{R(1+\sqrt{1-y^2/R^2})} - k \cdot y^4$$

where x is the distance from a reference plane transverse to said axis, y is the distance from said axis and R is the radius of an oscilating sphere, k being a constant on the order of $1/R^4$.

21. The combination defined in claim 18 wherein said supplemental lens member L_{200x}, said ancillary lens member L_{200y} and the lenses L_{201}–L_{205} of said varifocal lens group have radii of curvature r, axial thicknesses and separations d, refractive indices n_d and Abbé numbers ν_d substantially as given in the following table:

[57] **ABSTRACT**

A varifocal objective with a front component, axially shiftable for focusing purposes, and with a second and third component, axially displaceable by camming grooves in a control sleeve for changing the focal length, is provided with a coupling ring centered on the objective axis which is axially entrained by the lens mount of the front component. During normal operation, the coupling ring is indexed in a disengagement position. When the front component is in its infinity position and the control sleeve has cammed the second and third components into their wide-angle position, the coupling ring is manually rotatable into an engagement position in which it links the lens mount of the first component with that of the third component for joint axial shifting into a macro range by the focusing drive; such shifting is facilitated by an axial slot in the control sleeve preventing rotation of the latter in that range.

VARIFOCAL OBJECTIVE WITH MECHANISM FOR CLOSEUP FOCUSING

FIELD OF THE INVENTION

My present invention relates to a varifocal or zoom-type objective for a photographic or cinematographic camera in which an axial shift of an objective component, normally serving as a compensator to maintain a constant image-plane position during changes in focal length, facilitates the taking of closeup pictures in a macro range.

BACKGROUND OF THE INVENTION

Varifocal objectives of this type are well known per se, e.g. from U.S. Pat. Nos. 3,655,271 and 3,891,304. Reference in this connection may also be made to German printed specifications Nos. 2,023,804 and 2,029,254 as well as German published applications Nos. 2,634,941 and 2,634,964.

The term "macro range" encompasses distances closer than a normal focusing range, usually within limits giving image scales between 1:10 and 1:1. Whereas normal zooming involves the simultaneous displacement of the aforementioned compensator component (generally the third component as counted from the front or object side) and of the immediately preceding variator component (commonly the second one), the shift into the macro range is ordinarily carried out by the compensator component alone. The first or front component, considered stationary for the purpose of changing the overall focal length, is limitedly axially shiftable for focusing in both the normal and macro ranges.

OBJECT OF THE INVENTION

The object of my present invention is to provide a simple mechanism for enabling an axial shifting of the third or compensator component of a varifocal lens group, independently of the associated second or variator component, to facilitate the projection of images from objects closer than the normal focusing range upon the plane of a receiving surface such as that of a photosensitive film.

SUMMARY OF THE INVENTION

I realize this object, in accordance with my present invention, by the provision of a coupling element—preferably a milled ring—projecting outwardly from a lens barrel in which at least the first three components of a varifocal objective are located, this coupling element being manually rotatable about the objective axis between two alternate positions. A link member inside the lens barrel is connected with the coupling element for joint rotation therewith and is further connected with the first lens mount, carrying the front component of the objective, for axial entrainment thereby. This link member and the third lens mount, carrying the compensator component, are provided with complementary formations which are disengaged from each other in one of the aforementioned alternate positions but are aligned with each other in predetermined positions of a setting means serving for focusing and a camming means serving for focallength adjustment. Upon such alignment, a rotation of the coupling element into its alternate position interengages the complementary formations of the link member and of the third lens mount to facilitate a joint axial shifting of the front and compensator components into the macro range under the control of the aforementioned setting means.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 is an axial sectional view of a cinematographic camera provided with an objective embodying my invention;

FIG. 2 is a fragmentary top view, with parts broken away, of the objective shown in FIG. 1; and

FIG. 3 is an axial sectional view of part of a camming sleeve used on the objective.

SPECIFIC DESCRIPTION

The camera shown in the drawing comprises a varifocal or zoom-type objective, generally designated **1**, and a camera body or housing **2**. The objective **1** is provided with a lens barrel **3** which projects from the camera housing **2** and is centered on an optical axis O. Also centered on this axis are several lens members constituting a positively refracting front component **4**, two negatively refracting intermediate components **6**, **8** and a stationary rear component **10**. The latter, disposed outside lens barrel **3** within housing **2**, consists of a plurality of lenses not illustrated individually.

Components **6** and **8** are provided with respective lens mounts **5**, **7** and **9** which are individually displaceable along axis O. The shifting of lens mount **5** for focusing purposes is carried out by a mechanism similar to that disclosed and claimed in commonly owned U.S. patent application Ser. No. 894,031 filed Apr. 6, 1978 by Karl-Heinz Holderbaum. The focusing mechanism comprises an axially extending guide rod **22** which is slidably and nonrotatably received in an inner annular flange **3'** of lens barrel **3** and terminates inside housing **2** in a rear extremity **23** carrying male threads matingly engaged by a captive nut **32**. This nut, held against axial displacement by the flange **3'** and an end wall **33**, carries external gear teeth in mesh with a pinion **34** and with a toothed wheel **35**. Pinion **34** can be driven by a reversible motor **36**, via a slipping clutch **37**, whereas wheel **35** is rigid with a milled setting wheel **21** which is rotatable about an axis parallel to optical axis O. Setting wheel **21** may be provided with two distance scales relating to a normal focusing range and to a macro range, respectively. Motor **36** is energizable from a nonillustrated power supply, e.g. as described in commonly owned U.S. Pat. No. 3,165,044.

As disclosed in the above-identified Holderbaum application, lens mount **5** can be stabilized with the aid of an additional and preferably shorter guide rod not shown.

Lens mounts **7** and **9**, carrying the variator component **6** and the compensator component **8**, are displaceable in a manner well known per se by the rotation of a sleeve **19**, provided for this purpose with a knob **38**, which has camming grooves **27** and **28** engaged by respective pins **25** and **26** (see FIG. **3**) on these lens mounts, the cam-follower pins passing through an axially extending slot **39** of lens barrel **3**. Lens mounts **7** and **9** are slidably supported on axially extending guide rods including the rod **22** and at least one other rod **24**.

In accordance with my present invention, a milled coupling ring **11** projects outwardly from an annular groove in lens barrel **3** just ahead of camming sleeve **19**.

A lug 12 rigid with ring 11 extends inwardly through an arcuate slot in the lens barrel and engages in an axially extending slot 14 of a link member 13 whose front end is received in an arcuate cutout 16 of lens mount 5 centered on axis O. Link member 13 is peripherally displaceable inside cutout 16 between a normal angular position, shown in FIG. 2, and an alternate position in which a recess 15 on a rear part of that member is engaged by a stud 18 on a forward extension 17 of lens mount 9. A rotation of ring 11 into this alternate position is evidently not possible unless link member 13 and extension 17 are aligned with each other as illustrated in FIG. 2. Such alignment occurs when the camming sleeve 19 is in its limiting position at the wide-angle end of the varifocal range, with pins 25 and 26 lying at the lower ends of their cam tracks 27 and 28 as viewed in FIG. 3, and when setting wheel 21 has retracted the lens mount 5 into its extreme right-hand position to focus the objective on the distal end of the normal range, generally infinity.

If, under these circumstances, coupling ring 11 is rotated into its alternate position to interengage the complementary formations 15 and 18 of member 13 and lens mount 9, rotation of wheel 21 results in a joint axial displacement of objective components 4 and 8. Such displacement is facilitated by the provision of a spur 29 extending from the lower end of the rear of cam track 28, the entry of pin 26 into that spur preventing any rotation of camming sleeve 19. The forward shifting of compoents 4 and 8 by means of setting wheel 21 focuses the objective upon objects in the macro range whose images are thereby projected upon a film plane 30.

Ring 11 is yieldably retained in its alternate or coupling position by indexing means here shown as a ball check 20 lodged in camming sleeve 19. Thus, rotation of sleeve 19 from the position of FIG. 3 in the direction of the larger focal lengths automatically decouples the link member 13 from lens mount 9.

Although the manual control of lens mount 5 by a setting wheel 21 on the camera body 2 is very convenient, the illustrated arrangement could be modified to replace the wheel 21 by a focusing ring on the forward end of the lens barrel as disclosed and claimed in commonly owned U.S. patent application Ser. No. 896,588 filed 14 Apr. 1978 by Paul Himmelsbach.

I claim:

1. In a camera comprising a housing, a lens barrel projecting from said housing, said lens barrel being centered on an optical axis, and an objective centered on said axis, said objective including a front component held in a first lens mount, a variator component held in a second lens mount and a compensator component held in a third lens mount, said lens mounts being axially shiftable in said lens barrel, camming means operatively coupled with said second and third lens mount for axially shifting same to change the focal length of the objective between a wide-angle end and a telephoto end of a varifocal range while keeping an image plane of the objective coincident with a receiving surface, and setting means independent of said camming means coupled with said first lens mount for axially shifting same to project upon said receiving surface the images of objects located at different distances from the camera within a normal focusing range,

the combination therewith of a coupling element projecting outwardly from said lens barrel for manual rotation about said axis between two alternate positions, and a link member in said lens barrel connected with said element for joint rotation and with said first lens mount for axial entrainment thereby, said link member and said third lens mount being provided with complementary formations disengaged from each other in one of said alternate positions but aligned with each other in predetermined positions of said setting means and said camming means for enabling interengagement of said formations upon a rotation of said element into the other alternate position thereof, such interengagement facilitating a joint axial shifting of said front and compensator components into a macro range under the control of said setting means to project upon said receiving surface the images of objects closer than said normal focusing range.

2. The combination defined in claim 1 wherein said element is a ring held in said lens barrel against axial movement.

3. The combination defined in claim 2 wherein said first lens mount is provided with an arcuate cutout centered on said axis, said link member having a front end projecting into said cutout with freedom of peripheral displacement relative to said first lens mount, said link member further having an axial slot engaged by an inward projection of said ring.

4. The combination defined in claim 1 or 3 wherein said camming means comprises a rotatable sleeve centered on said axis and provided with front and rear tracks respectively engaged by cam followers on said second and third lens mounts, said rear track having an axially extending spur enabling the axial shifting of said third lens mount by said setting means in a predetermined position of said sleeve while locking the latter against rotation in said macro range.

5. The combination in claim 4 wherein said predetermined positions of said setting means are at a distal end of said normal focusing range and at said wide-angle end of the varifocal range, respectively.

6. The combination defined in claim 4 wherein said element and said sleeve adjoin each other and are provided with indexing means yieldably connecting said element in said other alternate position with said sleeve in said predetermined position thereof.

7. The combination defined in claim 1 wherein said setting means comprises a guide rod extending axially rearwardly from said first lens mount, said guide rod terminating in a threaded extremity within said housing, a captive nut in said housing meshing with said extremity, and drive means for rotating said nut.

[57] **ABSTRACT**

An objective lens system, for example of a Gauss or Tessar type is provided having the capability of adequately correcting aberrations even when the lens system is focussed at a relatively close object. The lens system is adaptable for use in cameras and comprises a first lens group including an aperture stop and a second lens group positioned on the image side of the first lens group. The second lens group includes a first lens sub-group of positive refracting power and a second lens sub-group of negative refractive power. The air spaces provided between the first lens group and the first lens sub-group and also between the first lens sub-group and the second lens sub-group are varied to compensate for changes in aberrations resulting from focussing at a relatively close object. More specifically, the first air space is increased while the second air space is decreased when the object distance of the lens system is decreased.

OBJECTIVE LENS SYSTEM WITH CLOSE OBJECT FOCUSING ABERRATION CORRECTION

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a photographic camera objective lens system, for example of the Gauss or Tessar type having a tendency to increase various aberrations when the photographic object is relatively close to the lens system, and more particularly to such an objective lens system which incorporates means for compensating aberrations when focussing at a close object.

2. Brief Description of the Prior Art

The prior art is familiar with the aberration problems that are created when it is desired to utilize a lens system for focussing at relatively close objects. For example, a lens system is known wherein an air space behind a diaphragm in the lens system is provided before a positive overall refractive power lens group. This air space is varied in coordination with focussing to compensate for any changes in aberrations. The axial rays passing through this air space are convergent. Thus, by widening this air space the height of the axial rays relative to the optical axis that are incident on the positive lens group can be reduced to accordingly reduce the refraction of the axial rays by the positive lens group and thereby compensate for spherical aberrations. Additionally, the height of the off-axial rays incident on the same positive lens group will also be varied to compensate for astigmatism and coma. An example of such an optical design approach to compensate for these aberrations is disclosed in U.S. Pat. No. 3,815,974.

However, a design problem exists, in that the convergent axial rays in the variable air space become divergent when the object distance becomes sufficiently close. Accordingly, when photographing an object at a relatively close distance a point will be reached in which it is no longer possible to obtain an effective compensation for spherical aberration. If this focussing range is sought to be increased by maintaining the convergence of the axial rays in the variable air space, the lens group at the object side of the variable air space must be provided with a considerably strong positive refractive power. The provision of this power distribution in the lens system, however, would create problems and would not provide a desirable design solution.

Another patent of general interest for its disclosure of various air spaces in a photocopier application can be found in U.S. Pat. No. 3,883,228.

The prior art is still seeking an optical design to optimize the correction of aberrations when focussing at close distances within a commercial priced lens system for the average photographer.

SUMMARY OF THE INVENTION

An object of the present invention is to overcome the compensation problems associated with focussing on an object at a relatively close distance, while at the same time providing a lens system that is capable of providing a balanced compensation for spherical aberration, astigmatism and coma.

Accordingly, an objective lens system for cameras and the like with a close focussing capability is provided having a first lens group which includes an aperture stop. On the image side of the first lens group, a second lens group is positioned and defines with the first lens group a first air space. The second lens group can be subdivided into a first lens sub-group of positive refractive power and a second lens sub-group of negative refractive power. The first and second lens sub-groups are spaced from each other to form a second air space.

Compensation for aberrations is provided by a compensation means which can increase the relative first air space displacement of the first lens group and the first lens sub-group when the object distance of the lens system is decreased during focussing at a close object. While, at the same time, the compensation means can decrease the second air space between the first and second lens sub-groups. The compensation means thereby provides adequate compensation for aberrations resulting from focussing at a close object.

Any variation in the focal length f, of the lens system resulting from variations in the axial air spaces, dA and dB, if any, are maintained with ± 3 percent of the focal length of the lens system while focussed at infinity.

The features of the present invention which are believed to be novel are set forth with particularity in the appended claims. The present invention, both as to its organization, and manner of operation, together with further objects and advantages thereof, may be best understood by reference to the following description, taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic cross-sectional view of a first embodiment of the present invention focussed at infinity;

FIGS. **2***a*, **2***b*, **2***c* and **2***d* disclose respectively the spherical aberration, astigmatism, distortion and coma for the lens system of FIG. **1**;

FIG. **3** is a schematic cross-sectional view of FIG. **1** focussed at an object distance corresponding to a magnification of 0.25;

FIGS. **4***a*, **4***b*, **4***c* and **4***d* respectively show the spherical aberration, astigmatism, distortion and coma for the lens system of FIG. **3**;

FIGS. **5***a*, **5***b*, **5***c* and **5***d* disclose the respective aberration curves resulting when the lens system of FIG. **1** has been shifted to a magnification of 0.25 without varying the variable air spaces;

FIG. **6** discloses a schematic cross-sectional view of a second embodiment of the present invention focussed at infinity;

FIGS. **7***a*, **7***b*, **7***c* and **7***d* show respectively the spherical aberration, astigmatism, distortion and coma of the lens system of FIG. **6**;

FIG. **8** shows the lens system of FIG. **6** focussed at an object distance corresponding to a magnification of 0.25;

FIGS. **9***a*, **9***b*, **9***c* and **9***d* show respectively the spherical aberration, astigmatism, distortion and coma of the lens system of FIG. **8**;

FIGS. **10***a*, **10***b*, **10***c* and **10***d*, are the respective aberration curves for the lens system of FIG. **6** focussed at an object distance corresponding to a magnification of 0.25 without varying the variable air spaces;

FIG. **11** shows a schematic cross-sectional view of a third embodiment of the present invention focussed at infinity;

FIGS. **12***a*, **12***b*, **12***c* and **12***d* show the resulting aberration curves for the embodiment of FIG. **11** when focussed at infinity;

FIG. **13** is a schematic view of FIG. **11** focussed to an object distance corresponding to a magnification of 0.25;

FIGS. **14***a*, **14***b*, **14***c* and **14***d* show the resulting aberration curves for the lens system of FIG. **13**;

FIGS. **15***a*, **15***b*, **15***c* and **15***d* are the aberration curves for the embodiment of FIG. **11** when the lens groups have been shifted to a magnification of 0.25 without varying the variable air spaces;

FIG. **16** shows a schematic cross-sectional view of a fourth embodiment of the present invention focussed at infinity;

FIGS. **17***a*, **17***b*, **17***c* and **17***d*, show the various aberration cirves for the lens system of FIG. **16** when focussed at infinity;

FIG. **18** shows the lens system of FIG. **16** focussed to an object distance corresponding to a magnification of 0.25;

FIGS. **19***a*, **19***b*, **19***c* and **19***d* show the resulting aberration curves for FIG. **18**; and

FIGS. **20***a*, **20***b*, **20***c* and **20***d* show the resulting aberration curves for the embodiment of FIG. **16** when the lens group has been shifted to a magnification of 0.25 without varying the variable air spaces.

BRIEF DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following description is provided to enable any person skilled in the optical art to make and use the invention and sets forth the best modes contemplated by the inventor of carrying out his invention. Various modifications, however, will remain readily apparent to those skilled in the art, since the generic principles of the present invention has been defined herein specifically to provide an objective lens system with close focussing capabilities.

The derivation of the values and their relationships as set forth in the tables, hereinafter, can be accomplished with the assistance of a computer. The present invention represents the parameters of a compromised balance of acceptable aberrations in an objective lens system for utilization, for example, with a camera.

In the accompanying drawings, which supplement the tables, the lenses in accordance with the present invention, are illustrated diagrammatically using reference symbols which indicate groups of lenses. As usual, in conventional lens diagrams, the light is assumed to travel from left to right, the radii of curvature of the lens are indicated by, r, with a subscript corresponding to consecutive surfaces of the lens elements and the axial spacings, d, along the optical axis are also indicated with a consecutive subscript. In the tables, the minus signs indicate surfaces concave toward the object side, while the surfaces without a sign are convex toward the object side. The value of the axial spacing symbol, d, includes both the axial spacing between the lens elements and the thickness of the lens elements. The axial spacings between the lens elements are positioned accordingly relative to the radii in the tables while the thicknesses are designated accordingly between the radii. Zero axial spacing indicates lens elements cemented to each other. All other axial spacings greater than zero refer to air spacings.

All linear dimensions are given in absolute values and are given with reference to the equivalent focal length of unity. The tables also provide with respect to each example, the intended relative aperture, the total angle of view, 2ω, and the back focal length, S, with reference to an object at infinity.

Referring specifically to FIG. **1**, a first embodiment of the present invention is schematically disclosed with the lens elements therein positioned for photographing at infinity.

A first lens group (I) can have either a positive or negative overall refractive power and includes a diaphragm or aperture stop. A second lens group (II) is axially displaced from the first lens group and has a positive overall refractive power. The resulting air space, dA, between the first lens group and the second lens group can be varied in association with focussing. Taking into account the appropriate design considerations, the height of the off-axial rays incident on the second lens group off the optical axis, can be varied to correct for astigmatism and coma.

The second lens group (II) comprises a positive lens and a negative meniscus lens respectively from object to image side and includes a second air space, dB, between these two lenses. The second air space has a cross-sectional configuration of a meniscus air lens with its concave side facing the diaphragm. By varying this second air space, dB, the distance of the intersection or incidence of the convergent axial rays, emergent from the positive lens, and off-set from the optical axis can be varied on the negative meniscus lens. Thus, when dB is narrowed, the height from the optical axis of the axial rays incident on the negative meniscus lens is increased so that the negative refractive power of the negative meniscus lens exerts a greater influence on the axial rays to positively displace the spherical aberration. In this arrangement, the axial rays in the air space, dA, need not be convergent, however, if the rays are convergent in the air space, dA, the spherical aberration can also be corrected in the same manner associated with the displacement or variation of the air space dB.

Because the air space of air lens, dB, has a configuration of a meniscus lens with its concave side facing the diaphragm, any variation in the axial spacing of dB, produces substantially no astigmatism. Therefore, the present inventor has discovered that by shifting the lens system for photographing a close object with magnification in the range of 0.25, a satisfactory aberration condition can always be maintained by increasing the air space, dA, especially to correct for astigmatism and coma. Further, by decreasing the air space, dB, it is possible to correct the spherical aberration.

FIGS. **2***a*, **2***b*, **2***c* and **2***d* show various aberration curves for respectively spherical aberration, astigmatism, distortion and coma when the lens system of FIG. **1** is focused at infinity.

The schematic cross-sectional view of the lens system of FIG. **3** discloses the lens system of FIG. **1** shifted to focus on a close object so that the magnification is $\beta=0.25$. As can be seen from FIG. **3**, the positive lens of the second lens group has been shifted toward the image side relative to the entire system when compared with FIG. **1** to thereby increase the air space dA, and decrease the air space dB. This shifting produces the desirable intersection or incidence of the convergent axial rays to thereby adequately compensate for the various aberrations. This compensation can be seen in the graphs of FIGS. **4***a*, **4***b*, **4***c* and **4***d*. In this arrangement, the air space dA=0.012 and the air space dB=0.011 with a lens system focal length f=1.002.

Simply for comparison sake, FIGS. **5***a*, **5***b*, **5***c* and **5***d* show aberration curves that have been plotted to dis-

close the situation that occurs when the lens system of Table 1 has been shifted to a magnification of $\beta=0.25$ without varying the air spaces dA and dB.

A second embodiment of the present invention is disclosed in FIG. **6**. The purpose of the air spacing and its effect on the incident axial rays are the same as described with respect to the first embodiment and, therefore, it is not necessary to repeat this description. The aberration curves for the second embodiment, focussed at infinity, are shown respectively in FIGS. **7***a*, **7***b*, **7***c* and **7***d*.

FIG. **8** discloses the second embodiment with the lens system focussed at a relatively close distance, magnification $\beta=0.25$, dA=0.048 and dB=0.013 with a focal length, f=1.009. The resultant aberration curves for this close focus position are shown respectively in FIGS. **9***a*, **9***b*, **9***c* and **9***d*. FIGS. **10***a*, **10***b*, **10***c* and **10***d* are the respective aberration curves produced when the lens system of FIG. **6** has been shifted for close focussing, $\beta=0.25$ (without varying the air spaces dA and dB).

Finally, a fourth embodiment of the present invention is disclosed in FIG. **16** focussed at infinity. The corresponding aberration curves for this mode of focussing operation are disclosed respectively in FIGS. **17***a*, **17***b*, **17***c* and **17***d*.

FIG. **18** shows the fourth embodiment of FIG. **16** with the lens elements positioned for close focusing. The magnification is $\beta=0.25$ and air space distances are dA=0.043 and dB=0.029 with a focal length f=1.009. The aberration curves set forth in FIGS. **19***a*, **19***b*, **19***c* and **19***d*, respectively disclose resulting aberrations with this close focusing position. FIGS. **20***a*, **20***b*, **20***c* and **20***d* set forth the aberration curves for simply comparison of the lens system of FIG. **16** shifted for a magnification $\beta=0.25$ without varying the air spaces dA and dB.

The values in each of the above Tables 1 through 4 are representative of their corresponding lens systems focussed at infinity.

As can be readily appreciated in veiw of the above description, the present invention utilizes a second lens group comprising, object to image side, a positive lens, a negative meniscus lens with the interposition of a variable air space, dB, therebetween so that spherical aberration may be compensated by taking advantage of the convergence of the axial rays in this variable air space. It should be realized, that the axial rays entering this variable air space dB, need not necessarily be convergent and dA, may be relied upon mainly for the correction of astigmatism and coma. By the specific selection of the aboveidentified lens elements, and their manipulation relative to the air spaces, it is possible to obtain a well-balanced correction for spherical aberration, astigmatism and coma while extending the range of photography to closer distances in the order of a magnification $\beta=0.25$. This is accomplished without placing an excessive design burden on the power of the first lens group. Thus, relatively easily assembled lens system compatible to conventional lens barrels can be produced. The advantages of the present invention are particularly valuable in increasing the relative object distance range for photography in an economical manner while still providing satisfactory aberration compensations to insure a high-quality lens system.

As can be readily appreciated, it is possible to deviate from the above embodiments of the present invention and will be readily understood by those skilled in the art that the invention is capable of many modifications and improvements within the scope and spirit thereof. Accordingly, it will be understood that the invention is not to be limited by the specific disclosed embodiment but only by the scope and spirit of the appended claims.

What is claimed is:

1. An objective lens system for cameras with a close focusing capability comprising;

a first lens group including an aperture stop;

a second lens group of an overall positive refractive power spaced from the image side of the first lens group to form a first air space, the second lens group consisting of a first lens sub-group of positive refractive power having an image side convex surface and a second lens sub-group of negative refractive power having an object side concave surface and an image side convex surface, the first and second lens sub-groups being spaced from each other to form a second air space, and

compensation means for increasing the relative first air space displacement of the first lens group and the first lens sub-group when the object distance of the lens system is decreased during focusing and decreasing the relative second air space between the first and second lens sub-groups to compensate for aberrations resulting from focusing on a close object.

2. The invention of claim 1, wherein the first lens sub-group consists of a single positive lens having an image side convex surface and the second sub-group consists of a negative meniscus single lens convex to the image side.

3. The invention of claim 2, wherein the first lens group has an image side convex surface.

4. The invention of claim 3, wherein the positive lens of the first lens sub-group has an object side concave surface.

5. The invention of claim 3, wherein the positive lens of the first sub-group has an object side convex surface.

6. The invention of claim 2, wherein the first lens group comprises, from the object to the image side, a positive meniscus lens convex to the object side, a first negative meniscus lens convex to the object side, an aperture stop and a second negative meniscus lens convex to the image side, the first negative meniscus lens consists of a positive lens element and a negative lens element cemented to the positive lens element at the image side thereof.

7. The invention of claim 6, wherein the positive meniscus lens of the first lens group consists of a single lens element and the second negative meniscus lens consists of a single lens element.

8. The invention of claim 2, wherein the first lens group comprises, from the object to the image side, a first positive lens, a biconcave lens, an aperture stop and a second positive lens.

9. The invention of claim 8, wherein one of the positive lenses of the first lens group consists of a cemented doublet and each of the other lenses of the first lens group consists respectively of a single lens element.

10. The invention of claim 2, wherein the first lens group comprises, from the object to the image side, a first positive meniscus lens convex to the object side, a second positive meniscus lens convex to the object side, a first negative meniscus lens convex to the object side, an aperture stop and a second negative meniscus lens convex to the image side.

11. The invention of claim 10, wherein the second negative meniscus consists of a negative lens element and a positive lens element cemented to the negative lens element at the image side thereof and each of the other respective lens elements of the first lens group consists of a single lens.

12. The invention of claim 1, wherein the position of the second lens sub-group is fixed relatively to the first lens group and the first lens sub-group is movable relatively to both the first lens group and the second sub-group for varying the first and second air spaces.

13. An objective lens system comprising a design parameter of approximately the values set forth within the following specification:

f=1.0 FNo.=2ω=47° Back Focal Length S=0.71

[57] **ABSTRACT**

An ophthalmoscopic camera with an achromatic objective arranged on a common optical axis of an image forming lens in front of a photographic film and adapted to project a ring-shaped bundle of illuminating light rays onto the cornea of an eye to be photographed as the illuminating light rays come from a light source through a relay lens after reflection from an apertured mirror positioned between the objective and the image forming lens at an angle with the optical axis thereof. For an increase in the angle of view, the objective is constructed in the form of a biconvex triplet consisting of a forwardly convex negative meniscus lens, an equiconvex lens and a rearwardly convex negative meniscus lens with its four refracting surfaces so configured and so separated that a beam of image forming rays passing through a central aperture of the illuminating mirror to the film can be made free from disturbing light reflections from these four lens surfaces by use of a single black spot positioned at a point between the light source and the mirror in coaxial relation thereto.

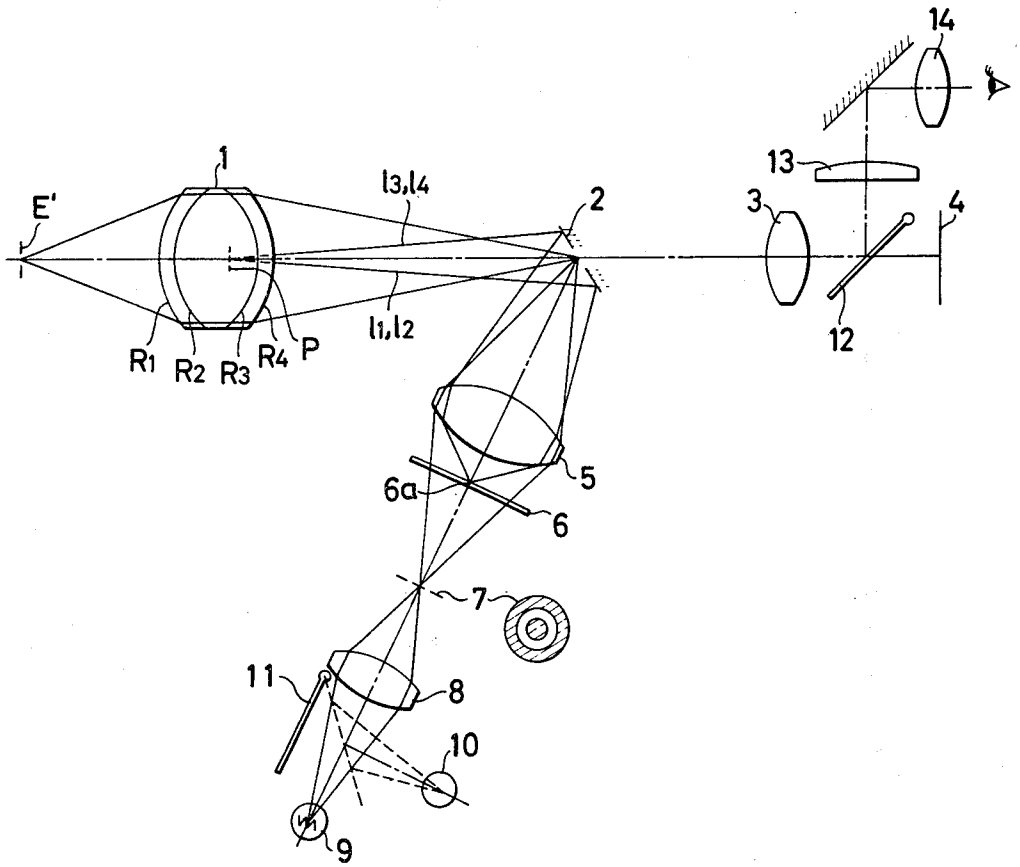

FIG. 1

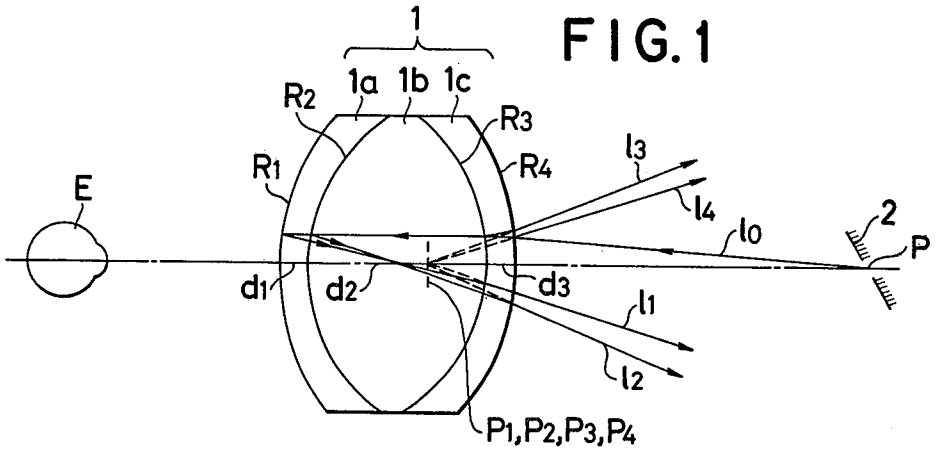

FIG. 2

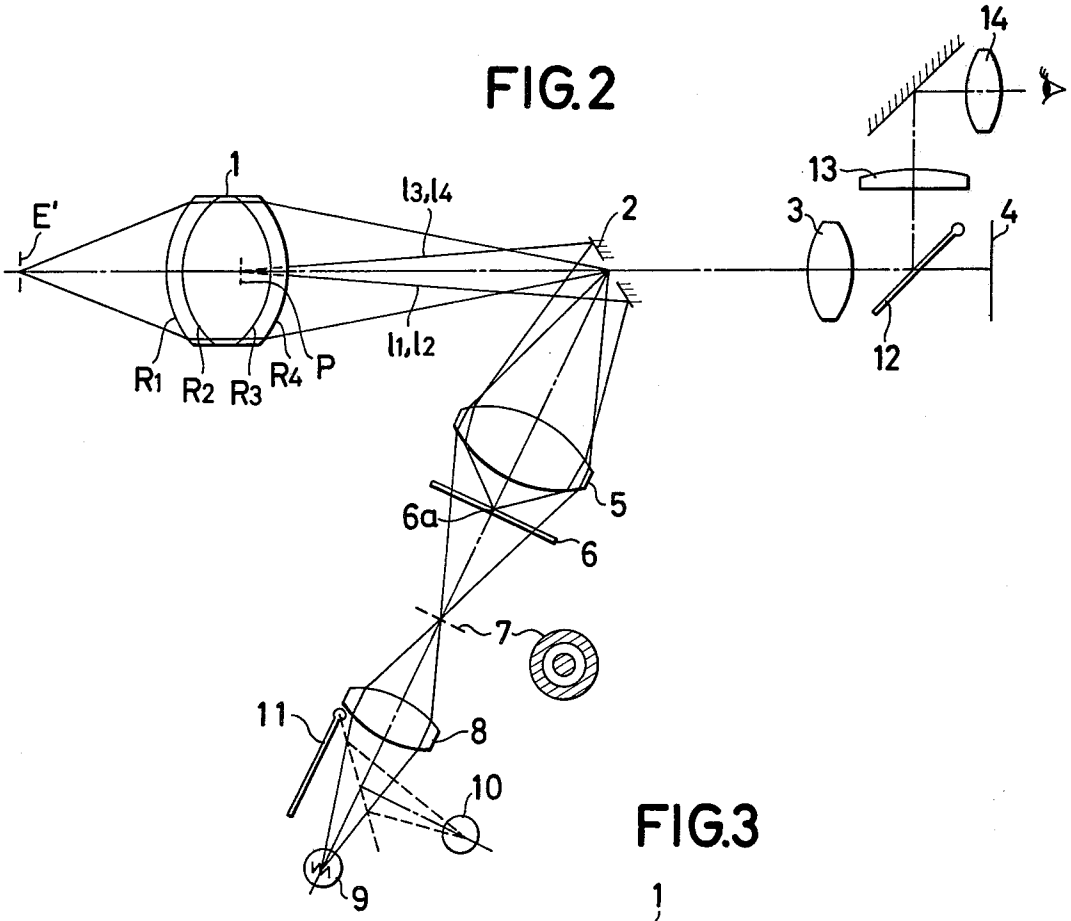

FIG. 3

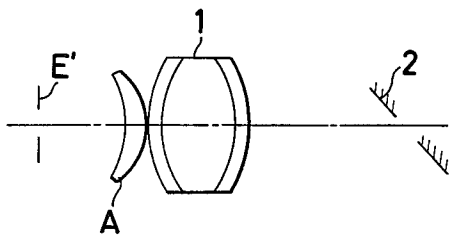

WIDE ANGLE OBJECTIVE FOR OPHTHALMOSCOPIC INSTRUMENT

BACKGROUND OF THE INVENTION

This invention relates to ophthalmoscopic instruments, and more particularly to a wide angle achromatic photographic objective for use in such ophthalmoscopic instruments.

In conventional ophthalmoscopes and eye-fundus cameras, a large proportion of the objectives are formed as a positive meniscus lens convex toward an object (human eye). With this type objective, however, the angle of view has to be limited to about 30 degrees or less, or otherwise a substantially lowered picture quality will be resulted.

To increase the angle of view up to about 45 degrees, the objective preferably takes a biconvex form. When a chromatic correction is required, the biconvex objective is generally designed to have a cemented surface or surfaces. This gives rise to introduction of disturbing reflections from the cemented surface or surfaces.

SUMMARY OF THE INVENTION

A primary object of the present invention is to increase the angle of view of an achromatic photographic objective for use in an ophthalmoscopic instrument.

A secondary object is to provide a wide angle achromatic objective with the cemented surfaces formed therein to a configuration suitable for eliminating the undesirable light reflected from the cemented surfaces as the illuminating light rays are projected through the objective to the cornea of an eye to be examined.

According to the present invention, the objective is constructed in the form of a triplet consisting of, in the direction in which the image forming rays enter, a negative meniscus lens convex toward the eye, a biconvex lens, and a negative meniscus lens concave toward the eye. By employing the biconvex form for the central constituent lens in the triplet, it is made possible to eliminate all the disturbing light reflections from the cemented surfaces as well as from the front and rear surfaces by limiting the necessary number of light obscuring spots to only one as arranged in the path of illuminating light rays.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram of one embodiment of an achromatic photographic objective according to the present invention with geometrical illustration of the effect on elimination of the disturbing reflections from the various surfaces thereof.

FIG. 2 is a schematic sectional view of an ophthalmoscopic camera with the objective of FIG. 1.

FIG. 3 is a lens block diagram showing an example of modification of the objective.

DESCRIPTION OF THE PREFERRED EMBODIMENT

In FIGS. 1 and 2 and especially FIG. 2, there is shown an ophthalmoscopic camera for photographing the fundus of an eye E with its pupil indicated at E'. The camera includes an achromatic photographic objective 1 and an image-forming lens 3 arranged along a common optical axis in starting from the object end in front of a photographic film 4. Positioned between the objective 1 and the image forming lens 3 is an apertured mirror 2 inclined at an angle to the optical axis with an aperture disposed at its center coincident to the optical axis. The mirror 2 constitutes part of an illuminating optical arrangement which further includes a relay lens 5 adapted to produce an image of a ring-shaped patch 7 on the mirror 2, a condenser lens 8 positioned behind the path 7 in optically alined relation thereto for selectively forming an image of either one of two light sources, namely, a filament coil of an incandescent lamp 9 and an arc of a flash-tube 10 on the path 7. A mirror 11 in the illuminating optical arrangement is pivotable between an illustrated position where the incandescent lamp 9 is selected for visual observation of the ocular fundus through a viewfinder optical system, and a position indicated by a dashed line where the flash-tube 10 is selected for the exposure of the film 4. The viewfinder optical system comprises a reflex mirror 12 movable between a viewing position illustrated and a non-viewing position, a field lens 13, and an eye-piece 14. When the mirror 12 is in the viewing position, a final image of the ocular fundus is formed on the field lens 13 and can, therefore, be viewed by an eye of an observer looking through the eye-piece 14. It is to be noted here that instead of using the eye-piece 14 a collective lens may be used in combination with a pick-up tube with its image receiving surface being position in coincidence with the focal plane of the collective lens, so that an image of the ocular fundus is displayed on the Braun tube.

With this illuminating optical arrangement, it is possible to illuminate an annular zone of the pupil E' while the central portion remains unilluminated, as the objective 1 is adapted to project a final image of the ring-shaped patch 7 on the plane of the pupil E'. The image forming rays reflected from the retina and emerging from the pupil E' are collected by the objective 1 to form an intermediate image of the retina in front of the illuminating mirror 2. The size of the aperture of the illuminating mirror 2 is adjusted so that only that portion of the emergent rays from the pupil E' which passes through the unilluminated central portion thereof is allowed to pass through the aperture of the illuminating mirror 2. That portion is then focused by the image forming lens 3 on the film 4, provided that the mirror 12 is in the non-viewing position. An image of the fundus of the eye E is thus recorded on the film 4.

The illuminating light rays are incident on the front and rear surfaces R_1 and R_4 respectively in a direction opposite to that of the image forming rays. Hence a certain fraction of the illuminating rays is reflected from the rear surface R_4 so they diverge, and an additional fraction is reflected from the front surface R_1 so they converge. Both serve as disturbing incident light on the film 4. It is known that such disturbing light reflections can be eliminated, as, for example, disclosed in Japanese Patent Application Publication No. Sho 44-8406 and No. Sho 47-44645. However, no care has been taken of the disturbing reflections from the cemented surface or surfaces in the achromatic objective.

FIG. 1 shows one embodiment of the photographic objective according to the present invention the lens is constructed in the form of an achromatic triplet 1 consisting of a negative meniscus lens 1*a* convex toward the eye E to be photographed, a biconvex lens 1*b*, in this instance, equiconvex lens, and a negative meniscus lens 1*c* concave toward the eye E cemented at their adjoining surfaces. The material of the two negative meniscus lenses 1*a* and 1*c* has a higher index of refraction and a

lower Abbe number than those of the material of the positive lens **1***b*.

In order to produce a beam of image forming light rays free from disturbing incident light rays between the objective **1** and the illuminating mirror **2**, specific requirements are set forth as follows. Assuming now that a light ray, l_0, emanating from a point P on the central plane of the aperture of the illuminating mirror **2** impinges on the objective **1**, four different virtual image points P_1, P_2, P_3 and P_4 are formed at different positions within the body of the objective by respective reflected rays, l_1, l_2, l_3, and l_4, from the respective surfaces R_1, R_2, R_3 and R_4 after the necessary successive refractions at the incident surfaces. In order to eliminate the four reflected rays, therefore, it is necessary to provide four black spots in the illuminating optical arrangement at respective positions conjugate to those of the virtual image points P_1 to P_4. If the positions of these four black spots deviate from one another to a large extent, the possibility arises of a lack of uniformity of illumination over the entire area of the fundus of the eye E. This would happen even when two of the image points, namely, P_1 and P_4 are made to coincide with each other by means known in the art.

According to the present invention, the four surfaces R_1 to R_4 are oriented in the same direction in each pair of adjacent surfaces, that is, in the front pair of surfaces R_1 and R_2, and the rear pair of surfaces R_3 and R_4, so as to bring the image points P_1 and P_4 into coincidence at a point, and the image point P_2 and P_3 into coincidence at that point. Thus the number of black spots necessary can be reduced to only one. Also provided for is the proper adjustment of the size of the spot. In the latter connection, it is to be noted that the size of the black spot can be minimized when the magnitudes of the virtual images points P_1 and P_4 of the spot are made equal to each other. To achieve this, it is required that the radii of curvature of the surfaces, R_1 and R_4 and the axial thicknesses of the constituent lenses, d_1, d_2 and d_3, must fulfill the following relationships:

$$|R_1| = |R_4| = d_1 + d_2 + d_3 \quad (1)$$

$$|R_2| = |R_3| = d_2 \quad (2)$$

$$d_1 = d_3 \quad (3)$$

Referring again to FIG. **2**, there is shown an example of arrangement and construction of a single black spot. This single black spot **6***a* is provided on a transparent plate **6** located between the relay lens **5** and the ring-shaped patch **7** at a point conjugate to that point at which the four image points P_1 to P_4 coincide with one another with respect to the combination of the illuminating aperture mirror **2** and the relay lens **5**. The size of the black spot **6***a* is found to be determined by the size of the aperture of the mirror and the magnifying power of the relay lens **5**. Because the magnitudes of the virtual images P_2 and P_3 are usually smaller than those of the virtual images P_1 and P_4, the size of the black spot **6***a* depends upon the latter images. Further, it is not necessary to establish the exact coincidence of the positions of the virtual images, because a small deviation therefrom can be compensated for by a small increase in the size of the spot.

An example of a specific achromatic triplet may be constructed in accordance with the numerical data given in the following table for the radii, R_1 to R_4, the lens thicknesses, d_1 to d_3, along with the corresponding indices of refraction, nd_1 to nd_3, for the spectral D line of sodium, and the Abbe numbers, Vd_1 to Vd_3, of the various lenses. The minus values of the radii, R_3 and R_4, indicate surfaces concave toward the image forming incident light. Instead of using the spherical surface as R_4, an aspheric surface may be used. In this case, the standard spherical surface for the aspheric surface applies to the relationships.

Focal length	f = 100	Angle of view	2ω = 45°
$R_1 = 95.70$			
	$d_1 = 9.57$	$nd_1 = 1.7552$	$Vd_1 = 27.5$
$R_2 = 76.56$			
	$d_2 = 76.56$	$nd_2 = 1.6170$	$Vd_2 = 62.8$
$R_3 = -76.56$			
	$d_3 = 9.57$	$nd_3 = 1.7552$	$Vd_3 = 27.5$
$R_4 = -95.70$			

As shown in FIG. **3**, the photographic objective of the present invention may include an aplanatic lens A as has already been proposed in a U.S. patent application Ser. No. 797,636 assigned to the assignee of the present invention. If so, the aplanatic lens A must be positioned in front of the triplet **1** of FIGS. **1** and **2** with the center of curvature of the front surface of lens A being in coincidence with the center of the aperture of the pupil E'. The rear surface of the lens A is an aplanatic surface.

What is claimed is:

1. An opthalmoscopic optical instrument having a wide angle of view of an object comprising;

objective lens means having a positive refractive power and including a triplet cemented lens consisting of a negative meniscus lens convex toward the object, a biconvex lens and a negative meniscus lens concave toward the object; said triplet cemented lens having outer lens surfaces and cemented surfaces

an image forming lens for re-imaging an image formed by said objective lens means; and

an illuminating system having at least one light source for illumination of the object, apertured mirror for directing the illuminating light rays toward the object, and optical means for transmitting the light rays emanating from said light source to said apertured mirror, said apertured mirror being positioned on the object end of said image forming lens group; said apertured mirror being positioned between said objective lens means and said image forming lens; masking means positioned between said light source and said apertured mirror for substantially eliminating reflection from the outer lens surfaces and cemented surfaces of said triplet cemented lens; light-detecting means positioned on the image end of said image forming lens and light directing means positioned between said image forming lens group and said light-detecting means to direct the imaging light to an observing system for observation of an image of the object.

2. An ophthalmoscopic optical instrument according to claim **1**, wherein said negative meniscus lens, biconvex lens, and negative meniscus lens are cemented together in the order stated.

3. An ophthalmoscopic optical instrument according to claim **2**, wherein the radius of curvature of each of the outer two negative meniscus lenses is substantially equal to the sum of the axial thicknesses of the two negative meniscus lenses and the biconvex lens, and

each radii of curvature of the surfaces of the biconvex lens is equal to the axial thickness of the biconvex lens.

4. An ophthalmoscopic optical instrument according to claim 1, wherein said optical means comprises a condenser lens group and a relay lens group.

5. An ophthalmoscopic optical instrument having a wide angle of view of an object comprising:

objective lens means having a positive refractive power and including a triplet cemented lens, said triplet cemented lens having a negative meniscus lens convex toward the object, a biconvex lens and a negative meniscus lens concave toward the object in the order mentioned;

an image forming lens for re-imaging an image formed by said objective lens means;

an illuminating system including at least one light source for illumination of the object, beam-reflecting means for directing the illuminating beam toward said objective lens means, and optical means for transmitting the beam emanating from said light source to said beam-reflecting means, said beam-reflecting means being positioned on the object end of said image forming lens; and

masking means positioned between said light source and said beam reflecting means for preventing the reflection of light at the lens surfaces of said triplet cemented lens;

the respective radii of outer surface of said triplet cemented lens being substantially equal to the compound axial thickness of said triplet cemented lens and the respective radii of the surfaces of said biconvex lens being substantially equal to the axial thickness of said biconvex lens.

6. An ophthalmoscopic optical instrument in accordance with claim 5, wherein one of the outer surfaces of said triplet cemented lens is aspherical.

7. An ophthalmoscopic optical instrument having a wide angle of view of an eye to be inspected comprising:

objective lens means having a positive refractive power and including at least one aplanatic meniscus lens concave toward the eye and a triplet cemented lens, said triplet cemented lens including a negative meniscus lens convex toward the eye,

a biconvex lens and a negative meniscus lens concave toward the object and arranged in sequence from the object,

an image forming lens for re-imaging an image formed by said objective lens means,

an illuminating system including at least one light source for illumination of the eye, beam-reflecting means for directing the illuminating beam toward said objective lens means, optical means for transmitting the beam emanating from said light source to said beam-reflecting and a masking means for preventing the reflection of light at the lens surfaces of said triplet cemented lens, said beam-reflecting means being positioned between said objective lens means and said image forming lens,

the center of curvature of the front surface of said aplanatic meniscus lens substantially coinciding with the center of the pupil of the eye to be inspected.

[57] **ABSTRACT**

The correlated positions of two axially shiftable components of a varifocal objective, i.e., a variator and a compensator, throughout a zoom range are stored in a memory from which they can be read out to control respective drives during a zooming operation. The readout rate is determined by a speed selector which sets a frequency for the pulsing of a control unit that scans successive memory addresses. The memory may also contain data for focusing control, either through axial adjustment of a front component of the objective or through modification of the positional correlation of the two shiftable components, as well as for an adjustment of a diaphragm with changes in the overall focal length.

FIG. 6

CONTROL SYSTEM FOR VARIFOCAL OBJECTIVE

CROSS-REFERENCE TO RELATED APPLICATION

This is a continuation-in-part of my application Ser. No. 778,933 filed 18, Mar. 1977 and now abandoned.

FIELD OF THE INVENTION

My present invention relates to a system for the control of a varifocal or zoom objective in an optical system such as a photographic, cinematographic or television camera or a copier.

BACKGROUND OF THE INVENTION

Conventional varifocal objectives comprise several (usually four) components of which two, generally the second and the third one, are axially shiftable to vary the overall focal length. The first of these axially shiftable components, termed a variator, determines that overall focal length whereas the second one, termed a compensator, maintains the position of the image plane constant throughout the zoom range. Thus, the positions of these shiftable and usually negatively refracting components are correlated in a predetermined manner according to a nonlinear law of relative displacement. Frequently, the objective also has a (usually positively refracting) front component which is limitedly axially adjustable, or includes an axially adjustable lens member, for focusing purposes. Alternatively, focusing (i.e. a change in the object distance) can also be carried out by modifying the relative position of the axially shiftable components used for zooming, yet this is more complicated since the extent of the supplemental shift required for focusing varies with the selected overall focal length.

In commonly owned U.S. Pat. No. 4,008,951 there has been disclosed a control mechanism in which the position of the second shiftable component, i.e., the compensator, is changed in response to stepping pulses generated upon the displacement of the first shiftable component, i.e., the variator, to maintain the requisite positional correlation of the two components.

A somewhat similar system has been described in German published specification No. 2,410,744 and corresponding U.S. Pat. No. 4,043,642 wherein the variator and the compensator are provided with respective position sensors working into a computer which sends corrective signals to the compensator drive for establishing the proper correlation. The operation of the computer may be modified to focus the objective upon an object located at a certain distance therefrom. The intervention of a computer in the positioning of the compensator introduces a certain delay into the adjustment of the compensator, thereby limiting the speed of the zooming operation. This delay, and the complexity of the computer, is aggravated if focusing is to be performed by modifying the positional correlation of the two shiftable components.

OBJECTS OF THE INVENTION

The general object of my present invention, therefore, is to provide a simplified control system for the purpose set forth.

Another object is to provide a control system which can be realized at moderate cost but whose sophistication can be increased at will for greater precision and/or a larger number of adjustment positions.

SUMMARY OF THE INVENTION

In accordance with my present invention, the correlated positional data for the two axially shiftable zooming components of a varifocal objective are stored in a memory from which sequences thereof are concurrently read out to respective drive means with the aid of control means having input connections to a source of zooming signals and, advantageously, also to a source of focusing signals. The focusing signals may be fed to a separate drive for another component of the objective, such as a front lens, or may be used to switch the readout among different sets of correlated positional data stored in the memory. The data read out from the memory can also be used, pursuant to a further feature of my invention, for the adjustment of a diaphragm in order to take into account the variations in luminosity occurring along the zoom range.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my present invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** is a diagrammatic overall view of an optical zooming system according to my invention;

FIG. **2** is a block diagram of an assembly of the control and drive units forming part of the system of FIG. **1**;

FIG. **3** is a block diagram similar to FIG. **2**, illustrating a modification;

FIG. **4** is a view similar to FIG. **1** of another optical zooming system according to the invention;

FIG. **5** shows details of a control unit included in the system of FIGS. **1–3**; and

FIG. **6** shows details of a control unit and a memory included in the system of FIG. **4**.

Specific Description

In FIG. **1** I have illustrated a conventional varifocal objective with a positive front component **17**, an axially shiftable negative component or variator **1**, an axially shiftable negative component or compensator **2**, and a fixed positive rear component **18** which may be part of a larger group of fixed lens members not further illustrated. An iris diaphragm **20** is inserted between components **2** and **18**.

Shiftable components **1** and **2** are provided with respective electromechanical driving units **5** and **6**; a similar driving unit **27** serves for a limited axial adjustment of front component **17** in order to focus the objective upon objects at different distances from component **17**. Driving units **27**, **5** and **6** are individually energizable by setting voltages appearing on output leads **33**, **31** and **32** of a read-only memory **3** which can be preprogrammed or selectively masked to provide a predetermined correlation between the voltages appearing at any one time on leads **31** and **32**. Diaphragm **20** is adjustable by a driving unit **28** energizable by memory **3** via another output lead **30**. Memory **3** is addressed by a control unit **4** to which signals are fed on respective input leads **34**, **35** and **36** from a focal-length selector **21**, a distance selector **19** and a speed selector **8** which may be manually operated. The selectors may be potentiometers producing variable d-c voltages; in the case of speed selector **8**, that d-c voltage is fed to a voltage/frequency

converter 7 emitting a train of stepping pulses of variable repetition frequency or cadence.

The voltage on lead **34** establishes the position within the zoom range to which the objective is to be adjusted at a speed determined by the cadence of the stepping pulses on lead **36**. Independently thereof, the voltage on lead **35** gives the displacement of front component **17** in order to focus the objective upon a desired object. Focal length, object distance and zooming speed may be indicated by suitable markings on the corresponding selectors.

Control unit **4** has two outputs **37** and **38** respectively addressing the zooming section and the focusing section of memory **3**. Output leads **30**, **31** and **32** extend from the zooming section whereas lead **33** originates at the focusing section. Leads **30–32** pass through a gate switch **26** which can be manually opened, upon attainment of a desired overall focal length, to halt the shifting of components **1** and **2** as well as the concomitant adjustment of diaphragm **20** regardless of the actual setting of selector **21**. Lead **30** terminates at an input **28'** of diaphragm drive **28** which also has another input **28''** for changing the diaphragm aperture; input **28''** may be energized manually, or automatically from a photometer. The setting signals from the two inputs are added electrically or mechanically, e.g. via a differential gearing.

As shown in FIG. **2**, the variator drive **5** and the compensator drive **6** comprise respective servomotors **9** and **10** provided with position sensors **11** and **12** which in this instance are of the analog type. The output signals of sensors **11** and **12** are fed back to the inputs of the associated servomotors by way of respective differential amplifiers **9'** and **10'** also receiving the signals on leads **31** and **32**, read out in digital form from memory **3**, via respective digital/analog converters **13**, **14**. Thus, the two servomotors operate in a forward or reverse direction until their input signals match the feedback signals from the position sensors. The driving units **27** and **28** for front component **17** and diaphragm **20**, not shown in FIG. **2**, may be similarly constituted.

In FIG. **3** the servomotors **9** and **10** work into digital position sensors **15** and **16**, thus obviating the need for digital/analog converters **13** and **14**.

The system of FIG. **4** differs from that of FIG. **1** in that the front component **17** of the varifocal objective is axially fixed and focusing is carried out by a supplemental shift of compensator **2** through a modification of the setting signals read out to driving unit **6** from memory **3**. A modified control unit **45** is used for this purpose to address the memory **3**, in response to selector signals on leads **34–36**, via connections **37'** and **37''** commanding the readout of certain positional data stored in the memory. Output leads **31** and **32** have branches addressing a further data store **24** for the readout of digital setting signals into a digital/analog converter **25** working into the input **28'** of diaphragm drive **28**.

Reference will now be made to FIG. **5** for details of the control unit **4** shown in FIGS. **1–3**. That unit comprises a reversible pulse counter **39** which receives the stepping pulses on input lead **36** and energizes an output lead **40** with a voltage proportional to its count. Leads **34** and **40** extend to respective inputs of a comparator **41** whose output directs the incoming stepping pulses, via an electronic switch **42**, to a forward-counting or a backward-counting input of counter **39** depending on the relative polarity of the voltages on these leads. When the two voltages are equal, counter **39** is stopped.

The output voltage of the counter is also applied to a switching input of a multiplexer **43** for directing a reading voltage V to any one of a number of leads forming part of a multiple which constitutes the output **37** of unit **4**. Another multiplexer **44** is switched by the setting signal on lead **35** to energize one of several leads in a multiple constituting the other output **38**. Each lead of multiple **37** has three branches terminating at homologous address inputs of respective sections of memory **3**, i.e., a first section delivering the setting voltage for driving unit **5** on lead **31**, a second section delivering the setting voltage for driving unit **6** on lead **32** and a third section delivering the setting voltage for driving unit **28** on lead **30**. The leads of multiple **38** extend to respective address inputs of a fourth memory section from which the setting voltages from driving unit **27** are read out on lead **33**. Thus, with gate switch **26** (FIG. **1**) closed, a given signal voltage on lead **34** will establish the selected focal-length setting and a corresponding diaphragm adjustment in successive increments determined by the stepping pulses on lead **36** whose cadence may be so chosen, for example, that the entire zoom range is traversed in a time period varying from 1 second to 10 minutes.

FIG. **6** shows a possible layout of the modified control unit **45** of FIG. **4** together with that of memory **3** which in this instance is divided into a multiplicity of cells forming an orthogonal array with columns A–H and rows a, b_1–b_8; the number of columns or rows in the array can of course be different from that shown. The cells of the top row a contain the positional data for variator **1**, to be read out on lead **31**; the cells of any one row b_1–b_8 contain the positional data, applicable to a given object distance, for compensator **2** which are to be read out on lead **32**.

An address generator **21** in unit **45**, which may comprise the pulse counter **39**, the comparator **41** and the electronic switch **42** of FIG. **5**, has its output lead **40** connected to a switching input of a multiplexer **22** having output multiples **37'** and **37''**, only one lead of multiple **37'** and a few leads of multiple **37''** having been shown for the sake of clarity. Reading voltage appearing on an output lead **46** of address generator **21** is fed to multiplexer **22** in order to address one of the cells of top row a of memory **3** as selected by the voltage on lead **40**. Another output lead **47** of address generator **21** applies reading voltage to a second multiplexer **23** whose output multiple **48** scans the rows b_1–b_8 of memory **3**, under the control of focusing voltage on lead **35**, through the intermediary of multiplexer **22**. Thus, if multiplexer **22** receives on lead **40** a voltage corresponding to column A of memory **3**, cell A/a will be addressed by the illustrated lead **37'** together with one of the other cells in column A, depending on which of the illustrated leads **37''** is energized in response to the voltage on lead **35**. If the energization of lead **40** changes, two memory cells in another column will be jointly addressed to set the variator **1** and the compensator **2** in a correlated manner determined by the selected focal length and object distance.

For the sake of low cost and high dependability, the several memory cells are preferably designed as semiconductors.

I claim:

1. In an optical zooming system wherein a varifocal objective has a plurality of components including an axially shiftable variator for changing its focal length

and an axially shiftable compensator for maintaining a constant image plane, the combination therewith of:

first drive means for axially shifting said variator;

second drive means for axially shifting said compensator;

memory means storing correlated positional data for said variator and said compensator;

a source of zooming signals; and

control means connected to said memory means and to said source for concurrently reading out respective sequences of said correlated positional data to said first and second drive means in response to said zooming signals whereby said variator and said compensator are axially shifted between different positions in a zoom range.

2. The combination defined in claim **1** wherein said control means includes a generator of stepping signals establishing a variable readout rate for said positional data to facilitate selection of different zooming speeds.

3. The combination defined in claim **2** wherein said generator comprises a voltage/frequency converter.

4. The combination defined in claim **1** wherein said objective is provided with focusing means for displacing another component thereof in response to distance data stored in said memory means, further comprising a source of focusing signals connected to said control means for the readout of said distance data to said focusing means.

5. The combination defined in claim **1** wherein said objective is provided with a diaphragm and with adjusting means for changing the diaphragm aperture, said memory means having an output connected to said adjusting means for automatically modifying said diaphragm aperture concurrently with a shifting of said variator and said compensator.

6. The combination defined in claim **1** wherein said control means is provided with separate inputs respectively connected to said source of zooming signals and to a source of focusing signals, said memory means containing different sets of correlated positional data selectable by said focusing signals for readout in response to said zooming signals.

7. The combination defined in claim **1** wherein said first and second drive means comprise each a servomotor coupled with the respective shiftable component, a sensor determining the instantaneous position of said respective component and feedback means for signaling said instantaneous position to said servomotor.

8. The combination defined in claim **7** wherein said positional data are stored in said memory means in digital form, said sensor being an emitter of digital signals.

9. The combination defined in claim **7** wherein said positional data are stored in said memory means in digital form, further comprising digital/analog conversion means inserted between said memory means and said servomotor, said sensor being an emitter of analog signals.

10. The combination defined in claim **1**, further comprising switch means inserted between said memory means and said first and second drive means for halting the shifting of said variator and said compensator independently of said zooming signals.

[57] **ABSTRACT**

This disclosure relates to a video microscope with wide potential range of magnification powers, including but not limited to from 10× to 1000× whose separate images originating from multiple objective lenses are combined on a half-silvered mirror and focused into a vidicon camera tube to produce a two dimensional composite image. Separation of the multiple objective lenses can be adjusted with a preloaded right-hand/left-hand lead screw arrangement without defocusing the image from either lens system. A third image such as a cross hair, grid pattern or graticule can be introduced via a light source which is projected on a silicon semiconductor wafer or other subjects through the objective lenses and in turn reflects as a composite image onto the face plate of the vidicon camera tube. The third projected image permits measurement of areas and linear dimensions of the subjects viewed. Digital null reference electronic techniques in the video output also is disclosed for auto correlation of images using servo controls. Selective deletion of scanning lines on a CRT viewing screen also provides a convenient means of measuring the vertical dimensions of subject matter being viewed, where the magnification in use in the system is accurately known. The viewed subjects are displayed on the cathode-ray tube (CRT) screen in a true relationship without image inversion, reversal or left-right ambiguity. Means are also disclosed for projecting an electronically generated image or laser beam onto the subject matter being viewed for optical printing or altering (i.e. trimming) the subject.

FIG. 3B

DUAL OR MULTIPLE OBJECTIVE VIDEO MICROSCOPE FOR SUPERIMPOSING SPACED IMAGES

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates generally to video systems, and more particularly, relates to video microscopes for comparing objects or images which can, for example, be used for aligning and locating the kerf between integrated circuit or discrete device chips formed in a silicon wafer.

2. Background of the Prior Art

In the past, fabrication of integrated circuit or discrete device chips from a single semiconductor wafer required the necessary step of separating the integrated circuit chips or, as the case may be, the discrete device chips. This separation step usually was known as a "sink and break" operation. In some cases a slurry saw was used to separate the chips without a sinking operation.

Several types of optical alignment systems are being used for positioning silicon wafers under a high speed diamond saw generally used for scribing circuit wafers. These prior art systems are all derivations of the binocular comparison microscope which was designed to superimpose two nearly identical images in registration for the purpose of examining image differences, if any.

Optical projection rather than viewing systems have been developed to reduce operator fatigue caused by the need to observe the work area through binocular eyepieces for extended periods. It should be observed that optical projection requires large aperture objective lenses, a high intensity light source and a complex arrangement of lenses and a projection screen which usually required a basic redesign of the work unit such as the alignment or processing machine.

There is also a limit to the intensity of visible and accompanying infrared light which can be projected onto work objects such as silicon wafers without risk of modifying their characteristics. Thus, optical projection systems designed for semiconductor wafer alignment usually have to be viewed in subdued light.

Accordingly, a need existed for a simplified object viewing or processing arrangement or a silicon wafer alignment system which provides a bright, sharp image from a comparatively low intensity light source and which can be easily incorporated into a wafer scoring or other micro viewing machine without extensive modifications. A need also existed for a projection system where the reproduced image of the viewed subject could be located to best serve the operator's requirements and where the reproduced image can be repeated at a supervisory position or elsewhere as often as desired.

SUMMARY OF THE INVENTION

Accordingly, it is an objective of this invention to provide an improved apparatus and method for comparing objects.

It is another object of this invention to provide an improved means of accurately aligning the margins or kerf areas between integrated circuits or discrete components on a silicon wafer for further processing by the scoring or scribing saw.

It is another object of this invention to provide an improved apparatus and method for providing alignment information of two or more superimposed images on a bright viewing screen of convenient size at a location which best serves the needs of the operator.

It is a further object of this invention to provide a means of laterally positioning two or more objective lenses over an object such as a silicon wafer or any focal plane surface with backlashfree differential screw controllers.

It is a still further object of this invention to provide an apparatus which has means to fix any objective lens of a multiple lens system over a point on the object's focal plane surface and move other objective lenses to desired points on the object's viewing plane with a simple screw controller mechanism.

It is still another object of this invention to provide an optical system with sufficient depth of focus to accommodate limited vertical variations in an essentially flat image and with inherent mechanical stability to produce a two dimensional image and to make refocusing and/or readjustment unnecessary during normal usage.

It is a still further object of this invention to provide an optical system which keeps the optical path length between viewing plane and a vidicon face plate constant between the outer and inner limits of the objective lenses regardless of whether multiple lenses are moved simultaneously, or only one objective lens is moved with respect to the other objective lenses.

It is a still further object of this invention to provide an optical system which facilitates projection of an accurately ruled grid pattern or linear scale on the focal plane surface of an object which will permit measurement of areas and linear dimensions of objects.

It is still another object of this invention to take advantage of the bilateral nature of optical transmission paths which will permit substitution of a small commercially available mini-CRT for a small commercially available vidicon and permit projection of two or more micro images on a focal plane surface, thus permitting a video microscope to be used as a micro printer for exposing silicon wafers or other light sensitive material or objects.

Alternatively, by installing an additional image splitter in series with the vidicon optical input, it is another objective of this invention to project the image from the mini-CRT onto the focal plane surface while viewing the result on the vidicon output screen.

It is a still further object of this invention to use the unused half of an image splitter to project another image from the subject plane surface or some other image source onto a vidicon face plate.

It is still another object of this invention to utilize, as an alternate to the mini-CRT projector of an optical system, a medium powered YIG or Niobium invisible output laser which can, for example, be used in a trimming operation.

The foregoing, and other objects, features, and advantages of the invention will be apparent from the following, more particular description of the preferred embodiment of the invention, as illustrated in the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a schematic diagram of the optical path through the dual or multiple objective video microscope of this invention from the right and left objective lens to the vidicon tube and from the light source to the illuminated area on each side of the object's turntable.

FIG. 2 is a simplified elevational, perspective view (with parts broken away) of the video microscope

showing mechanical construction and mechanisms for adjusting spacing of the objective lenses up and down movement for focusing and the viewing plane turntable adjustment.

FIGS. 3A and 3B depict block diagrams of electronic functions used for projection (black and white FIG. 3A, color FIG. 3B) of the dual or multiple optical input to the vidicon tube.

Referring to the schematic diagram of the optical paths shown in FIG. 1, the image on the right side of centerline 1, which is the centerline of a silicon wafer (not shown), turntable 2, passes through an objective lens 3A thence to a plane mirror 4A, to plane mirror 4B and to a half-silvered image-splitting mirror 5 which reflects the right side image from lens 3A into a vidicon tube 9. This path is shown by line 9B/9A.

The image on the left side of the centerline 1 is brought into focus from the wafer turntable 2 by objective lens 3B. The image then goes to plane mirror 4C, reflected through half-silvered mirror 5 to the vidicon tube 9. The optical path for the left image is shown by line 9C/9A.

A light source with condensing lens 6 is installed on the microscope centerline 1. The parallel beams from light source and lens system 6 go through the half-silvered mirror 5 to the plane mirror 4B, then to the plane mirror 4A, through the right side objective lens 3A to illuminate an area equal to the field of vision of the right microscope image. The path of the light source and lens system 6 to the right-hand image is shown by line 6A/6B. The image-splitting properties of the half-silvered mirror 5 reflect light from the combined light source and lens system 6 to mirror 4C, thence to the objective lens 3B which illuminates the field on the left-hand side of the video microscope. The path from the combined light source and lens system 6 to the left-hand image is shown by line 6A/6C.

A line grid, linear scale, cross-hair or secondary image can be projected simultaneously on the right and left side of the wafer turntable 2 by introducing a prepared slide at 7, below the condensing lens combined with light source 6. The projected image from the slide 7 is reflected in focus via optical paths 9C and 9B to 9A and to the vidicon tube 9.

A rigid mechanical linkage couples the vidicon tube 9 to the mirror 4C is indicated by reference numeral 8. The purpose of the rigid mechanical linkage 8 is to keep the optical path length uniform from the wafer turntable 2 through the objective lenses 3A and 3B to the vidicon tube 9 throughout lateral adjustment of the objective lenses 3A and 3B from their inner and outer limits of spacing from the centerline 1. The location of the centerline 1 and the position of the image-splitting mirror 5 and the combined light source and lens 6 is unchanged by adjustment of the objective separation lead screw (not shown in FIG. 1) which moves the objective lenses 3A and 3B laterally.

The optical path lengths shown schematically in FIG. 1 shows that, if the objective lens 3B is moved farther from the centerline 1, the optical path from the image-splitting mirror 5 and the plane mirror 4C is increased. If at the same time, the objective lens 3A is moved farther from the centerline 1, the optical path length from the plane mirror 4A to the plane mirror 4B is increased. This increase in optical path length to the objective lenses 3A and 3B is compensated by the rigid coupling of vidicon tube 9 through the linkage 8 to the mirror 4C. Thus, a lengthening of the optical paths to the mirror 4C, and to the mirror 4B to the mirror 4A is compensated by a shortening of the optical path from the stationary image-splitting mirror 5 to the moving vidicon tube 9. A secondary image splitting mirror may be installed as shown at 5A of FIG. 1. This secondary mirror 5A is also connected to the linkage 8. A mini-CRT or laser unit is installed as shown at 6E in FIG. 1 and is also connected to the linkage 8. The CRT or laser output from the unit 6 goes alone path 6C to the secondary mirror 5A where it is reflected to the main image splitter 5 of FIG. 1. The laser output from the unit 6B (FIG. 1) or 32A (FIG. 2) can be used, for example, to trim thick or thin film resistors located on the table 2 (FIG. 1) or table 10 (FIG. 2). The lower side of the secondary image-splitter mirror 5A may be used to feed a fifth image into the vidicon 9 via the optical path shown at 6 of FIG. 1. This fifth image would come from a third objective lens (not shown). Similarly, if desired, additional objective lenses can be added with corresponding additional image splitters.

FIG. 2 is a perspective, elevational view (with parts broken away) of the image comparison video microscope. Not shown are mounting arrangements which would be used to support the video microscope.

For example, a silicon wafer (not shown) requiring alignment for scribing is mounted on turntable 10 of FIG. 2 which is designed for angular rotation by worm and wheel adjustment mechanism 12. Objective lenses 14A and 14B (or part of the entire video microscope) are focused by a rack and pinion arrangement (not shown) using a control or adjustment wheel 16 which moves the complete microscope unit up and down with reference to the focal plane surface of the turntable 10. Differential movement of the dual objective lenses 14A and 14B to equal distances from the video microscope centerline 20 is accomplished with control or adjustment wheel 18 which turns a RH/LH combined thread lead screw 18A. Not shown are the use of spring loaded nuts on the back of the microscope tubes 20A and 20B which removes backlash while driving the microscope tubes 20A and 20B simultaneously toward and away from the centerline 20. While the embodiment of FIG. 2 shows the use of two microscope tubes and driving mechanism therefor, it should be understood that more than two microscope tubes can be utilized with associated driving mechanisms. Plane mirrors which reflect the images from the objective lenses 14A and 14B to a half-silvered image-splitting mirror 24 are shown at 22A, 22B and 22C. If desirable, redesign of the video microscope can be accomplished so that the objective lens 14A and 14B is fixed with the other lens being movable. Linkage 26 of FIG. 2 (corresponding to linkage 8 of FIG. 1) couples movement of the video microscope tube 20B to vidicon tube 28. A cable for transmitting the video signal to a video amplifier 42 (see FIG. 3A) and for transmitting scanning frequencies from a time base generator 44 (see FIG. 3A) to the vidicon tube 28 is shown at 30.

The light source and condensing lens required to illuminate the video microscope subject matter under the objective lenses 14A and 14B is shown by reference numerals 32 (corresponds to reference numeral 6 of FIG. 1). A slide mounting platform which may be used for introducing a third image into the system is shown at 34 (corresponds to reference numeral 7 of FIG. 1). Slip joints which exclude external light but allow lateral motion of the microscope tubes 20A and 20B to and from the centerline 20 are shown at 36A, 36B and 36C.

A secondary image-splitting mirror is shown at **24A** of FIG. 2. This splitter **24A** provides the means of introducing the output of a mini-CRT or laser unit **32A** into the image system terminating at the objective lenses **14A** and **14B**. The unused lower part of the splitter mirror **24A** provides an optical channel for introducing a fifth image to the vidicon tube **28**, if so desired.

Construction and Operation

The optical path length from the objective lens **14A** of FIG. 2 or objective lens **3A** (FIG. 1) to the image-splitting mirror (**5** in FIG. 1 and **24** in FIG. 2) must agree very closely with the optical path length from the objective lens **3B** to the mirror **5** (FIG. 1) or from the objective lens **14B** to the mirror **24** of FIG. 2. Control **16** in FIG. 2 moves the video microscope with reference to the viewing plane located in the turntable **10** thus focusing the right and left images together.

With respect to FIG. 1, the reflected images from the objective lenses **3A** and **3B** to the mirror **5** should be perpendicular to the plane of the wafer table **2** at all settings of the differential lead screw controlled by knob **18** (see FIG. 2). This means that the image centerline in the viewing tubes **20A** and **20B** must remain exactly parallel to all settings of the lead screw controlled by knob **18**. The angles of the plane mirrors **22A**, **22B** and **22C** must be set to 45 degrees within one or two seconds of an arc. If desired, optically finished prisms can be used as an alternative to the plane mirrors shown at **22A**, **22B** and **22C**. The planes of the 90 degree parts of the prism must be set exactly perpendicular to the image centerlines coming through the tubes **20A** and **20B**. These mechanical and optical requirements are to insure perfect registration of the right and left images at all settings of the lead screw controlled by the knob **18** and to prevent double imaging which would interfere with the azimuth setting capability of the video microscope of this invention.

The centerline of the video microscope (**1** in FIG. 1 and **20** in FIG. 2) must be exactly positioned over the center of the wafer turntable (**2** in FIG. 1 and **10** in FIG. 2). This requirement is to prevent undesired movement of the images when the turntable is rotated by the control mechanism **12**.

Other operational applications of the video microscope of this invention may include comparisons of individual circuits or devices on a chip or inspection of circuits or devices for visible defects. The dual or multiple image video microscope of this invention may also have application potential in ballistics comparisons, forensics or biological studies. Further operational applications of the video microscope of this invention may include usage of projected images from the mini-CRT (**6B** of FIG. 1 or **32** of FIG. 2) as an optical printer on a sensitized medium or to compare an electronically generated image with existing subjects or objects on the focal plane of the table **2** (FIG. 1) or **10** (FIG. 2). This electronically generated image technique could be used to reinforce, regenerate or correct an existing image. A driving source for the mini-CRT may be from the main cathode-ray tube (CRT) viewing unit via cable **46A** in FIG. 3, although alternate sources of electronically generated images, such as from unit **48** in FIG. 3, can be provided. As noted above, more than three directly viewed images can be accommodated by adding additional image splitters, objective lenses and associated supporting elements.

If magnification greater than 1200 power is desired, reproduced detail can be improved by operation of the video amplifier **42** (FIG. 3A) and time base generator **44** (FIG. 3A) at 1050 lines per frame at 15 frames per second instead of the conventional 525 lines per frame at 30 frames per second.

If operational applications would be enhanced by color reproduction, the video microscope of this invention can be adapted to color through usage of the three-channel red, green, blue "RGB" system as shown in FIG. 3B.

Functional Electronic Block Diagram

FIG. 3A is a simplified electronic block diagram showing the technique for processing the output of, for example, a 0.6 inch electrostatically scanned vidicon camera tube **40** and presenting the viewing results on a 12" to 20" (diagonal) monitor cathode-ray tube (CRT) **46**. The vidicon camera tube **40** drives the video amplifier **42** using a low capacity cable **41** (**30** in FIG. 2). For high definition reproduction, the video amplifier **42** should have a response to 8 Mhz. The output of the video amplifier **42** is connected to the CRT reproduction unit **46** via cable **43**. Synchronized line and frame scanning signals are generated by the time base generator **44** which drives the vidicon camera tube **40** and the CRT reproduction unit **46** through cables **44A**. If the subjects being viewed are motionless, or relatively so, it would be possible to operate the vidicon unit **40** with a lower frame frequency and a higher line frequency and thus obtain higher definition.

For additional flexibility for the video microscope, the cable **43** also can be used to drive a digitizer unit **43A** which could be used if it was necessary for the video microscope to be used in an automatic image comparison mode. The digitizer **43A** also receives a signal on cable **48A** from unit **48** which is either an actual stored image or an electronically generated image. Cable **50A** feeds a null reference comparator **50** which generates servo signals to drive controls or knobs **12** and **18** (see FIG. 2). Within specified limits, a servoed version of the video microscope of this invention will seek out and match images stored in image storage unit **48**. Video images from the microscope system may be transferred to any other system or viewing apparatus.

If it is desirable or necessary that the dual or multiple objective video microscope produce images in color, it is possible to accomplish this object with electronics shown in the block diagram in FIG. 3B. The vidicon camera arrangement **40** shown in FIG. 3B preferably consists of three 0.6 inch electrostatically scanned stacked vidicon tubes. The incoming visual signal going into the camera **40** is split into three color components with a dichroic mirror assembly shown in outline form by reference numeral **40A**. The input visual signal emerges from the three vidicons as red, green and blue (RGB) signals which are individually amplified by three video amplifiers **42A**, **42B** and **42C** which are driven by three cables **41** from the vidicon unit **40**.

The RGB output of the video amplifiers **42A**, **42B**, **42C** is fed to the CRT reproduction unit **46** through three cables **43**, which include voltage adjustment resistors, to permit setting of the white level and adjustment of color values.

The CRT reproduction unit **46** may incorporate a three-gun color tube or any of the single gun color tubes. As shown in FIG. 3B, the time base generator **44**

drives the vidicon assembly 40 and the CRT reproduction unit 46 through cables 44A.

While the invention has been particularly shown and described in reference to the preferred embodiment thereof, it will be understood by those skilled in the art that changes in the form and details may be made therein without departing from the spirit and scope of the invention.

We claim:

1. An optical vidicon apparatus comprising, in combination, multiple objective lenses, a vidicon optically coupled to said multiple objective lenses, display means coupled to said vidicon to display images received by said vidicon, means for moving at least one of said multiple objective lenses toward and away from at least another of said multiple objective lenses, and means for maintaining the length of the optical path between said one of said multiple objective lenses and said vidicon substantially equal to the length of the optical path between said other multiple objective lenses and said vidicon.

2. An optical vidicon apparatus in accordance with claim 1 wherein said multiple objective lenses comprising two objective lenses, said display means comprising a CRT.

3. An optical vidicon apparatus in accordance with claim 1 wherein said means for moving at least one of said multiple objective lenses toward and away from at least another of said multiple objective lenses comprising means for moving both said one and said other of said multiple objective lenses toward and away from each other.

4. An optical vidicon apparatus in accordance with claim 3 wherein said multiple objective lenses comprising two objective lenses, said display means comprising a CRT.

5. An optical vidicon apparatus in accordance with claim 1 wherein said means for maintaining the length of the optical path between said one of said multiple objective lenses and said vidicon substantially equal to the length of the optical path between said other multiple objective lenses and said vidicon comprising reflecting means located in the optical paths for transmitting the images of objects to said vidicon.

6. An optical vidicon apparatus in accordance with claim 5 wherein said means for maintaining the length of the optical path between said one of said multiple objective lenses and said vidicon substantially equal to the length of the optical path between said other multiple objective lenses and said vidicon further comprising at least one image-splitting means for splitting images received from said multiple objective lenses.

7. An optical vidicon apparatus in accordance with claim 6 wherein said at least one image-splitting means comprising a half-silvered mirror.

8. An optical vidicon apparatus in accordance with claim 7 including light source means optically coupled to said multiple objective lenses for projecting a source of light through said multiple objective lenses onto objects viewed by said multiple objective lenses.

9. An optical vidicon apparatus in accordance with claim 8 wherein said light source means comprising a source of light and a condensing lens coupled to said source of light.

10. An optical vidicon apparatus in accordance with claim 7 including CRT means optically coupled to said multiple objective lenses for projecting an image back through said multiple objective lenses.

11. An optical vidicon apparatus in accordance with claim 7 including laser means optically coupled to said multiple objective lenses for projecting a laser beam back through said multiple objective lenses.

12. An optical vidicon apparatus in accordance with claim 1 including light source means optically coupled to said multiple objective lenses for projecting a source of light through said multiple objective lenses onto objects viewed by said multiple objective lenses.

13. An optical vidicon apparatus in accordance with claim 12 wherein said light source means comprising a source of light and a condensing lens coupled to said source of light.

14. An optical vidicon apparatus in accordance with claim 12 including CRT means optically coupled to said multiple objective lenses for projecting an image back through said multiple objective lenses.

15. An optical vidicon apparatus in accordance with claim 12 including laser means optically coupled to said multiple objective lenses for projecting a laser beam back through said multiple objective lenses.

16. An optical vidicon apparatus in accordance with claim 1 including CRT means optically coupled to said multiple objective lenses for projecting an image back through said multiple objective lenses.

17. An optical vidicon apparatus in accordance with claim 1 including laser means optically coupled to said multiple objective lenses for projecting a laser beam back through said multiple objective lenses.

18. An optical vidicon apparatus in accordance with claim 1 including fixed image means coupled to said light source means for projecting a fixed image back through said multiple objective lenses.

19. An optical vidicon apparatus in accordance with claim 1 wherein said vidicon having means for permitting images viewed by said vidicon received from said multiple objective lenses to be viewed in color.

20. An optical vidicon apparatus in accordance with claim 1 including means coupled to said moving means for the autocorrelation of images viewed by said multiple objective lenses.

21. A method for superimposing and comparing spaced images comprising the steps of:

moving at least one of a multiple of objective lenses toward and away from at least another of the multiple objective lenses;

viewing the multiple images received from the multiple objective lenses with a vidicon;

visually displaying the images received by the vidicon; and

maintaining the length of the optical path between the said one of the multiple objective lenses and the vidicon to be substantially equal to the length of the optical path between said other of the multiple objective lenses and the vidicon.

22. A method in accordance with claim 21 wherein said multiple objective lenses being two.

23. A method in accordance with claim 21 including the steps of illuminating using a light source objects viewed by multiple objective lenses.

24. A method in accordance with claim 23 including the steps of projecting a static image between the light source and the multiple objective lenses to provide a measurement or comparison image.

25. A method in accordance with claim 23 including the step of visually displaying in color the images received from the vidicon.

26. A method in accordance with claim 23 including the step of autocorrelating images viewed by the multiple objective lenses to control the positioning of the multiple objective lenses.

27. A method in accordance with claim 21 including the step of projecting an electronically generated image back through the multiple objective images.

28. A method in accordance with claim 21 including the step of projecting a laser beam back through the multiple objective lenses.

29. A method in accordance with claim 21 including the step of visually displaying in color the images received from the vidicon.

30. A method in accordance with claim 21 including the step of autocorrelating images viewed by the multiple objective lenses to control the positioning of the multiple objective lenses.

[57] **ABSTRACT**

Apparatus for indicating and displaying the focus of an optical objective and particularly a photographic camera. An image of the object is projected by means of the objective onto a scanning disk or plate where the light rays are divided into two separate light beams originating from two different areas of the exit pupil of the objective. Two photoelectric detectors are provided behind said scanning disk with one of said light beams impinging on one detector. Each detector delivers an electrical signal, the phase difference between these signals being a measure of the degree of focus of the objective. For indicating said degree of focus two LED's (Light Emitting Diodes) are provided which are so coupled that for focus (phase difference = null) they are equally luminous and that for lack of focus they indicate the direction of the image offset from the focusing plane and approximately also the magnitude of this offset on account of their special coupling and their change in luminosity which is independent of object brightness.

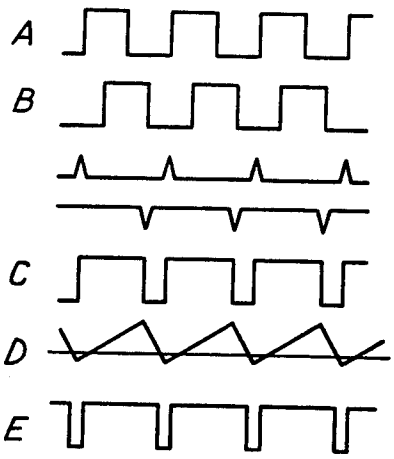

Fig. 4

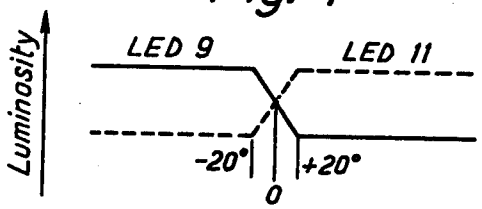

OPTICAL OBJECTIVE FOCUS INDICATOR AND DISPLAY

The present application is a continuation of application Ser. No. 711,462 filed Aug. 5, 1976 and now abandoned.

BACKGROUND OF THE INVENTION

The present invention relates to apparatus for indicating and displaying the focus of an objective, in particular that of a photographic camera.

It is known to the prior art, as regards focusing of objectives, to project an image of the object onto a scanning disk or plate located in one image plane of the objective. This disk or plate comprises a grating being moved normal to its grating lines. The light rays impinging on this grating are split into two separate light beams which originate from different areas of the exit pupil of the objective. Two photoelectric detectors are provided behind the scanning disk or plate, each of which delivers one electrical signal, the phase difference between the two signals representing a measure of the focus or lack of focus of the objective.

It is known to use a phase difference signal to control a servo motor displacing the objective by means of gearing into one direction or the other until the phase difference is null, that is, until the objective is focused on the object.

However, the objectives to be displaced frequently are fairly heavy, so that their displacement requires significant power and a strong motor is required, which in turn often is packaged only with difficulty in optical instruments. This is especially the case for camera objectives having long focal lengths.

The state of the art of scanning disks and gratings in combination with photoelectric detectors therebehind for measuring the focus of objectives may be ascertained by reference to U.S. Pat. Nos. 3,781,110 and 3,833,299 the disclosures of which are incorporated herein. The state of the art of the circuitry for auotomatic comparison of two beam photoelectric radiation may be ascertained by reference to U.S. Pat. No. 3,255,355, the disclosure of which is incorporated herein.

Having the above limitations in mind, it has been proposed therefore to make use of a simple control in lieu of a closed loop, that is, to provide semi-automatic focus instead of a fully automatic one, the objective being adjusted manually and a special focus indicator being provided.

Conceivably such a focusing display might be a simple measuring unit requiring displacing the objective until a given pointer position is reached. Such a measurement unit however will be disadvantageous if the light conditions for the object are poor, that is, when the object is fairly dark, because there would be difficulties in reading the pointer position.

SUMMARY OF THE INVENTION

Having the above in mind, it is an object of the present invention to have a focus display which would be largely independent of the object's brightness or illumination.

The present invention achieves this objective by providing a focus display consisting of a photo scale of two LEDs (Light Emitting Diodes) which are so powered as to be equally luminous for full focus (phase difference = 0). These LEDs because of their special circuitry ascertain the direction of the offset of the image from the focusing plane by their changes in luminosity independent of the object brightness when there is defocusing, and furthermore approximately also the amount of this offset.

Such a focusing display is independent of the object brightness whenever the luminosity of the LEDs of the photo scale depends only on the phase difference of the signals supplied by the photodetectors. If there is zero phase difference, both LEDs will be of an even and median luminosity. But if there is a phase difference, one of the LEDs will be brighter than the other, this difference in luminosity depending only on the phase difference and being independent of the object brightness.

However, in order to prevent any swamping of the view finder, it is desirable to adapt the median luminosity of the LEDs to the brightness of the view finder, that is, the LEDs are the more luminous the brighter the object, and the less luminous the lower the object brightness.

To make such allowance, it is further proposed to couple the two LEDs so that their median luminosity varies with object brightness.

When the display system of the present invention is used to indicate objective focus in a photographic camera, then preferably the two LEDs should be mounted approximately at the center of the view finder, and in particular so that they are visible at the edge of the part of the image field being evaluated.

BRIEF DESCRIPTION OF THE DRAWING

Further objects and features of the present invention may be ascertained by reference to the accompanying drawings wherein:

FIG. **1** is a schematic circuit drawing of one embodiment of the present invention;

FIG. **2** is a graphical representation of the signal processing in the circuit of FIG. **1** when the object is in focus;

FIG. **3** is a graphical representation of the signal processing of FIG. **1** when the objective is out of focus; and

FIG. **4** is a graphical representation of the luminosity angle relationship of the two LEDs.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The circuit shown in FIG. **1** is provided with two inputs A and B fed with square wave pulses from photoelectric detectors. These pulse trains are in phase for focus. Each input A and B is followed by a differentiator consisting of two diodes **1,2** and **3,4** and one resistance **5,6**.

A reset flip-flop RSFF is connected to the outputs of the differentiators, its own output being connected to an integrator in the form of an RC-circuit **7,8**. The integrator is followed by an amplifier V or high gain. The first LED **9** connects to the output of amplifier V, which is followed by an inverter **10**, the output of the latter being connected to the second LED **11**.

The other two terminals of LEDs **9** and **11** are jointly connected to the output of voltage follower **12** which is fed with its potential from photometer **13**. The last part of the circuit, that is the voltage follower in combination with light or photometer **13** is used to adjust the

median luminosity of LEDs **9** and **11** to the particular object brightness.

Reference numeral **21** designates a light bundle coming from an object to be measured. An objective **22** images the object in the plane of grating **35**. As a result of the relative movement between the grating **35** and the image, which may be generated stochastically by movements or vibrations of the user of the rangefinder, a time-variable signal of maximum amplitude occurs at the output of the push-pull amplifier **29** in the condition of sharp focusing. Diaphragms **25** and **26** have here, in connection with the objectives **23** and **24**, the purpose of defining the detection directions of the photoelectric detectors **27** and **28** in single valued manner so as to be unambiguous. The image sharpness is regulated by means of regulator **20** and objective **22**.

The circuit operates as follows:

The square wave pulses from the photodetectors are applied to inputs A and B, as shown in FIG. **2**, for zero phase shift. Differentiation in differentiators **1,2,5** generates pulses from wave train A following transition into Plus, whereas pulses are generated from wave train B by means of differentiators **3,4,6** when transiting into Minus. These pulses control the reset flip-flop RSFF, which for the assumed phase difference of zero of FIG. **2** delivers at its output a square wave train C with a keying ratio of 1:1.

This square wave train is applied to the RC circuit **7,8** (= integrator), which delivers an output in the form of a saw tooth wave D which, for focus — that is, for zero phase difference between the square wave trains at inputs A and B evenly fluctuates about the null point. Amplifier V again shapes curve D into a square wave E of 1:1 keying ratio. In this manner both LEDs **9** and **11** are controlled, furthermore making use of inverter **10**. Because of the 1:1 keying ratio of the square wave train E, the LEDs are equally luminous when focus has been obtained (i.e., when the phase difference between the square wave trains at inputs A and B is zero).

FIG. **3** on the other hand shows the signal-time relationship for the objective out of focus. In this case there is phase difference between the square waves at inputs A and B, which is proportional to defocusing.

Therefore the pulses delivered by differentiators **1,2,5** and **3,4,6** are not equally spaced upon comparison of the two pulse trains. In turn this causes keying ratio deviating from 1:1 in the square wave C at the output of the reset flip-flop RSFF. Then saw-tooth wave D no longer evenly fluctuates about the null point, but is offset to one side, and the square wave E after amplifier V therefore also deviates from 1:1 in its keying ratio. The end result is that the currents applied to LEDs **9** and **11** are unequal and these LEDs are of unequal luminosities, thereby displaying lack of focus.

The combination of the RC circuit **7,8** and amplifier V allows increasing the keying ratio of wave train E with respect to C, that is, to increase the discrimination slope.

FIG. **4** shows the luminosity of the two LEDs **9** and **11** as a function of the phase difference between the two square waves applied at inputs A and B. It is seen that for zero phase difference, the two LEDs are equally luminous. If however there is minus phase difference, the luminosity of LED **11** decreases while that of LED **9** increases. A boundary value is reached for a phase difference of about $-20°$, beyond which LED **11** is completely dark while LED **9** shines at constant and maximum brightness. When the phase difference is Plus, mirror-image relationships are obtained, so that beyond a phase difference of about $+20°$, LED **9** is dark while LED **11** shines with maximum luminosity.

The photo or light meter denoted by **13** is assumed to deliver a potential increasing with illumination. The potential applied to the LED is so controlled by means of that potential passing through the voltage follower and when appropriate through non-linear resistances that the LEDs are less luminous for lesser ambient brightness.

We claim:

1. In an apparatus comprising an optical objective, a scanning disk or a scanning plate and first and second photoelectric detectors all located along optical axes for indicating the focus of said optical objective which projects an image of an object onto said scanning disk or scanning plate for pupil division of the image into imaging beams, and projection of said imaging beams onto said photoelectric detectors, each of which generates an electrical impulse where a phase difference between said pulses is a measure of the degree of said focus of the objective, the improvement comprising first and second differentiators connected respectively to said first and second photoelectric detectors, a reset flip-flop having first and second input terminals connected respectively to said first and second differentiators and an output terminal, an integrator connected to said output terminal, an amplifier connected to said integrator, a first and a second light emitting diode, said first light emitting diode connected to said amplifier and said second light emitting diode connected to an inverter connected to said amplifier, a voltage follower connected to said first and second light emitting diodes, and means for photoelectrically measuring the object brightness, said means connected to said voltage follower for adjusting the median luminosity of said light emitting diodes in dependence on the object brightness.

Fig. 1

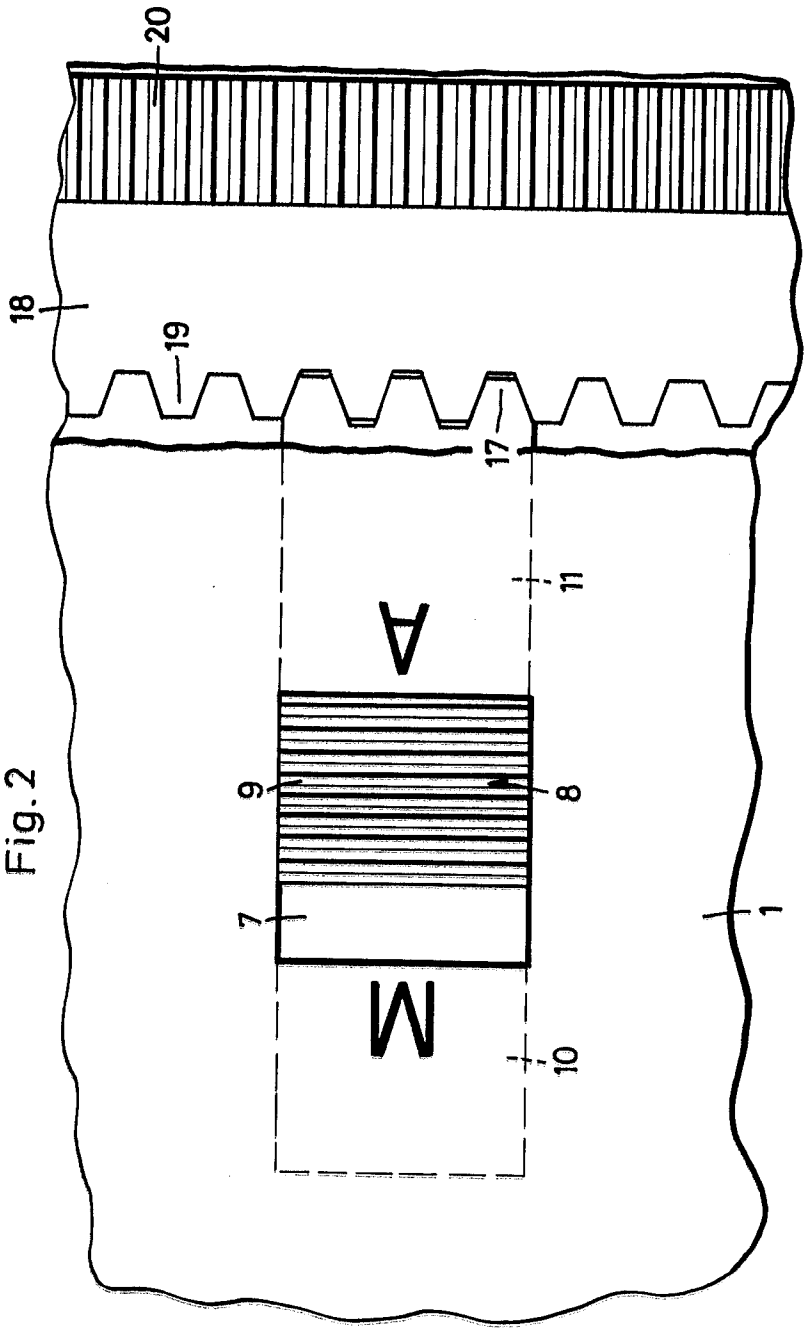

Fig. 2

COUPLING MECHANISM FOR THE ALTERNATE MANUAL AND AUTOMATIC ADJUSTMENT OF A VARIFOCAL OBJECTIVE

FIELD OF THE INVENTION

Our present invention relates to a photographic, cinematographic or television camera with a varifocal objective whose axially shiftable components can be adjusted either manually or automatically with the air of a rotatable camming sleeve centered on the objective axis.

BACKGROUND OF THE INVENTION

In commonly owned U.S. Pat. No. 3,095,794 there has been described a camera of this type in which a handle is shiftable in an objective housing between a "manual" position and an "automatic" position; a camming sleeve for the adjustment of the overall focal length is coupled with a reversible drive motor in the "automatic" position and is decoupled from that motor in the "manual" position in which the sleeve can be rotated by the handle. In a later U.S. Pat. No. 3,224,351, a rotary knob can be similarly shifted on an objective housing for selective manual or automatic adjustment. In both these instances the manual/automatic selector, i.e. the handle or knob, is decoupled from the sleeve in the "automatic" position and therefore does not participate in its rotation by the motor; thus, the selector position is not related to focal length and a separate indicator must be provided to inform the user of the position last reached by the camming sleeve.

German Pat. No. 2,345,078 describes a varifocal objective or zoom lens in which the drive motor rotates the camming sleeve through a gear train, acting as a step-down transmission, and can be decoupled therefrom by the separation of two gears of that train. Upon such decoupling, the sleeve can be manually rotated by a lever or the like not illustrated in that German patent. Since the manual adjustment entails the entrainment of several meshing gears of the step-down transmission, the user must overcome an added frictional resistance. Also, because of the unavoidable play of the gear teeth, a false impression of a defective mechanism may be created.

OBJECT OF THE INVENTION

The object of our present invention, therefore, is to provide means in such a camera for the selective changeover from manual to automatic adjustment or vice versa anywhere within the varifocal range and with a minimum of encumbrance in the manual position.

SUMMARY OF THE INVENTION

In accordance with our present invention, a control ring surrounding the camming sleeve is partly separated from that sleeve by an intervening clearance communicating with an axially extending slot of that ring. A slider axially displaceable in the clearance, provided with indexing means for yieldably representing manual and automatic operation, has an extension which passes outwardly through the slot of the ring to form a knob or other element manipulable by the user. A coupling ring coaxial with the camming sleeve has a toothed face confronting a toothed edge of the slider which is engageable with that toothed face in the "automatic" position but is disenaged therefrom in the "manual" position. In the "automatic" position, the sleeve is reversibly rotatable by drive means operatively connected with the coupling ring, advantageously through step-down transmission including a pinion in permanent mesh with a set of gear teeth on this ring. In the "manual" position, such rotation can be performed by a handle on the control ring.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 is a side-elevational view, partly in section, of a lens mounting for a camera embodying our invention; and

FIG. 2 is a fragmentary top view taken on the line II — II of FIG. 1 and drawn to a larger scale.

SPECIFIC DESCRIPTION

In FIG. 1 we have shown a varifocal or zoom objective comprising a control ring **1** that is manually rotatable, with the aid of a handle **25**, about the objective axis and coaxially surrounds a sleeve **2** with which it is rigidly connected by screws **26** (only one shown). Sleeve **2** is formed with a pair of camming grooves **3** and **4** engaged by pins **31** and **32** on respective lens mounts **33** and **34** which are axially shiftable therein and carry components **5** and **6** of the objective designed to vary its overall focal length. A short, axially extending slot **7** in ring **1** communicates with a clearance **27** existing between that ring and the carrying sleeve **2**, that clearance being here formed by a recess in the inner peripheral surface of the ring. A slider **8** has a knob **9** projecting outwardly through slot **7** and is guided by front and rear legs **10** and **11** integral therewith, these legs being received in clearance **27**. As shown in FIG. **2**, knob **9** is shiftable within slot **7** between a forward position marked M (for "manual") and a rear position marked A (for "automatic"); two depressions **15** and **16** in the outer surface of sleeve **2** coact with detent in a bore **14** of knob **9**, i.e. a ball check **13** loaded by a spring **12**, for yieldably arresting the slider **8** in either of these positions. Depressions **15** and **16** could be small dimples but may also be in the form of parallel peripheral grooves.

Leg **11** of slider **8** has a toothed edge **17** which, in "automatic" position A, engages a confronting toothed face **19** of a coupling ring **18** coaxially surrounding the rear end of sleeve **2** on which ring **18** is freely rotatable, being held against rearward displacement by a jump ring **28**. Coupling ring **18** has a set of peripheral gear teeth **20** in permanent mesh with a pinion **21** whose shaft **22** can be reversibly driven by a motor **29**. A manual switch **30** in the energizing circuit of that motor has two operating positions for forward and reverse rotation, respectively.

Rings **1** and **18** as well as sleeve **2** are carried on a lens barrel **35** which is also provided with the usual setting ring **23** for focusing purposes. A rear flange **24** on lens barrel **35** allows the latter to be removably secured to a camera housing **36** indicated only diagrammatically.

As will be readily apparent, an indexing of slider **8** in its "automatic" position A allows the focal length of the objective to be reduced or increased by the zoom drive **20 – 22, 29** under the control of three-position switch **30**; ring **1**, handle **25** and slider **8** participate in the rotation of camming sleeve **2**. In the "manual" position M, handle **25** allows the assembly **1, 2, 8** to be rotated without entrainment of ring **18** or pinion **21**. The established focal length can be ascertained in either case by the

angular position of handle **25** as read, for example, on a stationary scale engraved on lens barrel **35**.

In principle, the clearance **27** could also be formed by a recess in the outer surface of sleeve **2**. Moreover, the ball check **12, 13** or equivalent indexing means could be located elsewhere in the assembly, though the illustrated arrangement is particularly advantageous for its compactness.

The use of a coupling ring **18** (whose diameter substantially equals that of lens barrel **35**) as part of a step-down transmission between motor **29** and sleeve **2** eliminates the need for a multistage gear train of the type shown in the aforementioned German Pat. No. 2,345,078.

We claim:

1. In a camera provided with a varifocal objective having components shiftable along an optical axis with the aid of a camming sleeve centered on said axis,

the combination therewith of:

a control ring surrounding said sleeve, said control ring being partly separated from said sleeve by an intervening clearance and having an axially extending slot communicating with said clearance;

a slider axially displaceable in said clearance and provided with indexing means for yieldably arresting it in either of two axially spaced positions, said slider having an extension passing outwardly through said slot for manipulation by a user;

a coupling ring coaxial with said sleeve having a toothed surface confronting said slider, the latter having a toothed edge engageable with said toothed face in one of said positions but disengaged therefrom in the other of said positions; and

automatic drive means operatively connected with said coupling ring for reversibly rotating said sleeve through the intermediary of said slider in said one of said positions, said control ring being provided with handle means enabling manual rotation of said sleeve in said other of said positions.

2. The combination defined in claim **1** wherein said coupling ring is rotatably mounted on said sleeve.

3. The combination defined in claim **1** wherein said automatic drive means comprises a reversible motor connected with said coupling ring through a step-down transmission including a pinion in permanent mesh with a set of gear teeth on said coupling ring.

4. The combination defined in claim **1** wherein said extension is a knob provided with a bore open toward said sleeve, said indexing means comprising a ball check in said bore engageable with coacting formations on said sleeve.

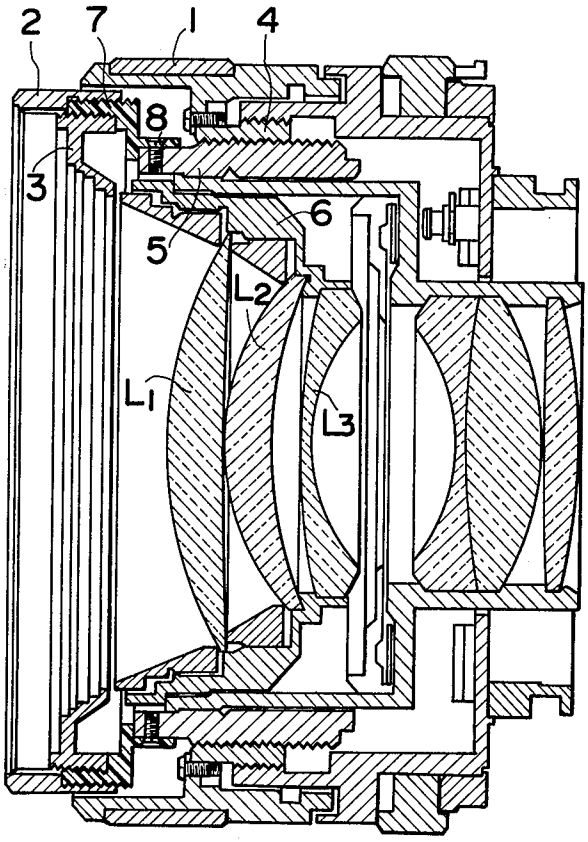
Figure



CUSHIONED OBJECTIVE LENS

BACKGROUND OF THE INVENTION

The present invention relates generally to improvements in optical devices and it relates particularly to an improved shock-proof lens barrel assembly.

In general, the conventional lens barrel is constructed of metal members of high rigidity, such as the operating ring which is exposed to the exterior of the lens barrel, the focussing means constituting an internal mechanism, one or more lens holding rings and the like. In addition, these members are directly interfitted or intercoupled providing a rigid assembly and construction. As a consequence, when a lens barrel is inadvertently struck by another article, or falls on the floor, then an impact is directly transmitted from an external member of the lens barrel to the internal mechanism, thus impairing the desired and proper functioning of the focussing mechanism or the optical system, or damaging the same. Once the damage occurs, then the function of the device as an optical instrument is diminished or lost and its repair, if possible, leads to an expenditure of much time and effort and is generally highly expensive.

SUMMARY OF THE INVENTION

It is accordingly an object of the present invention to provide a lens device such as an objective lens which will not suffer from loss of the desired and proper functioning of any internal mechanism and lens unit and damage thereto due to an impact applied to an external component of the lens device.

Another object of the present invention is to provide an improved lens barrel with a buffer or cushion of simple and rugged construction and of low manufacturing cost.

To accomplish the above objects, a lens barrel of the present invention includes a buffer or cushion interposed between an external component or bumper exposed to the exterior thereof and an internal mechanism disposed between a lens unit and the external component. With this construction, any impact exerted on the external component is absorbed by the buffer and weakened or highly attenuated when transmitted to the internal mechanism. As a result, there will be little or no danger of a strong impact being imparted to the internal mechanism and the lens unit, and thus these latter will not lose their desired or proper functioning nor will they be damaged.

The buffer is advantageously formed of a plastic or synthetic organic polymeric resin material which is in general less rigid and more flexible than a metallic material. Such a buffer of a plastic material can be manufactured by molding at low cost and will be simple in its construction and application.

In accordance with a preferred embodiment of the present invention, the buffer is advantageously made of a synthetic polymeric resin of high flexibility. The external component includes an ornament ring disposed in front of the lens unit and a barrel head sleeve disposed at a forwardmost portion of the lens barrel, the ornamental ring and barrel head sleeve being most liable to receive any impact among the members exposed to the exterior of the lens barrel. However, the external bumper component may include an operating member such as a focussing ring. Furthermore, the internal mechanism in the embodiment includes sleeves for shifting the lens units for focussing and members for holding the lens units.

Furthermore, parts of the external and internal mechanisms may be made of a plastic material as part of the buffer or cushion. That is, the buffer may include as a part thereof, a part of the external and/or internal mechanisms. With such a construction, the number of members is reduced, which results in lower manufacturing cost of the lens barrel.

The above and other objects and features of the present invention will be more apparent from the following description taken in connection with the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

The single FIGURE is a medial longitudinal cross-sectional view of a lens barrel according to an embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawing which illustrates a preferred embodiment of the present invention in the form of an exchangeable objective lens for use in a single lens reflex camera, the reference number **1** designates a focussing operating ring, a barrel head sleeve **2** having a threaded portion for use in securing attachments thereto and **3**, an ornament ring on which are marked the nomenclature of the lens and the like. The members **1**, **2**, and **3** are exposed to the exterior of the lens barrel. The internal mechanism of the objective lens includes focussing means composed of an outer helicoid sleeve **4** and an inner helicoid sleeve **5**, and a holding ring or collar **6** for holding lens groups **L1**, **L2** and **L3**. The outer helicoid sleeve **4** is integral and rotatable with focussing operating ring **1** and is fitted on the inner helicoid sleeve **5** by means of a helicoid thread. Lens holding ring **6** moves lens groups **L1**, **L2**, and **L3** as a unit along the optical axis, in response to the shifting of the inner helicoid sleeve **5** along the optical axis. Shown at **7** is buffer or cushion ring made of a synthetic resin of high flexibility and ring **7** threadingly engages the lens head ring **2** as well as the ornamental ring **3**, and is secured to inner helicoid sleeve **5** by means of a screw **8**.

With the aforesaid arrangement, in the event that an impact is applied to the barrel head sleeve **2** which is most likely to be subjected to an impact, then the impact is neutralized by means of buffer ring **7** by absorbtion and attenuation thereof, to a desired degree, so that inner helicoid sleeve **5** will not be adversely affected. Likewise, in case an impact is applied to ornament ring **3** from front of the lens barrel, the buffer ring **7** will absorb and attenuate the impact. As a result, there is little or no danger of a strong impact being imparted to and acting on inner helicoid sleeve **5** nor on the lens holding ring **6**, and thus these members or lenses will not lose their functions nor be damaged.

This embodiment provides a cushion or buffer member for the lens and the internal mechanism, which are most likely to be subjected to an impact. Alternatively, a buffer member may be provided between focussing operating ring **1** and the outer helicoid sleeve **4**. The ornament ring **3** or the inner helicoid sleeve in most cases are made of a metal of a high rigidity, but one or both of these members may be molded integrally with buffer ring **7** by using a synthetic resin, with an accompanying saving in manufacturing cost. In the embodi-

ment described, buffer ring 7, barrel head sleeve 2, and ornament ring 3 need not necessarily be threadingly interfitted, but may be simply fitted without using a threaded section.

The principle incorporated in the structure of the present invention may be applied to zoom lens barrels as well as to lens barrels of cameras of the types other than a single lens reflex camera.

While there have been described and illustrated preferred embodiments of the present invention, it is apparent that numerous alterations, additions and omissions may be made without departing from the spirit thereof.

9n

We claim:

1. A lens device comprising:

a lens barrel;

a lens unit disposed within said lens barrel;

an external component including a barrel head sleeve disposed at a forwardmost portion of said lens barrel and exposed to the exterior of said lens barrel so as to receive an impact applied from the front of said lens barrel;

an internal mechanism disposed between said lens unit and said external component; and

a buffer coupled to and interposed between said barrel head sleeve and said internal mechanism.

2. A lens device as defined in claim 1, wherein said buffer is made of a plastic material.

3. A lens device as defined in claim 2, wherein said buffer is made of a synthetic resin of high flexibility.

4. A lens device as defined in claim 2, wherein said external component includes an ornament ring disposed in front of said lens unit and coupled to said buffer.

5. A lens device as defined in claim 2, wherein said internal mechanism includes means for shifting said lens unit.

6. A lens device as defined in claim 2, wherein said internal mechanism includes means for holding said lens unit.

7. A lens device as defined in claim 2, wherein said external component includes a portion made of a plastic material and said buffer has said portion as a part thereof.

8. A lens device as defined in claim 2, wherein said internal mechanism includes a portion made of a plastic material and said buffer has said portion as a part thereof.

9. A lens device as defined in claim 5, wherein said barrel head sleeve is axially movable relative to said lens barrel, said lens unit shifting means includes a movable sleeve which is axially movable relative to said lens barrel for shifting said lens unit, and said buffer has a front end coupled to said barrel head sleeve and a rear end coupled to said movable sleeve.

10. A lens device as defined in claim 9, wherein said lens barrel includes a focussing ring accessible for actuating said lens unit shifting means such that said movable sleeve is axially moved relative to said lens barrel.

11. An objective lens comprising:

a lens barrel;

a lens unit disposed within said lens barrel;

an adjusting mechanism disposed within said lens barrel and supporting said lens unit;

a bumper component projecting axially forwardly of said adjusting mechanism and said lens barrel so as to be directly exposed to impact, applied externally of said lens barrel; and

an impact attenuating cushion member disposed between and intercoupling said adjusting mechanism and said bumper component.

12. The objective lens of claim 11 wherein said bumper member comprises a ring.

13. The objective lens of claim 12 wherein said bumper ring is formed of metal and said cushion member comprises a ring formed of a synthetic polymeric resin coaxial with and directly joined to said bumper ring.

[57] **ABSTRACT**

A varifocal object selectively focusable upon a normal range of object distances and a substantially shorter macro range can be supplemented by a negative component of one or more lenses whose focal length is less than the depth of the macro range and which forms a virtual image of a nearby object on the object plane of the objective when the latter is adjusted to a predetermined closeup position. A correlating linkage between a seat for the supplemental component and a control member designed to establish the closeup position serves to index the control member in that position or to prevent the emplacement of the supplemental component if the objective is in a different position.

WIDE-ANGLE ATTACHMENT FOR VARIFOCAL OBJECTIVE

FIELD OF THE INVENTION

Our present invention relates to an optical system of the varifocal type for a camera or other instruments such as microscopes or photographic copiers.

BACKGROUND OF THE INVENTION

In an objective of the pancratic type, more often referred to as a varifocal or zoom objective, it is known to provide two axially shiftable components, usually preceded by a stationary front component, whose displacement changes the overall focal length of the system while holding its image plane constant. Within a normal zoom range, the object plane lies at infinity or at a lesser distance that may be chosen by slightly displacing, for example, all or part of the stationary front component. This normal range is limited at one end by a telephoto position, in which the overall focal length has its maximum value f_{max}, and at the other end by a wide-angle position, the overall focal length then having a minimum value f_{min}.

As has been shown in U.S. Pat. No. 3,773,402, it is possible to reduce the effective focal length beyond that limiting value by a further shifting of one or both of the two axially movable components with concurrent displacement of the object plane, correlated with the stationary image plane, toward the objective. This enables the taking of closeup pictures of wide-angle format within the macro range which may be defined as one giving image scales between 1:10 and 1:1. Reference in this connection may also be made to U.S. Pat. No. 3,891,304. The transition from the normal range to the macro range is generally characterized by a reversal of the relative shift of the two movable components.

Alternatively, a foreshortening of the overall focal length with concurrent reduction in object distance can also be achieved — abeit less conveniently — by moving a normally withdrawn additional lens member into the path of the light rays within the varifocal objective.

In practice, conventional objectives of this type have overall focal lengths whose lower limit f_{min} in the normal range is not less than about 7 mm. This restricts the extent to which a camera so equipped can be used by, for example, an amateur photographer interested in taking indoor pictures.

OBJECTS OF THE INVENTION

The general object of our invention is to provide simple means in an optical system of the type discussed for allowing selective reduction of the effective focal length to a value enabling the taking of pictures of very wide angle at close range.

A more particular object is to provide an objective of this kind whose effective minimum focal length can be as low as 3 mm or less.

SUMMARY OF THE INVENTION

We realize these objects, in accordance with our present invention, by providing supplemental lens means of negative refractivity selectively insertable between the varifocal objective and an object to be imaged on a wide-angle scale, the supplemental lens means having a focal length which is less than the depth of the macro range. The varifocal objective includes movable lens means displaceable by a control member in order to shift the object plane from a normal range to a substantially shorter closeup or macro range, as defined above. A sensor responsive to the position of the supplemental and/or the movable lens means serves to correlate the establishment of a working position for the supplemental lens means with a displacement of the movable lens means into a predetermined focusing position in which the object plane lies at a distance from the objective at which virtual images of objects within the closeup range can be formed by the supplemental lens means.

The term "depth of the closeup (or macro) range" can be defined as the distance between the limit of that range proximal to the normal range and the varifocal objective itself, more particularly its object-side principal point.

The supplemental lens means may be an attachment consisting of one or more air-spaced lens members of negative refractivity, preferably meniscus-shaped with forwardly facing convex surfaces. Two or more lens members of this nature, preferably of similar optical parameters, could be used individually or jointly to provide different wide-angle effects.

Such a component will form a reduced, virtual, intermediate image of an object in a plane lying between itself and its own front-focal point. If that virtual-image plane coincides — within the focal-depth limits of the objective — with the object plane selected by adjustment of the control member, the object will be sharply reproduced on the fixed image plane of the varifocal system.

In the simplest case, the sensor may be a visual indicator operatively coupled with the movable lens means for alerting the user to the fact that the object plane has been shifted into the desired position within the macro range. Such an operative coupling need not include a physical connection but may be effected optically, as by light rays traversing the movable lenses and reaching a viewfinder equipped with a conventional focus indicator such as an image-splitting viewer or a ground-glass plate.

In a more sophisticated system, pursuant to another feature of our invention, the sensor forms part of a correlating linkage between a seat for the supplemental component and the control member used for adjusting the varifocal objective to the macro range. Such a linkage may either index the control member in the predetermined focusing position or prevent the emplacement of the wide-angle attachment in its seat as long as that focusing position is not established.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 diagrammatically shows the layout of an optical system embodying our invention;

FIGS. 2, 3 and 4 are detail views of the components of the system of FIG. 1 according to three different embodiments;

FIG. 5 is a fragmentary side view, partly in axial section, of a lens mounting for a system according to our invention provided with a position sensor;

FIG. 5A is a detail view relating to a modification of the position sensor of FIG. 5;

FIG. 6A is a side view of a camera equipped with another position sensor according to our invention;

FIG. 6B is a cross-sectional view taken on the line VIB—VIB of FIG. 6A;

FIGS. 7 and 8 are views similar to FIG. 5, illustrating further types of position sensors; and

FIG. 9 is part of a side view similar to FIG. 6A, showing another modification.

SPECIFIC DESCRIPTION

In FIG. 1 we have represented by thin-lens symbols the several components of a conventional varifocal objective 1 along with a supplemental component or front attachment B. Objective 1 comprises a fixed positive front component 2, two axially movable negative components 3, 4, another axially fixed positive component 5 and a positive rear lens group 6 separated from components 2–5 by a diaphragm space. Components 3 and 4 are simultaneously shiftable along optical axis O, at different rates and/or in different directions, to vary the overall focal length of objective 1 with maintenance of a constant image plane (indicated at IP in FIG. 4) as is well known per se. At the wide-angle end of the normal varifocal range, component 4 can be further displaced from its full-line position to its dotted-line position for the purpose of establishing an object plane OP in the macro range intersecting the axis O at a point 7, e.g. as described in the two above-identified U.S. patents.

Attachment 8 does not form part of the varifocal objective but can be selectively positioned in front thereof, pursuant to our present invention, for the purpose of increasing the angle of view in the macro range. The focal length of this attachment is less than the depth of the macro range as discussed above, its front-focal point preferably lying near the point 7 on axis O. With objective 1 focused upon plane OP, by a suitable positioning of component 4, a virtual image of a nearby object to be photographed is formed by attachment 8 in that plane whence the incident rays strike the front component 2 of objective 1 at angles giving a wide field of view.

In FIGS. 2–4 we have shown representative embodiments of the system of FIG. 1 including varifocal objectives 1′, 1″, 1‴ and attachments 8′, 8″, 8‴. It should be understood, however, that these attachments may be interchanged among the illustrated systems and that they could also be used with other varifocal objectives known per se, e.g. as given hereinafter with reference to Table D.

In FIG. 2 the attachment 8′ is a single negative meniscus L_1'. The positive first component 2′ of objective 1′ consists of a compound lens member L_2', L_3' and two further lenses L_4' and L_5' air-spaced therefrom. The axially shiftable negative second component 3′ consists of a singlet L_6' and a doublet L_7', L_8'. The axially shiftable negative third component 4′ is a single negative meniscus L_9'. The fixed positive fifth component 5′ consists of two biconvex lenses L_{10}' and L_{11}'. A reflex prism P and a diaphragm separate this latter component from the fixed-focus rear lens group 6′ consisting of a positive singlet L_{12}', a positive doublet L_{13}', L_{14}', a negative singlet L_{15}' and two positive singlets L_{16}' and L_{17}'.

Illustrative numerical values for the radii of curvature r_1'–r_{31}' and axial thicknesses d_1'–d_{17}' of all these lenses, their axial separations s_1'–s_{13}', their refractive indices n_d and their Abbé numbers ν_d are given in the following Table:

TABLE A

			n_d	ν_d
L_1'	$r_1' = +2.33$ $r_2' = 1.14$	$d_1' = 0.12$	1.805	25.4
		$s_1' = 0.34$		
L_2'	$r_3' = +9.929$	$d_2' = 0.10$	1.805	25.4

The numerical values for the radii, axial thicknesses, separations and focal lengths in the foregoing and following tables are based upon a value of unity for the median overall focal length f_{med} of the varifocal objective 1′ without the attachment 8′. The focal lengths f_{max} and f_{min} have the numerical values 1.91 and 0.40, respectively. Thus, the objective has a varifocal ratio of almost 5:1; its relative aperture is 1:1.2.

The combination of varifocal objective 1′ and attachment 8′ in the macro-range focusing position has an overall focal length of 0.22 and an image angle of 90°.

The prism P, of thickness d_p and with planar faces r_{p1}, r_{p2}, deflects some of the incident rays to a nonillustrated viewfinder which may serve as a position sensor for the

focusing lens L_9' in the macro range, as mentioned above.

In the embodiment of FIG. 3 the attachment 8'' is shown to comprise two air-spaced negative menisci L_1'' and L_2'' with identical front radii r_1'', r_3'' and with identical rear radii r_2'', r_4''; the axial thicknesses and other parameters of these two lenses are also the same, as will be apparent from the illustrative numerical values given below. These two lenses are advantageously mounted for individual interposition in the path of incident rays so that either one or both of these lenses can be utilized to provide different field angles and magnification ratios.

The several components of objective 1'' are generally similar to those of objective 1' (FIG. 2), except that lenses L_3'', L_4'' of the front member are air-spaced rather than cemented, the fourth component consists only of one positive lens L_{11}'', the second member of the rear group is a singlet L_{13}'' and the weakly refractive final positive lens L_{17}' has been omitted. A prism P, not shown in FIG. 3, could of course also be inserted into the diaphragm space of objective 1''.

The magnitudes of the radii r_1''–r_{29}'', thicknesses d_1''–d_{15}'' and separations s_1''–s_{13}'' of lenses L_1–L_{15}'', are refractive indices n_d and their Abbe numbers ν_d are listed in the following Table:

TABLE B

	$r_{29}'' = -0.639$				

Attachment 8'' has an individual focal length of 3.11. The overall focal length of objective 1'' (without the attachment) varies between values

$f_{max} = 2.03$

$f_{med} = 1$

$f_{min} = 0.43.$

This corresponds again to a varifocal ratio of nearly 5:1; the relative aperture is 1:1.9. The objective 1'' has the advantage of small loss of luminosity toward the image periphery as compared with similar objectives of the prior art.

The combined system 1'' + 8'' again has an overall focal length of 0.22 in the macro-range focusing position and an image angle of 90°.

The wide-angle attachment 8''' of FIG. 4 consists also of two optically identical negative menisci L_1''', L_2''' which could be used individually or in combination. The objective 1''' has a compound front member L_3''', L_4''' and is otherwise similar to objective 1'' of FIG. 3.

Illustrative numerical values for the parameters r_1'''–r_{29}''', d_1'''–d_{15}''', s_1'''–s_{12}''', n_d and ν_d of its lenses L_1'''–L_{15}''' are listed in the following Table:

TABLE C

L_{15}'''	$r_{28}''' = +0.967$	$d_{15}''' = 0.163$	1.720	50.4
	$r_{29}''' = -0.618$			

diaphragm space = 0.034 + 0.104

The overall focal length of objective 1''' (without attachment 8''') varies as follows:

$f_{max} = 2.219$
$f_{med} = 1$
$f_{min} = 0.299.$

This corresponds to a varifocal ratio of nearly 8:1. The objective has a relative aperture of 1:1.8. In combination with attachment 8''', whose individual focal length measures 1.033, it has an image angle of approximately 180° so as to give a "fish-eye" semipanoramic view. The focal length of the combination is 0.11.

In a practical realization, the median focal length f_{med} measured 19.134 mm. This corresponds to an overall focal length of 2.1 mm for the system illustrated in FIG. 4.

An attachment consisting of one or more lenses such as the one shown in FIG. 2, but of reduced power for better correction of aberrations, could be substituted for component 8''' in FIG. 4. Such a lens could have, for example, a front radius $r_1 = +2.18$, a rear radius $r_2 = +1.25$, a thickness $d = 0.18$, a refractive index $n_d =$

1.517 and an Abbé number $\nu_d = 62.2$. Its distance from lens L_3''' may be $s_2''' = 0.40$.

Another varifocal objective to be used with any of the herein disclosed front attachments has the same structure as objective **1'''** of FIG. **4** with the following parameters known per se from Austrian patent No. 325,325:

TABLE D

			n_d	ν_d

This objective has a relative aperture of 1:1.8 and focal lengths $f_{max} = 2.232$, $f_{med} = 1.006$, $f_{min} = 0.301$.

In FIG. **5** we have shown lens mounts **9** and **10** for the shiftable members **3** and **4**, these lens mounts being slidable along rods **11** and **12** paralleling the optical axis O of the objective. A cam disk **13**, rotatable by a nonillustrated zoom-control member on a shaft **14** transverse to the axis, has two slots **15** and **16** in which pins **17** and **18** on lens mounts **9** and **10** are guided. Sections α of these slots serve for the adjustment of the focal length within the normal range as discussed above; the illustrated limiting position of disk **13** corresponds to the maximum focal length f_{max}. At the opposite end of the range the slots **15** and **16** are provided with extensions β by which the two components **3** and **4** are shifted away from each other in the macro range.

A lens holder **19**, carrying the front attachment **8**, is receivable in a socket **20** of a camera housing illustrated in part at **21**. Upon such emplacement of holder **19**, a shoulder **19a** thereof bears upon a position sensor in the form of a pin **22** whose free end is urged into the socket **20** by a spring **25**. Pin **22** forms part of a linkage **26** articulated to a detent **23** which has a fixed pivot at **23a** and faces the periphery of cam disk **13**. Unless a notch **24** in that periphery confronts the detent **23**, pin **22** cannot be repressed and prevents the emplacement of holder **19** in the working position of attachment **8**. Notch **24** is an indexing formation which registers with detent **23** only when the pins **17** and **18** engage the macro sections β of slots **15** and **16**.

As shown in FIG. **5A**, detent **23** may be coupled with linkage **26** through another spring **27**, weaker than spring **25**, which allows the lens holder **19** to be operatively positioned whereby spring **27** is stressed to bias the detent toward the periphery of disk **13**, causing it to fall into the notch **24** and to lock the disk **13** in the desired focusing position within the macro range. The objective in this case advantageously includes a visual indicator designed to alert the user to the fact that the objective is still out of focus, e.g. a view-finder of the focus-indicating type referred to above and served by a reflex prism to the rear of the shiftable lenses as shown in FIGS. **2** and **4**. Such an indicator could also be a pair of marks **75**, **76** on a control member **74** of the objective housing as shown in FIG. **9**.

In FIGS. **6A** and **6B** we have illustrated a camera **30** with a setting lever **31** swingable about the objective axis for varying the focal length. The normal and macro ranges of the swing have again been designated α and β, respectively. A lens holder **32**, carrying the wide-angle front attachment, has an extension **36** which projects into the path of lever **31** to stop it in the correct focusing position within the macro range as indicated at β_1. The correct angular alignment of holder **32** and camera **30** is insured by a key **34** on the holder engaging in a keyway **35** on the camera body.

Reference may be made to U.S. Pat. No. 3,613,544 for a description of a focusing mechanism using such a swingable control member.

In FIG. **7** we have shown a camera **40** provided with a fitting **51** for receiving an attachment **50** which carries a supplemental component **8**. A rod **52** slidable in the camera housing is rigid with a lug **49** on a stepped sleeve **44** surrounding a lens barrel **41** with camming slots for the movable lens members, only a slot **42** controlling the second negative component **4** (FIG. **1**) being visible. Slot **42** is again subdivided into a section α for the normal range and an extension β for the macro range. A mode-selector switch **46** is coupled with sleeve **44** in order to interpose a step **47** of this sleeve into the path of a pin **43** guided by slot **42** when that switch is in its left-hand position, thereby preventing an adjustment of the objective beyond the normal range. Upon insertion of attachment **8**, **50**, rod **52** is repressed against the force of a spring **48** so as to shift the sleeve **44** to the right, thereby enabling a continuing displacement pin **43** to be moved into a position within the macro range in which that pin comes to rest against another step **53** of sleeve **44**. This axial shift of the sleeve entrains the mode-selector switch **46** into its midposition labeled "wide angle." The switch can also be manually moved into a right-hand position in which the step **53** is withdrawn from

the path of pin 43 to enable free adjustment of the objective (in the absence of attachment 8, 50) within the macro range. A suitable latch, not shown, preferably arrests the sleeve in the last-mentioned position against the force of spring 48.

FIG. 8 shows an arrangement similar to that of FIG. 7 in which analogous elements have been designated by the same numerals with the addition of a prime mark (′). Switch 46′ here has only its "normal" and "wide angle" positions, sleeve 44′ being provided with only a single step 47′. A rod 60, replacing the spring-loaded rod 52 of FIG. 7, positively prevents the emplacement of lens holder 50′ as long as the mode-selector switch 46′ holds the sleeve 44′ in its "normal" position in which the guide pin 43′ for the axially shiftable lens 4 is prevented from entering the extension β' of slot 42′. Thus, the user must first adjust the switch 46′ to "wide angle" before being able to fit the holder 50′ to the camera. It should be noted that slot section β' lies in a plane transverse to the axis so as to define the desired focusing position no matter how far the pin 43′ is moved past the junction of slot sections α and β'.

A lens holder 70 shown in FIG. 9 has a flange 71 with an internal recess 72 fitting onto a neck 77 of a lens mount rigid with a camera 73, this neck carrying the aforementioned control member 74 in the form of a ring which can be rotated for adjustment of the focal length and axially slid for the shifting of an objective component in the macro range. A non-illustrated spring biases the control ring 74 into the position shown in full lines in which normal-range adjustment by rotation is possible; the ring can be slid to the right, into its dotted-line position, only upon alignment of the two marks 75, 76. The width a of the free end of neck 77 is less than the depth b of recess 72 whereby the ring 74 is automatically shifted into the proper focusing position if the marks 75 and 76 register with each other. If not, the lens holder 70 cannot be emplaced. Naturally, this lens holder must be able to engage the neck 77 with sufficient friction to resist the force of the aforementioned spring unless suitable retaining means such as a bayonet coupling are provided therefor.

The various correlating linkages described above could also be used to indicate or bring about the movement of an additional lens from an off-axial position into line with the normal components of the varifocal objective, in order to establish the desired macro position, or to prevent the fitting of a wide-angle attachment to the objective housing as long as that additional lens is withdrawn.

We claim:

1. In a camera including a housing, a varifocal objective in said housing provided with movable lens means and with a control element for displacing said movable lens means from a normal operating range into a macro position, and supplemental lens means emplaceable on a seat formed by said housing in line with said objective for focusing same on nearby objects in a closeup range upon displacement of said movable lens means into said macro position,

the combination therewith of blocking means normally extending into the path of said control element for preventing the displacement of said movable lens means into said macro position, and a contact member on said housing coupled with said blocking means and engageable by said supplemental lens means upon emplacement thereof on said seat for removing said blocking means from the path of said control element.

2. The combination defined in claim 1 wherein said housing includes a lens barrel provided with a peripheral camming slot, said control element being a pin traversing said camming slot, said blocking means comprising a sleeve axially movable along said lens barrel, said sleeve having an edge extending across said camming slot in a normal axial position thereof.

3. The combination defined in claim 2, further comprising spring means urging said sleeve into said normal axial position, said contact member being a rod axially projecting from said sleeve toward said seat.

4. In a camera including a housing, a varifocal objective in said housing provided with movable lens means and with a control element for displacing said movable lens means from a normal operating range into a macro position, and supplemental lens means emplaceable on a seat formed by said housing in line with said objective for focusing same on nearby objects in a closeup range upon displacement of said movable lens means into said macro position,

the combination therewith of a contact member on said housing engageable by said supplemental lens means upon emplacement thereof on said seat for displacement toward said control element to arrest the latter in a position of adjustment corresponding to said macro position of said movable lens means, said contact member being provided with a resiliently biased extension bearing on said control element upon such displacement by said supplemental lens means, said control element having an indexing formation coacting with said extension in said position of adjustment.

5. The combination defined in claim 4 wherein said control element comprises a cam disk provided with a peripheral notch constituting said indexing formation.

6. The combination defined in claim 4 wherein said contact member is part of an articulated linkage.

7. In a camera including a housing, a lens barrel in said housing centered on an optical axis and provided with at least one peripheral camming slot, a varifocal objective in said hosuing including axially movable lens means, control means for displacing said movable lens means to vary the focal length of said objective, said control means including a pin traversing said camming slot, and supplemental lens means emplaceable on a seat formed by said housing in line with said objective for focusing same on nearby objects in a closeup range upon displacement of said pin into an extension of said camming slot with entrainment of said movable lens means into a macro position,

the combination therewith of a sleeve axially movable along said lens barrel, said sleeve having an edge extending in a normal axial position thereof across said camming slot for blocking the movement of said pin into said extension, and a contact member rigid with said sleeve extending into said seat in said normal axial position for preventing the emplacement of said supplemental lens means until the removal of said sleeve to an alternate position enabling the establishment of said macro position.

8. The combination defined in claim 7 wherein said contact member is a rod axially projecting from said sleeve toward said seat.

[57] **ABSTRACT**

A compact camera contains a plurality of objective lenses which are selectively alternatively advanced by external manipulation into registry with the camera photographing optical axis to vary the image magnification. A view finder optical system is provided which includes a lens member which is movable into and out of registry with the view finder optical system to vary the viewer field to correspond to the field of the operative objective lens. A lens storage space is provided between the laterally spaced view finder and photographing optical axis, one of the objective lenses when retracted occupies the storage space and when this lens is advanced to the photographic optical axis it may be replaced in the storage space by the retracted view finder lens member.

MULTIPLE OBJECTIVE LENS CAMERA

BACKGROUND OF THE INVENTION

The present invention relates generally to improvements in cameras and it relates particularly to an improved compact camera self-containing a plurality of objective lenses which are selectively alternatively transferred between displaced and operative positions and a view finder whose field is varied in accordance with the power of the operatively positioned objective lens.

With a camera of the type, in which the power of magnification of the picture-taking or objective lens system is varied by selectively moving two or more objective lenses built or self-retained in the camera into or out of the picture-taking or photographing optical path, it has been necessary to change the picture-taking field or range indicated within the associated view finder in conformity with the selected magnification of the picture-taking lens system.

Mechanisms proposed for changing the picture-taking range indicated within the finder may be classified into two types in which:

(1) The size of a view frame within the finder is changed, while maintaining the magnification of the image in the finder constant, thereby indicating the picture-taking field of the operative picture-taking lens system; and

(2) The magnification of the image in the finder is varied while maintaining the size of the view frame in a finder constant.

According to the first mechanism, the size of the view limiting frame consisting of an Albada finder system alone may be varied, without varying the magnification of the image in the finder, and hence the construction may be simplified. However, in case a picture-taking lens system is changed from a standard lens to a telephoto lens, the size of the view frame of the finder is reduced, and in addition, the finder image is reduced in size, because an object in general is located at a great distance, with the result that detailed observation of the object becomes difficult.

In contrast thereto, the second mechanism is devoid of the aforesaid shortcoming and provides advantages over the first mechanism. However, a complicated structure is required for varying the magnification of the image in the finder, with the resulting increase in the size of the finder as well as in the manufacturing cost.

Moreover, a mechanism has been proposed in which a zoom lens system is employed as a finder optical system for varying the magnification of the image in the field of view of the finder, providing the basic optical system as shown in FIG. **1** of the drawing herein. More particularly, the finder optical system proposed includes an inverse Galilean finder system consisting of a concave objective lens **1** and a convex movable lens **2**, a concave lens **3** for use in an Albada finder, and an eye-piece **4**, so that the magnification of the image in the finder may be varied by moving the convex movable lens **2** along the system optical axis in the direction of arrows e. In addition, as is well known, the size of the view limiting frame is so arranged as to be maintained constant by means of an optical image frame **4***a* formed on the object side of eye piece **4**, and mirror surface **3***a* which is formed on the image side of concave Albada lens **3** and shown by a thick line.

In general, important fundamental problems in the finder system are whether or not an optimum magnification is achieved for an image, and how far the image of an object is viewed, when observed in the finder, i.e., a dioptric power problem.

However, with the finder lens system as shown in FIG. **1**, when the image magnification of the finder remains substantially unchanged, i.e., in a range lower than 1.5, variation in magnification will not lead to a marked variation in dioptric power, thus providing desired practicability in actual application. However, when the finder magnification is increased to over 1.5, in response to a variation in the magnification of the picture-taking lens, then the variation in the dioptric power will exceed **1** diopter, so that in case the magnification exceeds **2**, then the view in the finder becomes hard to recognize, and in addition, marked distortion of the field results, thus failing to provide the desired practicability for a short-sighted photographer who suffers from an insufficient adjusting capability of the eyes.

This may be attributed to the fact that part of the lenses constituting the finder optical system is moved only along the optical axis of a finder, so that compensation for aberration cannot be positively achieved.

SUMMARY OF THE INVENTION

It is a principal object of the present invention to provide an improved camera for effecting variation in magnification by transferring one of two or more picture-taking or objective lenses built or self-contained in a camera body into or out of the photographing or picture-taking optical path, in which there is provided a finder capable of varying the magnification of the object image in the finder, with the size of the view finder limiting frame maintained constant, and yet with the dioptric power being maintained unchanged.

It is another object of the present invention to provide a camera of a compact size, in which a given space within the camera body may be alternately utilized as a common retracting position both for part of lenses in the finder optical system, which may be so arranged as to move into or out of the finder optical path, and for the movable picture-taking lenses which are self-contained in the camera body.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a side-elevational view showing one example of a prior art finder optical system in which the magnification of the finder image may be varied;

FIG. **2** is a side elevational view showing one example of a finder optical system in which an Albada system is obviated according to the present invention, the aforesaid finder optical system being capable of varying the image magnification without changing the dioptric power, and in which FIG. **2**(A) illustrates the condition of standard magnification, and FIG. **2**(B) illustrates the condition of a telephoto magnification;

FIG. **3** is a side elevational view of a finder optical system in which an Albada system is obviated according to another embodiment of the present invention, in which FIG. **3**(A) illustrates the case of a standard magnification, and FIG. **3**(B) illustrates the condition of a telephoto magnification;

FIG. **4** is a top plan view of a camera of a small size, showing the spaces alloted within the camera and in which the magnification may be varied;

FIG. **5** is a top plan view showing one example of the detailed arrangement of the picture-taking lenses posi-

tioned within the space shown in FIG. 4, in which FIG. 5(A) illustrates a standard picture-taking condition, and FIG. 5(B) illustrates a telephoto picture-taking condition;

FIG. 6 is a top plan view showing one example of the arrangement of the picture-taking lenses positioned in the space shown in FIG. 4, in which FIG. 6(A) illustrates a standard picture-taking condition, and FIG. 6(B) illustrates a telephoto picture-taking condition;

FIG. 7 is a perspective view showing an essential part of one embodiment of the present invention in a standard picture-taking condition;

FIG. 8 is a perspective view of the essential part of the camera shown in FIG. 7 in a telephoto picture-taking condition; and

FIG. 9 is a perspective view of another embodiment of the present invention shown in a telephoto picture-taking condition.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to FIGS. 2 to 8 which illustrate preferred embodiments of the present invention, FIGS. 2(A) and (B) show one embodiment of a finder optical system according to the present invention, in which FIG. 2(A) illustrates the condition of standard magnification, while FIG. 2(B) illustrates the condition of telephoto magnification, although an Albada system is not shown. For standard magnification, concave lens 5, concave lens 6 and convex lens 7 in a lens system are consecutively arranged in this order from the front or object side along the finder optical axis P–P', as shown in FIG. 2(A). For shifting from a standard magnification to a telephoto magnification, the concave lens 5 is transversely retracted in the direction of arrow *a* from the optical axis P–P', while concave lens 6 is moved toward the face of convex lens 7 in the direction of arrow *b* along its optical axis, as shown in FIG. 2(B).

FIG. 3 shows another embodiment of a finder optical system. For standard magnification, front concave lens 8 and successive convex lens 9 are arranged in a lens system as shown in FIG. 3(A). For shifting from standard magnification to telephoto magnification, concave lens 8 is moved in the direction of arrow *c* towards the face of convex lens 9, while convex lens 10 which has been retracted from the optical axis P–P' for standard magnification is moved into the optical axis P–P' in the direction of the arrow *d*, as shown in FIG. 3(B).

In either case, concave lens 6 or lens 8 should be moved along the optical axis P–P', while lens 5 or lens 10 should be moved into or out of the optical axis P–P'. Thus there is required a space, into which lens 5 or lens 10 is to be moved when retracted from the finder optical axis P–P'.

Further, FIG. 4 shows a small-size or compact camera of a flat cubic shape, into which a film cartridge may be loaded. This camera has a picture-taking lens system consisting of two or more lenses having different magnifications and effects the magnification by selectively moving one of the picture-taking or objective lenses onto the picture taking optical axis O–O'. The respective components of the camera are arranged as shown in FIG. 4 for reducing the size of the camera. As shown in FIG. 4 a film cartridge 12 is removably loaded in a predetermined position within the camera case 18, and thus the position of the picture-taking optical axis and focal or image plane is determined. Position sidewise of camera case 18 is a finder optical system P–P' consisting of lenses 5, 6, 7 and the like. Depending on the desired magnification of the picture-taking lens system, either one of standard objective lens system 15 and telephoto objective lens system 14 is positioned in either one of spaces A2 and A5 on the optical axis O–O' of a camera. The above condition is shown as a block diagram in FIGS. 5(A) and (B) or FIG. 6(A) or (B).

FIG. 5(A) shows the case of a standard picture-taking lens system, in which standard objective lens system 15 is positioned in a space A5 on the picture-taking optical axis O–O' of a camera. In this respect, assume that telephoto objective lens system 14 is positioned in a space A3 off the picture-taking optical axis O–O', then spaces A1, A2, A4, A6 are not occupied by a lens system. When telephoto objective lens system 14 is moved into the space A2 on the picture-taking optical axis O–O', as shown in FIG. 5(B), standard objective lens system 15 retracts into the space A4, while the spaces A1, A3, A5, A6 are not occupied by a lens system. In either case of FIGS. 5(A) (B), the spaces which are not occupied by an objective lens system remain to be A1, A6. Assume that the space A1 is allotted for a space for locating a shutter operating mechanism therein, while the space A6 is allotted for locating other camera mechanisms therein. When telephoto objective lens system 14 is moved into the space A2 on the picture-taking optical axis O–O', the space A3 on the side of the finder optical axis P–P' becomes empty. This empty space A3 may be used as a storage space for concave lens 5, when retracting from the finder optical axis P–P' in the direction of arrow *a*, as shown in FIG. 2(A), upon shifting from standard magnification to telephoto magnification in a finder optical system.

In FIG. 6(A), standard objective lens system 15 is located in the space A5 on the picture-taking optical axis O–O', telephoto objective lens system 14 is located in the space A3 offset from and out of registry with the optical axis O–O', and spaces A1, A2, A4, A6 are unoccupied by a picture-taking lens system. In the telephoto picture-taking condition as shown in FIG. 6(B), however, the telephoto objective lens system 14 is moved into the space A2 on the picture-taking optical axis O–O', and standard objective lens system 15 is moved from the space A5 on the optical axis O–O' into the space A6, while the spaces A1, A3, A4 A5 are unoccupied by a picture-taking lens system. As has been described earlier, a shutter operating mechanism and other camera mechanisms are located in the spaces A1, A6 which are not occupied by either of the objective lenses.

The space A6 which has remained empty as illustrated in FIG. 6(A) may be allotted as a space, into which convex lens 10 is retracted from the finder optical system in the direction opposite to the direction of arrow *d* in the finder optical system for the standard picture-taking condition, as shown in FIG. 3. As a result, a space into which convex lens 10 is retracted need not be additionally provided.

FIGS. 7 and 8 show one embodiment of the present invention, in which there is provided a camera as shown in FIG. 5, incorporating a finder lens system shown in FIG. 2.

Referring to FIG. 7 which shows the standard picture-taking condition, concave lens 5, concave lens 6, Albada lens 11 having a concave surface facing the eyepiece lens 7, and convex eyepiece lens 7 are consecutively located in this order from the front or object side on the finder optical axis, while optical image frame 7*a*

is formed on the surface of the eyepiece on the object side, and reflecting surface **11***a* is provided on the concave surface of Albada lens **11**.

On the other hand, objective lenses for the camera, i.e., standard objective lens **15** and telephoto objective lens **14** are mounted on respective arms of a V-shaped lever **13** which is pivoted to a camera body by means of a shaft **13***a* in a manner to be rotatable through a limited predetermined angle. Shown at **12** is film cartridge which is to be loaded in a predetermined position in the camera body, and film cartridge **12** is provided with an exposure window **12***a*. Shutter member **17** is operated by means of a shutter operating member **16** occupying the space A1 as shown in FIG. **5**.

In a standard picture-taking condition, the V-shaped lever **13** assumes a first position by turning in a clockwise direction from its home position, and the standard objective lens **15** is thus located on the picture-taking optical axis O–O′ passing through the center of exposure window **12***a* which lies in the camera focal plane and intersecting exposure window **12***a* at a right angle, and positioned in the space A5. In contrast thereto, telephoto objective lens **14** is positioned in the space A3 off the picture-taking optical axis.

For shifting or transferring from a standard picture-taking condition to a telephoto picture-taking condition as shown in FIG. **8**, V-shaped lever **13** is rotated in the direction of the arrow as shown in FIG. **7** in the counterclockwise direction, thereby shifting telephoto objective lens **14** from the space A3 to the second position in the space A2 on the picture-taking optical axis O–O′. At this time, standard objective lens **15** is moved from the space A5 on the optical axis O–O′ to the space A4 offset from the optical axis O–O′.

On the other hand, it is necessary for the finder optical system P–P′ that concave lens **5** be moved away from the optical axis in the direction *a* and concave lens **6** be moved along the optical axis P–P′ in an arrow direction *b* for varying the magnification of the finder image of the view finder in response to the selection of the objective lenses. At this time, telephoto objective lens **14** which has occupied the space A3 in the standard picture-taking condition is moved into the space A2, so that the space A3 becomes empty, and as a result concave lens **5** may retract into the space A3 as shown in FIG. **8**. Accordingly, a space, into which concave lens **5** retracts, should not be additionally provided thus contributing to a reduction in the size of the camera.

As is apparent from the foregoing description, when the magnification of a finder optical system is varied, part of the lenses in the optical system may be not only retracted from the optical path but also moved along its optical axis, without changing its dioptric power. In addition, the aforesaid part of lenses in the finder optical system may be moved into a space, from which an objective lens has been moved from its retracting position to the position on the optical path for varying a magnification, so that a space into which part of the finder optical system is to retract, should not be additionally provided thereby permitting efficient utilization of the space within the camera body.

FIG. **9** shows another embodiment of the present invention, in which there is provided a camera shown in FIG. **6**, incorporating the finder lens system as shown in FIG. **3**.

In FIG. **9** showing a telephoto picture-taking condition, concave lens **8** and convex lens **10** are positioned on the axis P–P′ of the finder optical system from the object side, as shown in FIG. **3**, followed by Albada lens **11**′ having a concave surface facing the eyepiece lens **9**, and the rear convex eyepiece lens **9** consecutively in this order, while as in FIG. **7**, an optical image frame and a reflecting surface (not shown) are provided on the surface of convex eyepiece lens **9** on the object side as well as on the concave surface of Albada lens **11**′ respectively.

Telephoto objective lens **14** is mounted on a first slide plate **20** which is slidingly movable over a predetermined range in a direction perpendicular to the picture-taking optical axis, by means of know pin-slot coupling or the like. First slide plate **20** is spring-loaded by a tension spring **21** provided between the slide plate **20** and a stationary portion of the camera in a manner that telephoto objective lens **14** held by one end thereof is urged to a position on the picture-taking optical path. On the other hand, standard objective lens **15** is mounted on second slide plate **22** which is slidably movable over a predetermined range in the direction parallel with first slide plate **20** and is urged to a position on the picture-taking optical path by means of a tension spring **23** provided between the second slide plate **22** and a stationary portion of the camera body. Meanwhile, one end **22***b* of second slide plate **22** extends up to a finder mechanism for supporting convex lens **10** in the finder optical system, in a manner that convex lens **10** is moved into or from the finder optical path in response to the movement of standard objective lens **15**. Pins **24**, **25** are carried by first and second slide plates **20**, **22**. Shown at **26** is a control lever coupled to and cooperating with a switching dial **27** provided on the outer surface (not shown) of the camera body, while both arm portions **26***a*, **26***b* of control lever **26** engage pins **24**, **25** at all times. Shown at **28** is a click spring for locking control lever **26** in a given rotational position by releasably engaging respective notches in the central section of lever **26**. Shown at **12** is a film cartridge loaded in a predetermined position within the camera body, as has been described earlier, and the film cartridge is equipped with an exposure opening **12***a*.

As shown in FIG. **9**, in the telephoto picture-taking condition, control lever **26** is in the rotational position which has been assumed by lever **26** when rotated through a predetermined angle in the counterclockwise direction so that first slide plate **20** is located in the position effected by the spring **21** and second slide plate **22** is urged by arm **26***b* in the direction opposite to the biasing direction of spring **23**. Accordingly, the telephoto objective lens **14** occupies the space A5 of FIG. **6** on the picture-taking optical axis O–O′ passing through the center of exposure opening **12***a* and perpendicularly incident on the opening **12***a*. In contrast thereto, standard objective lens **15** remains in the space A3 offset from the picture-taking optical axis O–O′.

For shifting from the above condition to the standard picture-taking condition, switching dial **27** is rotated from a TELE position to a STANDARD position, by returning the switching dial externally of the camera. Clockwise rotation of control lever **26** then causes first slide plate **20** to be moved in the direction opposite to the biasing direction of spring **21**, while causing second slide plate **22** to be moved to a position drawn by spring **23**. As a result, telephoto objective lens **14** is retracted from the space A2 on the optical axis O–O′ to the space A3 offset from the optical axis, while standard objective lens **14** is moved from the space A6 into the space A5 on the picture-taking optical axis O–O′, (FIG. **6**(a)).

On the other hand, in the finder optical system P–P', concave lens **8** is moved by known means along the optical axis P–P' in the direction of arrow B in response to the selection of objective lenses, while concave lens **10** mounted on second slide plate **22** is moved in the direction of arrow A. At this time, the space **A6** within the camera body becomes empty due to the removal of standard objective lens **15** therefrom, so that convex lens **10** may retract into the space **A6**, which is empty. Accordingly, the space **A6** may be used as a common retracting space both for standard objective lens **15** and for convex lens **10** in the finder system, thus dispensing with an additional space for convex lens **10** to retract with the resulting reduction in size of a camera.

When the camera shown in FIG. **6** is employed as the space **A3** into which telephoto objective lens **14** is retracted at the time of standard picture-taking becomes empty, such space **A3** may be used as a retracting space for part of the lenses in the finder optical system. This permits the use of the finder optical system as shown in FIG. **2**.

While there has been described and illustrated preferred embodiments of the present invention, it is apparent that numerous alterations, omissions and additions may be made without departing from the spirit thereof.

We claim:

1. A camera comprising:

a body having a lens storage space and a photographic optical axis perpendicularly incident on a focal plane in said body;

a plurality of objective lenses located in said body and selectively transferrable between advanced and retracted positions respectively in and out of registry with said optical axis for varying the camera image magnification;

a finder optical system proximate said storage space and including a field varying lens member transferrable between advanced and retracted positions respectively in and out of registry with said finder optical system, said lens member in its retracted position occupying said lens storage space; and

operating means for selectively advancing and retracting a first of said objective lenses, said first objective lens in its retracted position occupying said storage space and in its advanced position being out of said storage space and permitting the occupation thereof by said lens member.

2. A camera as set forth in claim **1**, wherein said objective lenses include a standard objective lens for use in photographing at a predetermined magnification, and a telephoto objective lens for use in photographing at a magnification higher than that of said standard objective lens.

3. A camera as set forth in claim **2**, wherein the optical axis of said finder optical system and the photographic optical axis are located in a common plane perpendicular to said focal plane and said standard objective lens and said telephoto objective lens are movable with the optical axes thereof maintained along said plane.

4. A camera as set forth in claim **3**, wherein said finder optical system comprises an inverse Galilean type finder and includes an Albada optical element positioned to form a view-limiting frame delineating a picture-taking range.

5. A camera as set forth in claim **4**, wherein at least said telephoto objective lens is movable from its retracted position in said storage space in the vicinity of said finder optical path to its advanced position, and said lens member comprises a concave lens which occupies said storage space when in retracted position from the finder optical path, said storage space being the space which has been occupied by the retracted telephoto objective lens before moving to is advanced position.

6. A camera as set forth in claim **5**, wherein said operating means includes a V-shaped lever including two arms one of which holds said telephoto objective lens and the other of which holds said standard objective lens, said lever being swingable through a predetermined angle so as to selectively transfer said lenses between their advanced and retracted positions.

7. A camera as set forth in claim **5**, wherein said operating means comprises a first slide plate slidably movable over a given range and supporting said telephoto objective lens for movement therewith between its retracted position occupying said storage space in the vicinity of said finder optical path and its advanced position; a second slidably movable slide plate supporting said standard objective lens for movement therewith between its retracted position and its advanced position; and an externally operable control member for moving said first and second slide plates to selectively advance said telephoto objective lens and said standard objective lens into registry with said photographic optical axis.

8. A camera as set forth in claim **4**, wherein said standard objective lens is movable from its retracted position in said storage space in the vicinity of said finder optical path to its advanced position, and said lens member comprises a convex lens which may enter said storage space from which said standard objective lens has advanced into registry with said camera body optical axis.

9. A camera as set forth in claim **8** wherein said operating means comprises a first slide plate supporting said telephoto objective lens and slidably movable with said telephoto objective lens over a given range between its retracted position and its advanced position; a second slide plate slidably movable over a given range and supporting said standard objective lens for movement therewith between its retracted position in said storage space in the vicinity of said finder optical path and its advanced position; and an externally operable control member for moving said first and second slide plates for selectively moving said telephoto objective lens and said standard objective lens to their advanced positions.

10. A camera comprising:

a camera body having a lens storage space and a photographic image optical axis;

a plurality of objective lenses selectively movable between respective advanced positions in registry with said photographic image optical axis and transversely offset from said photographic image optical axis, a first of said objective lenses in its retracted position occupying said lens storage space;

a view finder optical system including a lens member movable between an advanced position in registry with the optical axis of said view finder optical system and a retracted position occupying said lens storage space transversely offset from said view finder optical system to vary the field of view of said view finder; and

means for selectively alternatively transferring said objective lenses to their respective advanced posi-

tions, said storage space being empty of said first objective lens when said first objective lens is in its advanced position to permit the retraction of said view finder lens member into said storage space.

11. The camera of claim 10 wherein the optical axes of said view finder optical system and the camera photographic axis are laterally spaced and said storage space is disposed between said axes.

12. The camera of claim 11 including means for advancing and retracting said view finder lens member with the retraction and advance respectively of said first objective lens.

[57] **ABSTRACT**

A varifocal camera objective, having a rotatable control ring for adjustment to a desired focal length in a zoom range and to a closeup position in a macro range, is provided with a pair of independently settable stop members for selectively limiting the adjustability to less than the entire zoom range and for optionally excluding the macro range. The stop members coact with edges of a stepped recess in a rim of the control ring and are each indexable in an advanced and in a retracted position.

VARIFOCAL CAMERA OBJECTIVE WITH ADJUSTMENT-RANGE SELECTION

FIELD OF THE INVENTION

My present invention relates to a photographic or cinematographic camera equipped with a varifocal or zoom objective and with displaceable control means, such as a ring rotatable about the objective axis, for selecting a desired focal length within the zoom range as well as for focusing the camera upon a nearby object in a so-called macro range.

BACKGROUND OF THE INVENTION

The well-known varifocal objectives have a pair of axially shiftable components whose displacement with the aid of a camming ring changes the overall focal length from a maximum value in a telephoto position to a minimum value in a wide-angle position. It is also known to design the camming mechanism in such a way that further rotation of the ring beyond the wideangle position will move only one of these shiftable components to displace the previously stationary image plane so as to permit the taking of closeups in the macro range which is usually defined as encompassing image ratios between **1:10** and **1:1**.

While it is convenient to have a single control element available for both zooming and closeups, it is frequently desirable to prevent an accidental overshooting of the zoom range when the object or scene to be filmed or photographed is distant from the camera. Furthermore, working near the telephoto end of the zoom range generally requires a steadier support for the camera in order to prevent objectionable blurring, making it desirable to limit the extent of the varifocal adjustment when no tripod or the like is available. It is also known to provide varifocal objectives with diaphragms which automatically increase the relative aperture with changes in the focal length, e.g. from a midposition of the zoom range to the telephoto position. In this case, again, it may be undesirable under certain lighting conditions to move beyond the position where the relative aperture begins to grow larger.

It has already been proposed (see German Pat. No. 1,169,280) to provide a zoom-type camera with a stop which arrests a camming ring in an intermediate position unless the user makes a special effort to deactivate that stop. This mode of operation requires a higher degree of alertness on the part of an operator wishing to utilize the full zoom range.

OBJECT OF THE INVENTION

It is, therefore, the object of my present invention to provide means in such a photographic or cinematographic camera for enabling the operator to select beforehand the extent of the range of adjustment he wants to use, thereby allowing him to concentrate entirely on the normal tasks of focusing and zooming without paying special attention to the self-imposed range limitations.

SUMMARY OF THE INVENTION

I realize this object, in accordance with my present invention, by the provision of first and second stop means selectively settable independently of each other to coact with a camming ring or other control means for blocking movement thereof from the wide-angle position to the telephoto position beyond a predetermined intermediate position and away from the telephoto position past the wide-angle position, respectively.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of my invention will now be described in detail with reference to the accompanying drawing, the sole FIGURE of which shows a varifocal camera objective embodying the present improvement.

SPECIFIC DESCRIPTION

The drawing shows, diagrammatically, a camera **20** having a rear lens mount **3** fixedly secured thereto, this lens mount carrying a nonillustrated fixed-focus lens group supplemented by a varifocal front attachment of conventional type disposed within a housing. Rotatably mounted on this housing is a focusing ring **1** with a distance scale **1***a*, graduated in meters and feet, and a control ring **2** provided with a handle **4**, carrying a focal-length scale **2***a* graduated in millimeters. In the illustrated embodiment, the zoom range extends from a wide-angle position with $f = 6$ mm to a telephoto position with $f = 70$ mm. Scale **2***a* also indicates, adjacent the lower limit of the zoom range, a macro range to which the objective can be adjusted by an upward movement of knob **4** beyond the illustrated wide-angle position.

In accordance with my present invention, control ring **2** has an annular end face proximal to lens mount **3** which is formed with a stepped recess **6**. The deepest part of this recess is bounded by edges **9** and **10**, a shallower extension **7** of the recess terminating at an edge **11**. On its opposite side the recess **6** has a still shallower extension **5** bounded by an edge **8**.

Two stop members **13** and **15** in the form of axially extending pins are lodged in lens mount **3** and are provided with actuating knobs **12** and **14** received in slots of that lens mount in order to facilitate a shifting of these pins between an advanced position at left and a retracted position at right. The pins can be indexed in either of their positions by respective spring-loaded ball checks **18** and **19** engaging in notches **16** of pin **13** and notches **17** of pin **15**. With pin **13** in its advanced position, as illustrated in full lines, the zoom range is curtailed to end in the 40-mm position in which the pin comes to rest against edge **10** as indicated in phantom lines at **13'**. With pin **15** advanced, as also shown in full lines, the upward movement of handle **4** is stopped in the wide-angle position in which this pin abuts the edge **9**. Retraction of pin **13** opens up the full zoom range from 6 to 70 mm, the pin engaging the edge **11** in the telephoto position as indicated in phantom line at **13''**. The macro range is available upon retraction of pin **15** which then engages the edge **8** as indicated in phantom lines at **15'**. Recess edges **8** and **11** could also be replaced by lugs projecting from ring **2** toward lens mount **3**.

Obviously, the peripheral separation of pins **13** and **15** along the recessed end face of ring **2** must be at least equal to the angular extent of the macro range if the end of that range is to be determined in the aforedescribed manner by the coaction of pin **15** with edge **8**. With edge **9** higher than edge **10**, however, the macro range could also be limited by contact between edge **9** and pin **13** in either its advanced or its retracted position. In either case, the two stop pins **13** and **15** allow a preliminary selection to be made among four different working modes, namely:

(a) full zoom plus macro range,

(b) curtailed zoom plus macro range,
(c) full zoom without macro range,
(d) curtailed zoom without macro range.

With the objective focused on the macro range, the advance of pin **15** is prevented by the bottom of recess extension **5**. Similarly, pin **13** cannot be advanced in the upper part of the zoom range in which it confronts recess extension **7**.

While the embodiment described above is designed for manual adjustment of ring **2**, it will be apparent that the same range limitations can be selectively imposed if the ring is electrically driven by a reversible motor through the intermediary of a friction clutch, e.g. as described in commonly owned U.S. Pat. Nos. 3,165,044, 3,656,422 and 3,682,072.

I claim

1. In a camera having a varifocal objective provided with control means displaceable between a telephoto position and a wide-angle position for adjusting the focal length of the objective in a zoom range, said control means being further displaceable beyond said wide-angle position for focusing the objective upon nearby objects in a macro range, the combination therewith of:

first stop means coupled with said objective and selectively settable to coact with said control means for blocking movement thereof from said wide-angle position toward said telephoto position beyond a predetermined intermediate position; and

second stop means coupled with said objective and selectively settable independently of said first stop means to coact with said control means for blocking movement thereof away from said telephoto position past said wide-angle position.

2. The combination defined in claim **1** wherein said control means comprises a manually rotatable ring centered on the objective axis, said first and second stop means comprising a pair of axially shiftable members engageable with abutments on said ring.

3. The combination defined in claim **2** wherein said ring has an annular end face provided with a stepped recess with edges constituting said abutments, said members are peripherally spaced along said ring face within the bounds of said recess.

4. The combination defined in claim **2** wherein said members are provided with indexing means for alternate retention in an advanced position and in a retracted position.

WIDE ANGLE OBJECTIVE

This application is a continuation-in-part of co-pending application Ser. No. 392,118 filed Aug. 27, 1973, now abandoned.

This invention relates to lenses, and more particularly to those known as wide angle lenses of the retrofocus type.

Wide angle lenses may be defined as those in which the diameter of the film or image frame of the camera with which the lens is used is substantially equal to or greater than the equivalent focal length of the lens. Moderately wide angle rectrofocus objectives covering field angles of approximately 80° have been known for many years. Typically these lenses have been large in length and diameter resulting in considerable manufacturing expense and a lack of portability. In order to reduce the size, it is necessary to increase the lens element powers which normally increase the lens surface aberration contributions. When wide angle objectives of reduced size configuration are constricted to relative apertures of *f*/2.8, the need to correct large aperture dependence aberrations is apparent; however, when relative apertures of approximately *f*/2.0 or greater are desired, the amount of zonal spherical aberration and aperture dependent coma is considerably increased. Moreover, due to the large lens element powers, the amount of field curvature of third order and greater becomes excessive. Even though the aperture dependent aberrations may be well corrected, the zonal field curvature and astigmatism will severely limit resolution.

The present invention provides a new and improved lens configuration for wide angle objectives through the employment of a new lens grouping arrangement which minimizes the lens element powers in order to obtain the necessary back focal distance and front vertex distance as required to be useful in single lens reflex cameras. The minimization of the lens group powers decreases the surface contributions to distortion and various aberrations.

Briefly stated, a wide angle lens embodying the invention comprises a first lens group from the object end to the image end which is afocal, a second diverging group, third and fourth converging groups, a fifth diverging group and a sixth converging group. The lens groups and elements, and particularly the fourth group, have relative powers and configurations to achieve the objects of the invention, as hereinafter more specifically pointed out.

An object of this invention is to provide a new and improved wide angle lens of the retrofocus type.

Another object of this invention is to provide a lens of the type described of large relative aperture with minimized field curvature and astigmatism.

A further object of this invention is the provision of a lens of the type described having the capability of focusing to very close object distance without introduction of unacceptable field curvature and astigmatism.

The features of the invention which are believed to be novel are particularly pointed out and distinctly claimed in the concluding portion of this specification. However, the invention both as to its organization and operation, together with further objects and advantages thereof, may best be appreciated by reference to the following detailed description taken in conjunction with the drawings, wherein:

FIGS. **1** – **3** are side elevations of lens embodying the invention;

FIGS. **4** and **5** are curves illustrating the improved performance of the lens of FIG. **1**;

FIGS. **6** – **10** are side elevations of additional lens embodying the invention; and

FIGS. **11** and **12** are curves illustrating the improved performance of the lens of FIG. **8**.

In all lens designs, the elemental groupings and spacings thereof are chosen to minimize aberrations and distortion of the overall lens and generally provide a true image of an object. The lens groupings are chosen to provide a lens of given field angle or equivalent focal length for a specified image quality. Therefore, the contribution of each lens group or element in multi-element lens is incapable of precise definition inasmuch as all lens configurations are selected in view of the others to provide the desired result.

The objects of the present invention are achieved by the provision of a new grouping of lens elements as hereinafter described.

A lens embodying the invention as disclosed comprises six lens groups from the object end to the image end as follows:

I. A two element group of negative power.
II. A meniscus of negative power.
III. A positive element having a convex front surface.
IV. A positive element or doublet having a concave front surface and a convex rear surface.
V. A meniscus of negative power, and
VI. A positive doublet.

A first lens **10** embodying the invention is set forth in FIG. **1**, and comprises nine lens elements **L1** - **L9**, arranged in six lens groups. The surfaces of the elements **L1** – **L9** are defined in radii **R1** – **R16** as shown. The first group viewed from the object end to the image end comprises elements **L1** and **L2** which are, as a combination, afocal with respect to the equivalent focal length (EFL) of the overall lens. The second group II is comprised of a meniscus **L3** of negative power (diverging). The third group III is comprised of a biconvex element **L4** of positive power (converging). The fourth group IV is comprised of a contacting doublet **L5** and **L6** of positive power (converging). The fifth group V is comprised of a negative meniscus (diverging) and the sixth group VI is a contacting doublet of positive power (diverging). This lens is defined by the data set forth in Table I.

A second lens **11** embodying the invention is set forth in FIG. **2** and comprises lens elements **L1** – **L8**, arranged in six groups of the same relative powers as the lens of FIG. **1**. Lens **11** differs from lens **10** primarily in that Group IV comprises a single element **L5**, but which is still of positive power (converging). Lens **11** is defined by the data set forth in Table II.

Another lens **12** is shown in FIG. **3** and comprises the six group I – VI of the same relative power as lens **11**, having eight elements **L1** – **L8**. The lens surfaces are defined on radii **R1** – **R15** as shown. Lens **12** differs from lens **11** primarily in that Group VI, elements **L7** and **L8**, is comprised of a meniscus and a contacting bi-convex element in that order, rather than vice-versa, as lens **11**. Lens **12** is defined by the data as set forth in Table III.

In the tables the index of refraction is denoted as N_d and the dispersion as referenced by the Abbe number is denoted by V_d.

Table I sets forth data on lens 10 of FIG. 1 scaled to an EFL of 28.7mm for a 24 × 36mm image frame, and having a relative aperture of F/1.9.

	R14	31.429			
L8			4.000	1.776	50.6
	R15	−43.746			

BFL = 39.9mm

The aperture stop is located 10.79mm behind L3. The spacing between elements L2 and L3 varies between 0.25mm and 4.00mm for focusing from inifinity to 178mm. Elements L3 – L8 move in fixed relation as a group for focusing while L1 and L2 are stationary.

In the examples of Tables I - III, all lens have a rated EFL of 28mm and a rated equivalent aperture of F/1.9, as scaled to a film or image frame size of 24 × 36mm. The lenses may, of course, be scaled to other image frame sizes, and EFL's.

FIGS. 4 and 5 exemplify plots of image height versus focal plane shift for the lens of FIG. 1, and a known wide angle lens scaled to 28mm EFL and a stated relative aperture of F/2.0, respectively, as shown in U.S. Pat. No. 3,736,049. Comparisons were made at a magnification of M = −0.025 for a half image height of 20mm, for both sagittal S and tangential T rays.

The curves of FIG. 4 are relatively close together evidencing essential elimination of astigmatism. The curves of FIG. 4 have less deviation from the vertical, and are generally flatter than those of FIG. 5, to evidence a substantial reduction in field curvature.

The lenses of Tables I, II and III are designed for the first group elements L1 and L2 to be stationary while the rear elements are shifted in fixed relation as a group for focusing, as disclosed and claimed in the copending application of John A. Lawson, Ser. No. 492,413, filed July 29, 1974.

However, the lens Groups may also be arranged to move differentially as in the conventional wide angle objectives. For example, the entire objective may be shifted for focusing, while the fourth and fifth lens Groups move differentially in a well known manner. Also, the lens may be arranged to move only Groups V and VI for focusing, as disclosed and claimed in U.S. Pat. No. 3,975,090.

Further examples of lenses embodying the invention are set forth in FIGS. 6 – 10, and Tables IV – IX. In all

of the examples, Group IV is an air spaced doublet L5, L6.

Table IV sets forth data on the lens 13 of FIG. 6 as scaled to an EFL of 28.5mm for a 24 × 36mm image plane, and having a relative aperture of F/1.9.

The aperture stop is located 7.18mm after L3. The BFL varies from 39.68mm to 44.34mm as the lens is focused from infinity to an object distance of 174.7mm. All lens elements move for focusing and the space between Groups IV and V moves differentially as shown.

Table V sets forth data on a lens 14 substantially as shown in FIG. 7 scaled to an EFL of 28.6mm for a 24 × 36mm frame size and a relative aperture of F/1.9.

TABLE V

L9	R16	−18.940	2.700	1.805	25.5
	R17	−42.358			

The aperture stop is located 12.3mm after L3. The BFL varies from 39.2mm to 43.2mm as the lens is focused from infinity to an object distance of 203mm. Groups I–IV are stationary while Groups V and VI (elements L7–L9) move in fixed relation for focusing.

Table VI sets forth data on lens 15 of FIG. 8 scaled to an EFL of 35.0mm for a 24 × 36mm image frame, and a relative aperture of F/2.0.

TABLE VI

	R16	−20.430			
L9			2.700	1.805	25.5
	R17	−44.190			

The aperture stop is located 11.5mm behind L3, Groups V and VI move from a BFL of 39.2mm to 43.2mm for focusing from infinity to 203mm while Groups I – IV are fixed with respect to the film plane.

FIGS. 11 and 12 exemplify further comparison of the focal plane shift of the lens of FIG. 8 and the lens of the previously mentioned patent at a magnification of M = −0.025 for a half image height of 20mm, for both sagittal S and tangential T rays.

The curves of FIG. 11 are relatively close together evidencing substantially less astigmatism than FIG. 12. The curves of FIG. 11, particularly in the saggital have less deviation from the vertical, evidencing reduction in field curvature.

As previously mentioned, the contribution of each lens group to an overall lens is incapable of precise definition since properties of one or more elements and groups serve the same function and are complimenting and supplementing each other. However, in the new lens form described, Group IV is designed to provide certain contributions to the overall lens.

Group IV provides a substantial correction for the Petzval sum of the lens. The axial spacing of the front and rear surfaces contributes to correction of field curvature convex toward the object. Additionally, it provides positive power required to shorten the EFL of the overall lens while maintaining the required back focal length (BFL) to make the lens of the retrofocus type. The EFL of Group IV (F_4) should have the following relation to the EFL of the overall lens (F_o).

$$2.5\ F_o \leqq F_4 \leqq 6.5\ F_o$$

The foregoing is a critical relation, and other preferred relationships exist which do not have the same criticality. The radius R_{44} of the rear surface is less than F_o, or

$$F_o > R_{44}$$

This relationship contributes to correction for distortion. The axial separation D_4 between front and rear surfaces is a substantial percentage of the EFL of the lens and preferably is in the range of

$$0.4\ F_o \geqq D_4 \geqq 0.20\ F_o$$

Additionally, to maintain the desired power contribution the combined EFL of Groups III and IV (F_{34}) is preferably

$$2.0\ F \geqq F_{34} \geqq 1.0\ F_o$$

As shown Group IV may be a single element or a doublet, either cemented or air spaced. It might also be defined in three elements. The front surface of Group III, L4, is convex. However, the rear surface may be other than convex depending on the design.

Groups V and VI are of positive power of a magnitude determined by the power of the other elements but in the preferred designs have an EFL (F_{56})

$$4.0 \geqq F_{56} \geqq 1.0$$

while the EFL (F_6) of Group VI is

$$2.0 > F_6 \geqq 1.0$$

Group III is of positive power to supplement the positive power of Group IV and preferably has an EFL (F_3) range

$$2.5 \geqq F_3 \geqq 1.2F_o$$

The ranges set forth above may be better appreciated in consideration with Table X which tabulates the ratio of the EFL of each group and combinations thereof to the overall EFL of the lens.

TABLE X

	RATIO OF EFL OF LENS GROUPS TO EFL OF LENS								
TABLE	GROUP I	GROUP II	GROUP III	GROUP IV	GROUP V	GROUP VI	GROUPS V & VI	GROUPS I - IV	GROUPS III & IV

The lenses disclosed may be focused on an object as close as 6.25 EFL's or less than seven inches in the case of the lens of Table IV. In the case of the lens of Table I, the lens is focused to 6.37 EFL or 7.02 inches with minimal astigmatism and field curvature, as exemplified in FIG. 4.

Table XI exemplifies the close focusing capability of the various lens disclosed.

TABLE XI

LENS		CLOSE FOCUS DISTANCE (FD)		$FD/_{EFL}$
TABLE	I	178mm	7.02 in.	6.20
	II	178	7.02	6.20
	III	178	7.02	6.20
	IV	175	6.91	6.14
	V	203	7.99	7.12
	VI	230	9.06	6.57
	VII	221	8.70	6.31
	VIII	258	10.20	7.37
	IX	203	7.99	7.12

It may thus be seen that the objects of the invention set forth above as well as those made apparent are efficiently attained. The invention provides a new wide-angle lens of the retrofocus type having a large relative aperture which will focus to an object distance of less than seven EFL's with minimal astigmatism and field curvature.

While preferred embodiments of the invention have been set forth for purposes of disclosure, other embodiments and modification to the disclosed embodiment of the invention may be derived by others skilled in the art. Accordingly, the appended claims are intended to cover all embodiments and applications of the invention and reversals thereof which do not depart from the spirit and scope of the invention.

What is claimed is:

1. A lens of the retrofocus type which comprises a plurality of lens elements arranged in six groups along a common optical axis from the object end to the image end as follows: a first group of negative power including positive and negative lens element, a second negative group in the form of a meniscus having a concave image side surface, a third positive group having a convex object side surface, a fourth positive group having a concave object side surface and convex image side surface, a fifth negative group consisting of a meniscus having a convex object side surface, and a sixth positive group consisting of a biconvex doublet.

2. The lens of claim 1 further defined by

$$6.5\ F_o \geqq F_4 \geqq 2.5F_o$$

where F_o is the equivalent focal length of the overall lens, and F_4 is the equivalent focal length of the fourth group.

3. The lens of claim 1 further defined by

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

where F_{34} is the combined equivalent focal length of the third and fourth groups, and F_o is the equivalent focal length of the overall lens.

4. The lens of claim 1 further defined in that the first surface of said fourth group is concave and the distance D_4 between the first and last surface thereof is

$$0.45\ F_o \geqq D_4 \geqq 0.20\ F_o$$

where F_o is the equivalent focal length of the overall lens.

5. The lens of claim 1 further defined by

$$2.0\ F_o \geqq F_6 \geqq 1.0\ F_o$$

where F_o is the equivalent focal length of the overall lens and F_6 is the equivalent focal length of the sixth group.

6. The lens of claim 1 further defined by

$$2.5\ F_o \geqq F_3 \geqq 1.2\ F_o$$

where F_3 is the equivalent focal length of said third group, and F_o is the equivalent focal length of the overall lens.

7. The lens of claim 1 further defined by

$$5.5\ F_o \geqq F_4 \geqq 2.5\ F_o$$

where F_4 is the equivalent focal length of said fourth group and F_o is the equivalent focal length of the overall lens.

8. The lens of claim 1 defined by substantially the following data as scaled to an equivalent focal length of 28.7mm.

Lens		Radius	Axial Distance Between Surfaces	N_d	V_d

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

where F_{34} is the combined equivalent focal length of the third and fourth groups, and F_o is the equivalent focal length of the overall lens.

18. The lens of claim 2 further defined in that the axial distance D_4 between the first and last surface of said fourth group is

$$0.45\ F_o \geqq D_4 \geqq 0.20\ F_o$$

where F_o is the equivalent focal length of the overall lens.

19. The lens of claim 2 further defined by

$$2.5\ F_o \geqq F_3 \geqq 1.2\ F_o$$

where F_3 is the equivalent focal length of said third group, and F_o is the equivalent focal length of the overall lens.

20. The lens of claim 2 further defined by

$$2.0\ F_o \geqq F_6 \geqq 1.0\ F_o$$

where F_o is the equivalent focal length of the overall lens and F_6 is the equivalent focal length of the sixth group.

21. The lens of claim 1 further defined by

$$6.5\ F_o \geqq F_4 \geqq 2.5\ F_o \text{ and}$$

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

where F_4 is the equivalent focal length of said fourth group, F_{34} is the combined equivalent focal length of said third and fourth groups and F_o is the equivalent focal length of the overall lens.

22. A retrofocus lens consisting of nine elements and from the object side comprising a first two element group including a positive and a negative lens element of overall negative power, a third element in the form of a negative meniscus having a convex object side surface, a fourth positive element having a convex object side surface, fifth and sixth elements, said fifth element having a concave object side surface and said sixth element having a convex image side surface, said fifth and sixth elements being of overall positive power, a seventh element in the form of a negative meniscus having a convex object side surface, and eighth and

ninth elements cemented together and being overall bi-convex.

23. The lens of claim 22 further defined by

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

where F_{34} is the combined equivalent focal length of the third and fourth groups, and F_o is the equivalent focal length of the overall lens.

24. The lens of claim 22 further defined in that the axial distance D_4 between the first and last surface of said fourth group is

$$0.45\ F_o \geqq D_4 \geqq 0.20\ F_o$$

where F_o is the equivalent focal length of the overall lens.

25. The lens of claim 22 further defined by

$$2.5\ F_o \geqq F_3 \geqq 1.2\ F_o$$

where F_3 is the equivalent focal length of said third group, and F_o is the equivalent focal length of the overall lens.

26. The lens of claim 22 further defined by

$$2.0\ F_o \geqq F_6 \geqq 1.0\ F_o$$

where F_o is the equivalent focal length of the overall lens and F_6 is the equivalent focal length of the sixth group.

27. A retrofocus lens consisting of eight elements and from the object side comprising a first two element group including a positive and negative lens element of overall negative power, a third element in the form of a negative meniscus having a convex object side surface, a fourth positive element having a convex object side surface, a fifth positive element having a concave object side surface and a convex image side surface, a sixth element in the form of a negative meniscus having a convex object side surface, and seventh and eighth elements cemented together and being overall bi-convex.

28. A lens of the retrofocus type which comprises from the object end a first group of a positive and a negative element of overall negative power, a second group of negative power in the form of a meniscus having a concave image side, a third group of positive power having a convex object side surface, a fourth positive group comprising two elements and having a concave object side and a convex image side, a fifth group and a sixth group, said fifth group consisting of a negative meniscus having a convex object side surface, said sixth group consisting of a biconvex doublet.

29. The lens of claim 28 further defined by

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

where F_{34} is the combined equivalent focal length of the third and fourth groups, and F_o is the equivalent focal length of the overall lens.

30. The lens of claim 28 further defined in that the axial distance D_4 between the first and last surface of said fourth group is

$$0.45\ F_o \geqq D_4 \geqq 0.20\ F_o$$

where F_o is the equivalent focal length of the overall lens.

31. The lens of claim 28 further defined by

$$2.5\ F_o \geqq F_3 \geqq 1.2\ F_o$$

where F_3 is the equivalent focal length of said third group, and F_o is the equivalent focal length of the overall lens.

32. The lens of claim 28 further defined by

$$2.0\ F_o \geqq F_6 \geqq 1.0\ F_o$$

where F_o is the equivalent focal length of the overall lens and F_6 is the equivalent focal length of the sixth group.

33. The lens of claim 28 further defined by

$$1.5\ F_o \geqq F_{34} \geqq 1.0\ F_o$$

$$0.45\ F_o \geqq D_4 \geqq 0.20\ F_o$$

$$2.5\ F_o \geqq F_3 \geqq 1.2\ F_o$$

$$2.0\ F_o \geqq F_6 \geqq 1.0\ F_o$$

where

F_o is the equivalent focal length of the overall lens,

F_{34} is the combined equivalent focal length of the third and fourth groups,

D_4 is the axial distance between the front and rear surfaces of the fourth group,

F_3 is the equivalent focal length of the third group, and

F_6 is the equivalent focal length of the sixth group.

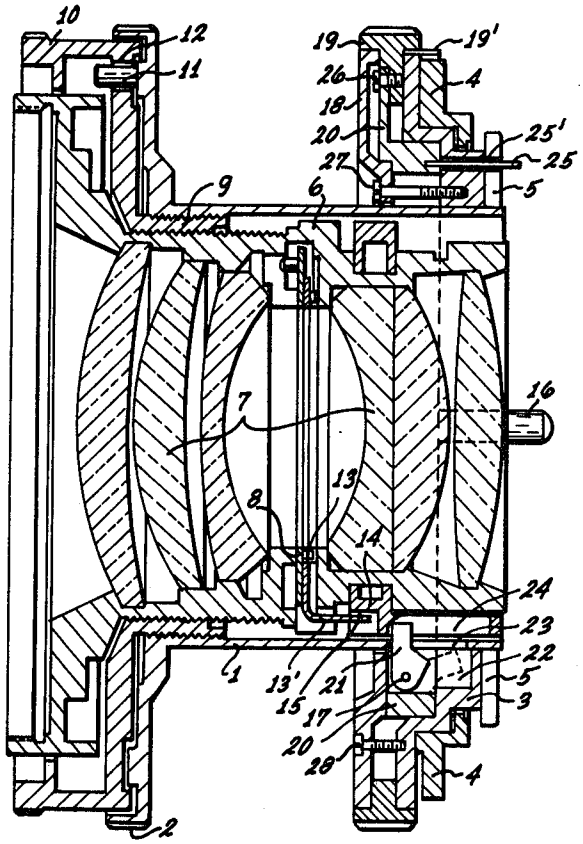
[57] **ABSTRACT**

An interchangeable objective for a camera to provide diaphragm control. The objective has an objective tube and a lens mounting axially movable in the tube. A bayonet ring is provided for connecting the objective tube to a camera. Further means are provided for axially moving said objective tube within the bayonet ring to bring said tube into and out of the camera housing and for engaging said tube into the bayonet ring in the position ready for exposure. A diaphragm adjustment ring is rotatably mounted on the bayonet ring, and a diaphragm control ring rotatably disposed on the lens mounting transmits the adjustment of the adjustment ring upon the diaphragm. A coupling element on the adjustment ring is disengageable from and capable of being engaged into the diaphragm control ring.

4 Claims, 3 Drawing Figures



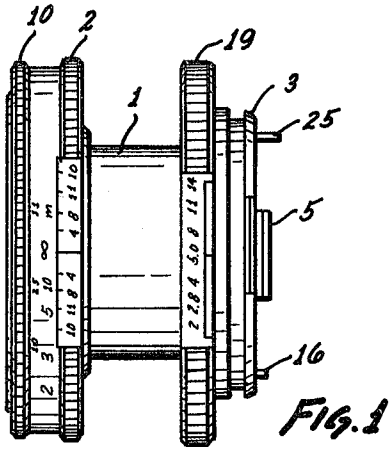


Fig. 1

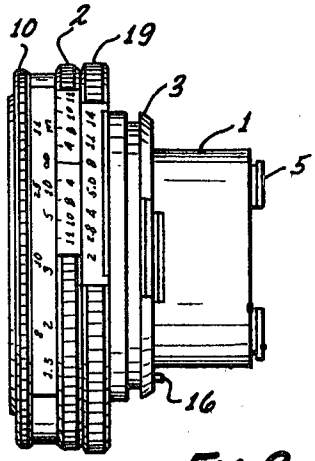

Fig. 2

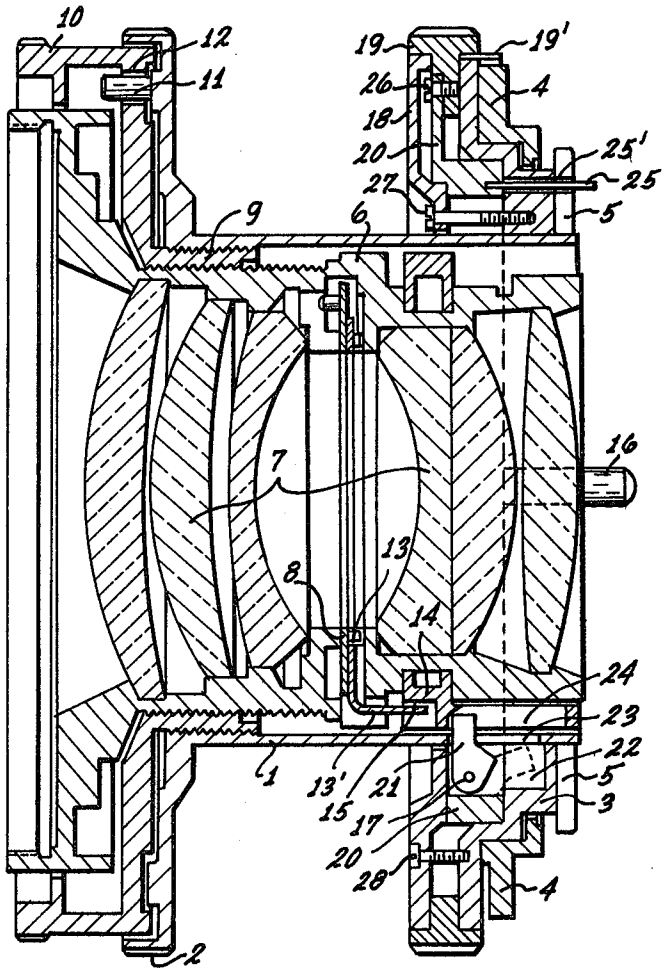

Fig. 3

INTERCHANGEABLE OBJECTIVE FOR CAMERAS

BACKGROUND OF THE INVENTION

The present invention relates to interchangeable objectives for cameras of the type having an objective tube and a lens mounting axially displaceable thereon so that the diaphragm may be adjusted after the objective has been inserted.

Objectives for cameras of the type referred to above are known. These known objectives are focussed by axial displacement of the lens in the objective tube. A knurled ring is arranged at the objective tube for turning, and a worm gear translates the turning motion into an axial displacement of the lens mounting in the objective tube. The objective may be focussed and the diaphragm may be adjusted, e.g. by means of a diaphragm adjustment ring, even when the objective has been removed from the camera. Also, the objective tube carrying the lens with the diaphragm, the knurled ring and the diaphragm adjustment ring may be moved at will within the bayonet ring of the objective regardless of whether the objective is mounted at the camera bayonet mounting or not.

Cameras are known having an exposure metering or exposure control system which require coupling with the objective diaphragm. In this case, it is conventional practice to provide the diaphragm adjustment ring with a plunger extending from the objective in direction to the camera or with a pin which can be swivelled. Such a plunger or pin engage a coupling element in the camera to couple the diaphragm with the exposure metering or control system when the objective is introduced and locked to the camera. The coupling must be coordinated with the introduction or removal of the objective that the coupling elements and plungers or pins clearly cooperate in a form-locking and positive-drive position.

SUMMARY OF THE INVENTION

It is accordingly an object of the present invention to provide a reliable connection or coupling of an interchangeable objective to a camera.

It is another object of the present invention to improve interchangeable objectives having a tube for holding the objective proper, a diaphragm and a bayonet connection.

It is a particular object of the present invention to improve the construction of interchangeable objectives not only having a lens which moves axially for focusing - inclusively its diaphragm - but being also displaceable with its objective tube over a larger distance without requiring long and complicated transmission devices or rods.

In accordance with the present invention, a diaphragm adjustment ring is rotatably mounted on the bayonet ring of the objective. The adjustment ring carries a coupling element which may be disengaged from or engaged with a diaphragm control ring being rotatably mounted on a lens mounting of the objective. The diaphragm control ring adjusts the diaphragm. Hence, the diaphragm adjustment ring is spatially fixedly mounted with respect to the objective bayonet ring. Therefore, the known simple coupling with the coupling portions of the camera for transmitting or controlling the diaphragm may be retained.

Preferably, the coupling element is comprised of a lever that turns about a tangential axis at the diaphragm adjustment ring. The lever may be selectively turned into the path of an axial projection of the diaphragm control ring or be moved into a cutout of the objective bayonet ring.

Further in accordance with the invention, an opening may be provided at the objective tube for this lever which is so limited in its axial direction that it permits passage of the lever only in the exposure position of the objective tube. When the objective tube is introduced it displaces the lever outwardly and hence locks the diaphragm adjustment ring at the objective bayonet ring. Accordingly, the diaphragm adjustment ring will function for adjustment of the diaphragm only when the tube has been pulled out. Vice versa, removal of the objective from the camera is possible only when the objective tube has been pushed in. Furthermore, the diaphragm adjustment ring has a double function in that it serves on the one hand as diaphragm adjustment ring proper, and on the other hand as actuating ring or handle for connecting the objective to the camera or removing it therefrom.

According to a further extension of the invention, the cutout of the objective bayonet ring is correlated to a predetermined position of the diaphragm adjustment ring, preferably corresponding to the largest opening of the objective diaphragm in such a manner that the lever may drop into the cutout only in this position. Thus, the diaphragm adjustment ring and diaphragm control ring may disengage only then, and the coupling of diaphragm adjustment ring with the bayonet ring and the introduction of the objective tube into the camera housing is likewise possible only in this position.

DESCRIPTION OF THE DRAWINGS

While the specification concludes with claims particularly pointing out and distinctly claiming the subject matter which is regarded as the invention, it is believed that the invention, the objects and features of the invention and further objects, features and advantages thereof will be better understood from the following description taken in connection with the accompanying drawings, in which:

FIG. **1** is a side elevational view of the interchangeable objective of the invention, the objective tube being pulled out;

FIG. **2** is a side elevational view corresponding to that of FIG. **1** with the objective tube pushed in; and

FIG. **3** is a longitudinal section of the entire objective and a camera bayonet mounting corresponding to the position of FIG. **1**.

Referring now to the drawings, there is illustrated an objective tube **1** having a frontal flange with a knurled ring **2** which serves as a handle. Tube **1** is axially slidably mounted in an objective bayonet ring **3**. The objective bayonet ring **3** can be inserted into bayonet mounting **4** shown in FIG. **3**, mounting **4** pertaining to the camera housing. The tube **1** carries also a bayonet ring **5** which faces the camera and serves as an axial stop. When the tube is in the pulled out position and ready for exposure, bayonet ring **5** can be inserted and locked into the objective bayonet ring **3**. The objective tube **1** is locked in the position ready for exposure as shown in FIG. **3**.

A lens mounting **6** with a lens system **7** and a diaphragm of iris **8** is provided in tube **1**. A worm gear that is disposed in a sleeve **9** having inner and outer threads guides the lens mount. The adjustment knurled ring **10** of the sleeve **9** is turned to move the lens **7** in an axial

direction for purposes of focussing. Turning of ring **10** or of the sleeve **9** is limited to an adjustment range by a pin **11** mounted on the knurled ring **2** of the tube **1** and by an arcuate slot **12** of the adjustment knurled ring **10**.

The diaphragm **8** is arranged within the lens system in a known manner. The blade or lamella drive ring **13** is adjusted by a follower lever **13'** being connected thereto. Lever **13'** is controlled by a diaphragm control ring **14** by means of its radial cam track **15**. The diaphragm control ring **14** is rotatably mounted on the lens mounting **6**. A diaphragm adjustment ring **20** is, in turn, rotatably mounted between the objective bayonet ring **3** and a bayonet ring housing **18**, the latter being connected with the objective bayonet ring **3** by screws **27** and **28**.

Ring **20** is connected to knurled ring **19** by a screw **26**. This knurled ring **19** will be gripped by the user for manipulating ring **20**. Ring **19** covers partially the diaphragm scale **19'** disposed at the upper portion of the objective bayonet ring **3**. A lever **21** is mounted at the diaphragm adjustment ring **20** for turning about a tangential axis **17**. The objective bayonet ring **3** is provided with an axial cutout **22** into which the lever **21** may be pushed as shown in dotted lines at **21'**. This requires, of course, that lever **21** and cutout **22** are in alignment with each other. On the other hand, an opening **23** is provided in the tube **1** and is traversed by the lever **21**, whereby the lever **21** projects into the interior of the tube. Insertion of lever **21** into cutout **22** occurs when tube **1** is pushed into the camera. As lever **21** is inserted in cutout **22**, the diaphragm adjustment ring **20**, or respectively the knurled ring **19**, is locked to the objective bayonet ring **3**. This opening **23** extends over that portion of the circumference of the tube which corresponds to the region of adjustment of the diaphragm. The axial length of the opening **23** is selected, at least in one place, so that lever **21** can only pass through this opening when the tube has been pulled out or extended.

The cutout **22** of the objective bayonet ring **3** and the position of the tube opening **23** having the greates axial length for the insertion of the lever **21**, are arranged so that they permit the introduction of the lever only for one very particular position of the diaphragm adjustment ring corresponding to a particular predetermined position of the diaphragm; this corresponds preferably to the largest adjustable diaphragm opening.

The diaphragm control ring **14** carries an axial extension **24** which, for example, is constructed to have the configuration of a fork into which the lever **21** may move through the opening **23** of the tube **1** due to the action of a spring not illustrated. The diaphragm adjustment ring **20** and the diaphragm control ring **14** are coupled in this manner. The axial length of the extension **24** depends upon the greatest axial movement of the lens mounting **6** during focussing.

Since the extension **24** is constructed as a fork, lever **21** provides a rigid coupling between the diaphragm **8** and the diaphragm adjustment ring **20** or its knurled ring **19**. By means of a tappet **25** which extends rearwardly from the diaphragm adjustment ring **20** through the arcuate slot **25'**, a rigid connection is provided to the exposure and diaphragm control at the camera in the conventional manner.

For cameras having a measurement with open diaphragm and wherein the diaphragm is closed only and moved to the correct aperture value when the shutter is released, the extension **24** is preferably not arranged as a fork but should be provided as a simple stop. As the shutter is released in this case the diaphragm **8** is closed in the known manner by means of a diaphragm plunger **16** and against the action of a spring or under the action of a spring; that is the diaphragm control ring **14** is turned until closure movement of the diaphragm is stopped by the stop **24** intercepting lever **21**. In this known camera the diaphragm is again fully opened after exposure, independently of the diaphragm value previously adjusted on the scale **19'**. In this case, the most favorable solution for the position of the cutout **22** for the lever **21** for the adjustment of the diaphragm adjustment ring **19** corresponds to the largest opening of the diaphragm at scale **19'**.

The position of the objective as illustrated in FIG. 3 shows the objective attached to the camera and ready for exposure; focussing is accomplished by turning the knurled ring **10**, while the diaphragm is adjusted by turning the ring **19**. After adjustment of the diaphragm to the above mentioned, predetermined aperture value, the tube **1** may be disengaged by means of the handle **2** at the bayonet ring **3** and may be pushed into the camera housing. While the tube is pushed in, the lever **21** is displaced into the cutout **22** of the bayonet ring **3**. Thus, the diaphragm adjustment ring **20** is now locked to the objective bayonet ring **3** so that the objective can be disengaged by means of the knurled handle **19** from the camera bayonet ring **4** and removed from the camera.

In the opposite case, when the objective has been removed from the camera or the tube had been pushed in the camera housing, adjustment of the diaphragm is not possible. The diaphragm **8** or the diaphragm blade drive **13** is disengaged from the diaphragm adjustment ring when the objective tube is pushed in. However, the diaphragm retains this position without the necessity of an additional locking device because an adjustment of the diaphragm is not possible without engaging the interior of the objective. The only possibility is to manually operate the plunger **16**. This, however, will not result in any damage because the plunger is returned to its rest position by the action of a spring.

The invention is not limited to the embodiments described above but all changes and modifications thereof not constituting departures from the spirit and scope of the invention are intended to be included.

I claim:

1. Interchangeable objective for a camera to provide diaphragm control, said objective comprising:

(a) an objective tube; a lens mounting being disposed in and axially movable in said objective tube;

(b) a lens or lens system and a diaphragm mounted in said lens mounting;

(c) a bayonet ring for connecting said objective tube to the camera, said objective tube being axially movably disposed in the bayonet ring for purposes of inserting the tube into the camera and pulling the tube out of the camera;

(d) releasable means for engaging said objective tube with the bayonet ring in a position ready for exposure after the tube has been pulled out of the camera and for disengaging the tube from the ring for pushing the tube into the ring and the camera;

(e) a diaphragm adjustment ring being rotatably mounted on said bayonet ring;

(f) a diaphragm control ring for transmitting the adjustment of said adjustment ring upon the diaphragm, said control ring being rotatably disposed on said lens mounting; and

(g) a coupling element being movably disposed on said diaphragm adjustment ring and capable of being engaged with and disengaged from the diaphragm control ring, respectively, when the objective tube has a pulled out and an inserted position.

2. Objective as defined in claim **1**, wherein said coupling element includes a lever for turning about a tangential axis on said diaphragm adjustment ring, a cutout on said bayonet ring, an axial projection on said diaphragm control ring, said lever being capable for selective turning into the path of said axial projection of said control ring and into said cutout of said bayonet ring.

3. Objective as defined in claim **2** wherein an opening is provided in said objective tube for the passage of said lever, said opening being limited in an axial direction in such a manner that the passage of said lever is only permitted when said objective tube is in a position ready for taking exposures, and said opening displacing said lever during the insertion of said objective tube into the camera outwardly into said cutout of said bayonet ring.

4. Objective as defined in claim **2** wherein said cutout of said bayonet ring is coordinated with a predetermined position of said diaphragm adjustment ring so that it permits the passage of said lever and therefore the insertion of said objective tube into the camera only in said predetermined position.

[57] **ABSTRACT**

A varifocal forward lens group of a camera objective, with a pair of axially shiftable negative components bracketed by a pair of substantially fixed positive components, has its negative third component more widely separated from its positive fourth component in a wide-angle position of minimum overall focal length than in a telephoto position of maximum overall focal length. The effective diameter of that third component is just large enough to let a bundle of axially incident light rays fully illuminate the fourth component in the wide-angle position, with less than full illumination in the telephoto position. The positive first component is also just large enough to provide full illumination of the effective area of the third component by axial rays in the telephoto position.

FIG. 6B

CAMERA OBJECTIVE OF VARIABLE FOCAL LENGTH

FIELD OF THE INVENTION

Our present invention relates to a camera objective of the pancratic type, having a variable focal length, in which a four-component varifocal forward lens group is coaxially juxtaposed with a fixed-focus rear lens group.

BACKGROUND OF THE INVENTION

In such objectives it is customary to assemble the varifocal front group from two axially shiftable components of negative refractivity bracketed by two positively refracting components whose axial position is substantially fixed (allowance being made for a limited axial adjustability, for focusing purposes, of especially the first component or at least a front lens forming part thereof). A typical varifocal or pancratic objective of this description has been disclosed in U.S. Pat. No. 3,433,559 and in our copending application Ser. No. 713,224 filed Aug. 10, 1976.

There are certain relationships in such a system between their optical qualities, such as relative aperture and varifocal ratio, and their structural parameters including front-lens diameter and total axial length. These relationships are well understood in the art; reference may be made, by way of example, to Austrian Pat. No. 317,576.

It is generally convenient to design the varifocal front group as an afocal system in order to allow interposition of ancillary elements, such as a shutter, a diaphragm and a reflex prism, in a field of parallel rays between the two groups. Since the fourth component of the front group is positively refracting, the combination of the three preceding components must be of dispersive character so that axially incident rays diverge from the axis between the third and fourth components. The extent of this divergence increases, of course, in proportion to the axial separation of the two components; an axial ray bundle fully illuminating the stationary fourth component passes, therefore, through a smaller portion of the third component when the latter is in a forward position than when it lies close to the fourth component.

Systems are known (e.g. from Austrian Pat. Nos. 317,576 and 316,891) in which the axial movement of the third component, designed to keep constant the image plane of the objective during changes of the overall focal length, follows a substantially symmetrical course as the second component is shifted rearwardly from a wide-angle position of minimum focal length f_{min} to a telephoto position of maximum focal length f_{max}. In such a case, the third component moves forwardly during a changeover from f_{min} to an intermediate focal length f_{med} and then recedes at about the same rate during a changeover from f_{med} to f_{max}, being substantially equidistant from the fourth component in the two limiting positions of the varifocal range.

Alternatively, e.g. as known from French Pat. No. 1,459,076 and German published Specification No. 2,164,937, the motion of the third component may be an unsymmetrical function of the displacement of the second component, so chosen that the third component approaches the fourth component more closely in the telephoto position (f_{max}) than in the wide-angle position (f_{min}).

OBJECT OF THE INVENTION

The object of our present invention is to provide a more compact varifocal objective of the type specified in which the lens diameters, especially that of the front lens, can be significantly reduced with only a minor loss of illumination in certain positions of adjustment.

SUMMARY OF THE INVENTION

In accordance with our present invention, the first three components of a varifocal forward lens group as defined above have lens diameters sufficient for full illumination of the fourth component by axially incident light rays in the wide-angle position, in which the third and fourth components are relatively widely separated, with such dimensioning of the third component as to make its effective area sufficient for full illumination of the fourth component by axially incident light rays in the wide-angle position, yet with restriction of that bundle of light rays in the telephoto position to less than full illumination of the fourth component.

Thus, taking advantage of the aforedescribed unsymmetrical law of displacement in which the third and fourth components are far apart with the overall focal length $f = f_{min}$ but are closely spaced with $f = f_{max}$, we provide a maximum aperture ratio in the wide-angle position and a slightly reduced aperture ratio in the telephoto position in which a small loss of luminosity at the center of the image (e.g. on the order of one diaphragm stop) can be readily tolerated. This minor restriction of the relative aperture of the objective at the telephoto end of the varifocal range allows a considerable reduction in the diameter of the front lens which can thus be manufactured much more inexpensively and accommodated in a camera housing of correspondingly decreased dimensions. The lowering of the aperture ratio at large overall focal lengths has the incidental advantage of an increased depth of field in the telephoto position.

According to another feature of our invention, the effective area of the third component is circumscribed by an ancillary diaphragm carried thereon, preferably at the forward face of a constituent lens of that component. The ancillary diaphragm may be part of the lens mount for that component.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. 1 is a schematic view of a conventional pancratic objective with a symmetrical law of displacement for the third component, shown in five different positions;

FIG. 2 is a view similar to FIG. 1 but showing, again in five different positions, a pancratic objective with an asymmetrical law of displacement to which our invention is applicable;

FIG. 3 shows the objective of FIG. 2 provided with an ancillary diaphragm reducing its entrance pupil in the telephoto position;

FIGS. 4A, 4B, and 4C are more detailed presentations of an objective of the type shown in FIGS. 2 and 3, illustrated in its wide-angle, intermediate and telephoto positions, respectively;

FIG. 5 is a view similar to FIG. 4A, showing another objective according to our invention in its wide-angle position; and

FIGS. 6A and 6B are more detailed diagrammatic views of the objective of FIG. 3 in its wide-angle and telephoto positions, respectively.

SPECIFIC DESCRIPTION

The conventional pancratic or zoom objective shown in FIG. 1, which may be designed for a camera of the Super-8 type, has a varifocal front attachment consisting of a substantially stationary positive front component 1, two axially shiftable negative components 2 and 3, and a fixed positive component 4; this attachment is coaxially juxaposed with a fixed-focus rear lens group or basic lens system 5. At Z we have shown a limiting ray of an axially incident light bundle focused on a point F_5 which is a focal point of component 5 inasmuch the group 1 – 4 is considered to be afocal. Point F_5 lies on an image plane I_5 whose position is unaffected by the correlated axial displacement of components 2 and 3. Components 1 – 5 have all been represented as thin lenses.

In graph A of FIG. 1, which illustrates the wide-angle position of minimum focal length, component 2 is at extreme left while component 3 is closely spaced from component 4. With component 2 moving progressively toward the right into the telephoto position illustrated in graph E, component 3 is shifted first to the left (graphs B and C), then begins to move back to the right (graph D) and ends up at its original small spacing from component 4 (graph E).

As further shown in graph E of FIG. 1, the limiting ray Z is refracted by component 1 toward its focal point F_1 located in an image plane I_1 of that component, is intercepted by component 2 so as to seem to originate at an image plane I_2, is further refracted by component I_3 which increases its divergence from the optical axis to make its apparent origin in an image plane I_3 coincide with the focal point F_4 of component 4, and then passes parallel to the axis to component 5 (the image plane of component 4 being thus at infinity).

The object distance of component 2, between that component and image plane I_1, has been designated a_{II}; the corresponding image distance between that component and plane I_2 is designated b_{II}. In an analogous manner we have designated by a_{III} the object distance of component 3 (measured from plane I_2) and by b_{III} the image distance of component 3 (extending to plane I_2). With the generally symmetrical law of displacement of component 3 the system satisfies the relationships

$$a_{IIW} = -b_{IIT}$$

and

$$b_{IIW} = -a_{IIT}$$

where the subscripts W and T indicate the wide-angle position of FIG. 1 (A) and the telephoto position of FIG. 1 (E), respectively. In the middle position of FIG. 1 (C), we have

$$a_{IIM} = -b_{IIM}.$$

The magnification ratio β_{II} of the second component 2 in the wide-angle position is the reciprocal of that in the telephoto position, i.e.

$$\beta_{IIW} = 1/\beta_{IIT}.$$

In the middle position of FIG. 1 (C), with $f = f_{med}$, we find

$$\beta_{IIM} = -1.$$

For the third component 3 we have

$$a_{IIIW} = a_{IIIT},$$

$$b_{IIIW} = b_{IIIT},$$

$$\beta_{IIIW} = \beta_{IIIT}.$$

If the position of the limiting ray Z is determined by the diameter of component 4, then the effective area of component 3 varies inversely with its distance d_{III} from component 4. The radius of this effective area has been indicated at h_{III} in FIG. 1(A) and is the same in the wide-angle and telephoto positions. The relative aperture B_{III} of component 3 can thus be expressed by

$$B_{III} = f_{III}/2h_{III}$$

where f_{III} is the individual focal length of this component. It follows that, in the system of FIG. 1,

$$B_{IIIW} = B_{IIIT}.$$

In the system of FIG. 2 the separation d_{IIIW} between components 3 and 4 in the wide-angle position, graph A, substantially exceeds the corresponding spacing d_{IIIT} in the telephoto position of graph E. With zooming from the position of FIG. 2 (A) to that of FIG. 2 (E), component 3 moves forward into the position of FIG. 2 (B) and reaches its most advanced point in the intermediate position of FIG. 2 (C). In that position we again have the relationships

$$a_{IIM} = -b_{IIM}$$

and

$$\beta_{IIM} = -1.$$

With further increases in the overall focal length, component 3 recedes into the position of FIG. 2 (D) before reaching its final position closest to component 4 according to FIG. 2 (B).

Instead of the equations relating to the system parameters of FIG. 1, we now have the following inequalities:

$$a_{IIW} < -b_{IIT},$$

$$-b_{IIW} > a_{IIT},$$

$$d_{IIIW} < d_{IIIT},$$

$$B_{IIIW} < B_{IIIT}.$$

The final inequality results from the fact that, owing to the close spacing of components 3 and 4 in the telephoto position, radius h_{IIIT} is significantly larger than the corresponding radius h_{IIIW} in the wide-angle position.

In accordance with our present invention, and as shown in FIG. 3, the effective radius h_{III} is limited in the telephoto position (graph E) to the value h_{IIIW} which it assumes in the wide-angle position (graph A). This limitation is here brought about by the provision of an ancillary diaphragm 6 fastened to the front face of component 3, the presence of this diaphragm being without

effect upon the width of the axially incident light bundle in the positions of graphs B and C in which the spacing of component 3 from component 4 exceeds that of graph A. In FIG. 3(D) the axial separation of these components is slightly less than in graph A so that diaphragm 6 begins to restrict the effective diameter of component 3, thereby reducing the entrance pupil of the objective. In FIG. 3(E) this restriction results in a limiting ray Z' traversing the front component 1 at a point whose distance h'_I from the axis is substantially less than the corresponding distance h_{IT} of ray Z. Thus, the diameter of component 1 can be materially reduced without significantly restricting the brightness of the image except in positions at or close to the telephoto end of the varifocal range.

The ancillary diaphragm 6 may be part of the lens mounting of component 3. Even if that diaphragm were omitted, the reduction of the diameter of the front component would have an equivalent effect on the axially incident ray bundle.

The relationships briefly discussed above will be better understood from a reference to FIGS. 6A and 6B in which the focal points of positive component 1, negative components 2, 3 and positive component 4 have been indicated at F_1, F_2, F_3 and F_4. An axially incident bundle of parallel light rays, with limiting rays Z, impinges upon component 1 and converges toward its focal point F_1 whose image plane I_1 also constitutes the object plane O_2 of component 2. The light bundle intercepted by the latter component appears to originate at an image plane I_2 which is also the object plane O_3 of component 3. The relative positions of components 2 and 3 are so chosen that the image plane I_3 of component 3, also constituting the object plane O_4 of component 4, always passes through the focal point F_4 whereby the light bundle is focused on infinity after leaving the lens group 1 - 4.

In view of the afocality of this lens group, focal point F_4 constitutes the vertex of a light cone whose base has a diameter equal to that of component 4. As component 3 approaches component 4, its own effective diameter must increase if it is to pass all the rays of this light cone that can be collected by component 4 in the wide-angle position of FIG. 6A. The incident cylindrical light bundle corresponding to this cone fills only a limited central zone of front component 1. In the telephoto position of FIG. 6B, however, component 1 must have a large diameter in order to allow full illumination of component 4. By making the effective diameter of component 3 in the telephoto position equal to that in the wide-angle position, we can substantially reduce the diameter of component 1 with only a minor diminution of the total quantity of incident light as indicated by the hatched areas in FIG. 6B.

In FIGS. 4A, 4B and 4C we have shown the wide-angle position, the middle position and the telephoto position of a representative objective conforming to the one indicated diagrammatically in FIGS. 1, 2 and 3. Component 1 comprises a front lens member in the form of a doublet consisting of a negative meniscus L_1 with radii r_1, r_2 and thickness d_1 cemented onto a nearly planoconvex lens L_2 with radii r_2, r_3 and thickness d_2. Component 1 further includes two positive lenses L_3 (radii r_4, r_5 and thickness d_3) and L_4 (radii r_6, r_7 and thickness d_4) with intervening air spaces s_1 and s_2. A variable air space s_3 separates lens L_4 from the axially shiftable component 2 consisting of a singlet L_5 in the form of a negative meniscus (radii r_8, r_9 and thickness d_5) separated by an air space s_4 from a doublet consisting of lenses L_6 (radii r_{10}, r_{11} and thickness d_6) and L_7 (radii r_{11}, r_{12} and thickness d_7). Another variable air space s_5 lies between component 2 and component 3 which consists of a single lens L_8 in the form of a negative meniscus with radii r_{13}, r_{14} and thickness d_8. In dotted lines we have illustrated an alternate position of component 3 designed to facilitate, in a manner known per se, the taking of pictures in a so-called macro range with image ratios between 1: −10 and 1: −1. A third variable air space s_6 lies between component 3 and axially fixed component 4 which in this instance consists of two air-spaced biconvex lenses L_9 (radii r_{15}, r_{16} and thickness d_9) and L_{10} (radii r_{17}, r_{18} and thickness d_{10}), the intervening air space having been designated s_7.

A reflex prism P of thickness d_p, whose planar faces have been designated r_a and r_b, is separated by an air space s_8 from lens L_{10} and by a diaphragm space s_d from component 5, the latter space containing an iris diaphragm 7 distinct from the invariable ancillary diaphragm 6 on face r_{13} on lens L_8. Component 5 consists of five air-spaced singlets, namely a biconvex lens L_{11} (radii r_{19}, r_{20} and thickness d_{11}), a positive meniscus L_{12} (radii r_{21}, r_{22} and thickness d_{12}), a biconcave lens L_{13} (radii r_{23}, r_{24} and thickness d_{13}), a planoconvex lens L_{14} (radii r_{25}, r_{26} and thickness d_{14}) and another positive meniscus L_{15} (radii r_{27}, r_{28} and thickness d_{15}); the intervening air spaces have been designated s_9, s_{10}, s_{11} and s_{12}.

In the following Table A we have given representative numerical values for the parameters $r_1 - r_{28}$, $d_1 - d_{15}$ and $s_1 - s_{12}$ of the optical system of FIGS. 4A - 4C, based upon a mean overall focal length $f_{med} = 1$ in the middle position of FIG. 4B. The Table also gives the refractive indices n_d and the Abbe number ν_d of the various lenses.

L_{14}	r_{25}	=	∞				
				$d_{14} = 0.21$	1.713	53.8	
	r_{26}	= −	0.772				
				$s_{12} = 0.01$			
L_{15}	r_{27}	= +	0.953				
				$d_{15} = 0.14$	1.620	60.3	
	r_{28}	= +	4.297				

This system has a minimum focal length $f_{min} = 0.46$, a maximum focal length $f_{max} = 3.44$, a relative aperture varying between 1: 1.2 (in the wide-angle position) and 1 : 1.5 (in the telephoto position), and an image diagonal $2y' = 0.47$. As indicated in the Table, the effective diameter D_{8eff} of lens L_8 has the numerical value 0.78. Thus, the objective has a varifocal ratio $f_{max} : f_{min}$ of about 8 : 1, with $f_{min} \approx 2y'$. The reduced diameter of front component **1**, realized by a decrease of the relative aperture in the telephoto position, amounts to about 85% of the diameter that would be required for full illumination of component **4** in that position.

FIG. **5** shows another embodiment of our invention in the wide-angle position. Its front component **1'** comprises a positive doublet consisting of lenses L'_1 (radii r'_1, r'_2 and thickness d'_1) and L'_2 (radii r'_2, r'_3 and thickness d'_2) closely followed by two positive menisci L'_3 (radii r'_4, r'_5 and thickness d'_3) and L'_4 (radii r'_6, r'_7 and thickness d'_4), the intervening air spaces s'_1 and s'_2 being practically zero. A variable air space s'_3 separates component **1'** from component **2'** which again consists of two lens members, i.e. a singlet L'_5 (radii r'_8, r'_9 and thickness d'_5) and a doublet made up of lenses L'_6 (radii r'_{10}, r'_{11} and thickness d'_6) and L'_7 (radii r'_{11}, r'_{12} and thickness d'_7). After another variable air space s'_5 there follows the third component **3'**, again consisting of a single negative meniscus L'_8 (radii r'_{15}, r'_{16} and thickness d'_8), separated by a third variable air space s'_6 from the fourth component **4'** which in this instance is a single biconvex lens L'_9 (radii r'_{15}, r'_{16} and thickness d'_9). A reflex prism **P'**, of thickness d'_p and with planar faces r'_a, r'_b, is separated from lens L'_9 by an air space s'_7 and from the rear component **5'** by a diaphragm space s'_d.

Component **5'** consists here of four singlets, namely a positive lens L'_{10} (radii r'_{17}, r'_{18} and thickness d'_{10}), a positive lens L'_{11} (radii r'_{19}, r'_{20} and thickness d'_{11}), a negative lens L'_{12} (radii r'_{21}, r'_{22} and thickness d'_{12}) and a positive lens L'_{13} (radii r'_{23}, r'_{24} and thickness d'_{13}); the intervening air spaces have been designated s'_8, s'_9 and s'_{10}.

Representative numerical values for parameters $r'_1 - r'_{24}$, $d'_1 - d'_{13}$ and $s'_1 - s'_{10}$, again based on a mean focal length $f_{med} = 1$, are given together with refractive indices n_d and Abbe numbers ν_d in the following Table B.

TABLE B

This system has a minimum focal length $f_{min} = 0.27$ and a maximum focal length $f_{max} = 2.78$. Its relative aperture ranges from 1 : 1.8 (in the wide-angle position) to 1 : 2 (in the telephoto position); its image diagonal is $2y' = 0.31$. The effective diameter of lens L'_8, given in the Table, is $D'_{8eff} = 0.47$. The minimum focal length f_{min} falls here short of the image diagonal $2y'$ by more than 10%. The objective of Table B is not as fast as that of Table A but has a higher varifocal ratio, slightly exceeding 10 : 1.

In practice, the reduction of the diameter of the front component **1** cannot be carried quite as far as diagrammatically illustrated in FIG. **6B** because of the adverse effect this would have on nonaxially incident light bundles. Hence, component **3** and diaphragm **6** are chosen to determine the relative aperture of the system throughout its varifocal range.

We claim:

1. In a camera objective of variable focal length including a varifocal forward lens group and a fixed-focus rear lens group centered on a common optical axis, said forward lens group consisting of a substantially axially fixed positive first component, an axially shiftable negative second component, an axially shiftable negative third component and an axially fixed fourth component, said second and third components being displaceable between a wide-angle position of minimum overall focal length and a telephoto position of maximum overall focal length with maintenance of an invariant image plane behind said rear lens group, said third component approaching said fourth component more closely in said telephoto position than in said wide-angle position, the combination of said first, second and third components being of dispersive character, the improvement wherein said first, second and third components have lens diameters sufficient for full illumination of said fourth component by axially incident light rays in said wide-angle position but wherein said third component has an effective area sufficient for full illumination of said fourth component by a bundle of axially incident light rays in said wide-angle position but restricting said bundle to less than full illumination of said fourth component in said telephoto position.

2. The improvement defined in claim **1** wherein said third component is provided with diaphragm means circumscribing said effective area.

3. The improvement defined in claim **2** wherein said diaphragm means is carried on a front face of a constituent lens of said third component.

4. The improvement defined in claim **2** wherein said diaphragm means forms part of a lens mount for said third component.

5. The improvement defined in claim **1** wherein said first component consists of four lenses L_1, L_2, L_3 and L_4,

said second component consists of lenses L_5, L_6 and L_7, said third component consists of a lens L_8 and said fourth component consists of lenses L_9 and L_{10}, said lenses having radii of curvature $r_1 - r_{18}$, axial thicknesses $d_1 - d_{10}$ and axial spacings $s_1 - s_7$ whose numerical values, based upon a numerical value of unity for an intermediate overall focal length, together with their refractive indices n_d and Abbe numbers ν_d are substantially as given in the following table:

		n_d	ν_d
$r_1 = +\ 21.9$			
	$d_1 = 0.15$	1.81	25
$r_2 = +\ 3.2$			
	$d_2 = 0.46$	1.61	60
$r_3 = -\ 262.6$			
	$s_1 = 0.01$		
$r_4 = +\ 3.7$			
	$d_3 = 0.32$	1.69	50
$r_5 = +\ 30.3$			
	$s_2 = 0.01$		
$r_6 = +\ 3.0$			
	$d_4 = 0.29$	1.74	45
$r_7 = +\ 8.9$			
	$s_3 = \begin{cases} 0.06 \ldots f_{min} \\ 0.95 \ldots f_{med} \\ 1.77 \ldots f_{max} \end{cases}$		
$r_8 = +\ 5.9$			
	$d_5 = 0.08$	1.69	55
$r_9 = +\ 1.0$			
	$s_4 = 0.39$		
$r_{10} = -\ 1.3$			
	$d_6 = 0.15$	1.85	24
$r_{11} = -\ 1.0$			
	$d_7 = 0.06$	1.57	63
$r_{12} = +\ 6.8$			
	$s_5 = \begin{cases} 1.54 \ldots f_{min} \\ 0.58 \ldots f_{med} \\ 0.18 \ldots f_{max} \end{cases}$		
$r_{13} = -\ 1.0$			
	$d_8 = 0.06$	1.74	45
$r_{14} = -\ 3.9$			
	$s_6 = \begin{cases} 0.42 \ldots f_{min} \\ 0.49 \ldots f_{md} \\ 0.06 \ldots f_{max} \end{cases}$		
$r_{15} = +\ 5.6$			
	$d_9 = 0.17$	1.62	60
$r_{16} = -\ 2.4$			
	$s_7 = 0.01$		
$r_{17} = +\ 3.9$			
	$d_{10} = 0.14$	1.62	60
$r_{18} = -\ 5.9$			

6. The improvement defined in claim 5 wherein the effective diameter of lens L_8 has a numerical value of substantially 0.78.

7. The improvement defined in claim 1 wherein said first component consists of four lenses L'_1, L'_2, L'_3 and L'_4, said second component consists of lenses L'_5, L'_6 and L'_7, said third component consists of a lens L'_8 and said fourth component consists of a lens L'_9, said lenses having radii of curvature $r'_1 - r'_{16}$, axial thicknesses $d'_1 - d'_9$ and axial spacings $s'_1 - s'_6$ whose numerical values, based upon a numerical value of unity for an intermediate overall focal length, together with their refractive indices n_d and Abbe numbers ν_d are substantially as given in the following table:

		n_d	ν_d
$r'_1 = +\ 123.1$			
	$d'_1 = 0.11$	1.81	25
$r'_2 = +\ 2.8$			
	$d'_2 = 0.43$	1.62	60
$r'_3 = -\ 5.2$			
	$s'_1 = 0$		
$r'_4 = +\ 2.3$			
	$d'_3 = 0.17$	1.62	53
$r'_5 = +\ 4.2$			
	$s'_2 = 0$		
$r'_6 = +\ 1.6$			
	$d'_4 = 0.24$	1.64	48
$r'_7 = +\ 4.0$			
	$s'_3 = \begin{cases} 0.03 \ldots f_{min} \\ 0.99 \ldots f_{med} \\ 1.37 \ldots f_{max} \end{cases}$		
$r'_8 = +\ 4.3$			
	$d'_5 = 0.04$	1.69	55
$r'_9 = +\ 0.5$			
	$s'_4 = 0.23$		
$r'_{10} = -\ 1.1$			
	$d'_6 = 0.04$	1.62	60
$r'_{11} = +\ 0.6$			
	$d'_7 = 0.15$	1.81	25
$r'_{12} = +\ 3.2$			
	$s'_5 = \begin{cases} 1.40 \ldots f_{min} \\ 0.26 \ldots f_{med} \\ 0.16 \ldots f_{max} \end{cases}$		
$r'_{13} = -\ 1.0$			
	$d'_8 = 0.01$	1.79	47
$r'_{14} = -\ 4.0$			
	$s'_6 = \begin{cases} 0.12 \ldots f_{min} \\ 0.30 \ldots f_{med} \\ 0.03 \ldots f_{max} \end{cases}$		
$r'_{15} = +\ 1.0$			
	$d'_9 = 0.10$	1.68	48
$r'_{16} = -\ 3.6$			

8. The improvement defined in claim 7 wherein the effective diameter of lens L'_8 has a numerical value of substantially 0.47.

[57] **ABSTRACT**

An iris diaphragm of a reflex camera, spring-biased into a wide-open position, is settable to a preselectable stop position via a linkage including a cam follower on an integral extension of a resilient swing ring oscillatable about an off-axial fulcrum. The cam follower coacts with a cam disk which is manually rotated against the force of a restoring spring during a windup operation and, upon subsequent release, displaces the cam follower and the swing ring which entrains the setting ring of the diaphragm through a yieldable coupling to the selected stop position and restores it to the wide-open position in the course of a revolution. During windup, a beveled flank on the high dwell of the cam disk axially displaces the extension of the swing ring which is thereby made ineffectual and prevented from reducing the diaphragm aperture.

DIAPHRAGM PRESELECTOR FOR CAMERA OBJECTIVE

CROSS-REFERENCE TO RELATED APPLICATION

This is a continuation-in-part of our copending application Ser. No. 752,833 filed Dec. 21, 1976.

FIELD OF THE INVENTION

Our present invention relates to an iris diaphragm for a camera equipped with a reflex-type viewfinder

BACKGROUND OF THE INVENTION

In such cameras, especially in those provided with interchangeable objectives in which the reflex mirror must be disposed behind an iris diaphragm, it is known to provide a preselector which is adjustable to a desired stop position, the diaphragm being normally biased into its wide-open position from which is it briefly displaced into the preselected position just before the tripping of a shutter by a release button or the like. This enables the operator to use full illumination when sighting and focusing upon an object to be photographed.

Such cameras are generally equipped with a windup handle which is manually operated to advance the film, cock the shutter and possibly carry out additional functions such as reactivating the viewfinder after its disablement upon the previous exposure. With the subsequent actuation of the shutter release, by which a control member coupled with the handle is returned to its original position by a restoring spring, the motion of this control member can be utilized to displace the iris diaphragm into its selected stop position and back to its wide-open position in timed relationship with the opening and closure of the shutter. Such an arrangement, which does not use the windup stroke itself for diaphragm control, has been disclosed in German Pat. No. 2,062,230. That system comprises a cam disk executing a full forward rotation during the windup stroke and a full reverse rotation during the return stroke, a coacting cam follower being connected with the setting ring of the diaphragm through a linkage including a yieldable coupling. The linkage further comprises a relatively complicated system of levers and springs designated to facilitate the escapement of the cam follower during the next windup stroke without entrainment of the setting ring.

OBJECT OF THE INVENTION

The object of our present invention is to provide an improved preselecting mechanism of this character which is of simplified construction and has a reduced number of relatively movable parts.

SUMMARY OF THE INVENTION

In accordance with our present improvement, the linkage between the cam follower and the setting ring of the iris diaphragm comprises a swingable member having a fulcrum offset from the diaphragm axis (which is also the axis of the associated objective), the cam follower being rigid with a resilient extremity of this member which lies substantially diametrically opposite the fulcrum with reference to that axis. The cam disk and the cam follower are provided with coating surfaces serving for the axial deflection of the cam follower, and thereby of the extremity of the swingable member on which it is supported, at the beginning of each windup stroke whereby the cam follower is disaligned for the remainder of that stroke from a radially effective ramp surface of the disk normally engaged by it; thus, the aforementioned camming surfaces form part of a unidirectionally effective escapement mechanism which deactivates the setting control during windup. An abutment coacting with the axially deflected extremity facilitates realignment of the cam follower with the ramp surface at the end of each windup stroke; this abutment preferably forms a contact surface on the cam disk engageable by the cam follower itself.

In a preferred embodiment of our invention, the swingable member comprises an oscillating ring substantially centered on the diaphragm axis at least in the wide-open position in which the cam follower engages a low dwell on the coating ramp surface, the aforementioned extremity being an extension of this ring.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** is an exploded perspective view of an iris diaphragm and an associated preselecting mechanism according to our invention;

FIG. **2** is an axial view of part of the assembly, taken on the line II—II of FIG. **1**;

FIG. **3** is a view similar to FIG. **2**, showing an alternate position;

FIG. **4** is a detail view, drawn to a larger scale, of a camming mechanism included in the assembly of FIGS. **1–3**; and

FIG. **5** is a cross-sectional view taken on the line V—V of FIG. **4**.

SPECIFIC DESCRIPTION

In order to facilitate a comparison between the system of the aforementioned German Pat. No. 2,062,230 and our present improvement, the same reference numerals have been used wherever practical. The illustrated assembly comprises a mounting ring **1** of an iris diaphragm having lugs **3** with holes **2** for pins **5** of a set of iris leaves **4** having other pins **7** receivable in inclined guide slots **8** of a setting ring **9** rotatable with reference to ring **1** about a common axis **0**. A preselecting ring **13**, centered on the same axis, carries a lug **14** with a pointer **15** co-operating with a stationary diaphragm scale **16**. Ring **13** has a cutout **13***a* with an edge **17**, not centered on the diaphragm axis, engageable by a pin **18** on an arm **12** of a bell-crank lever having a fixed fulcrum **35**. A second arm **11** of this lever has a bifurcate end engaging a stud **10** which is rigid with setting ring **9**. Another stud **36** on ring **9** is connected to a coil spring **34** which is anchored to the objective housing and tends to rotate the ring **9** counterclockwise (as viewed in FIGS. **2** and **3**) into a wide-open position in which the iris leaves **4** are fully withdrawn as shown in FIGS. **1** and **2**. With pointer **15** confronting a selected mark on scale **16**, the curvature of edge **17** determines a point beyond which the ring **9** will not be able to rotate clockwise against the force of spring **34**.

In accordance with our present invention, an oscillating ring **27** of resilient sheet material (e.g. punched from a metallic or plastic foil) is swingable about a fixed fulcrum **28** on one side of the objective axis **0**, i.e. at the top as shown in FIGS. **1–3**, and is provided at its opposite side (thus at the bottom) with an integral extension **27***a* rigidly connected with a cam follower **29**. The

latter coacts with a cam disk **25** on a shaft **22** having a coupling head **23** provided with a slot **24** through which it is linked with a nonillustrated control element, such as a shaft of a pinion driven through approximately **360°** upon the displacement of a windup handle coupled with a gear or rack in mesh with that pinion. A restoring spring **26** is tensioned during a clockwise windup stroke after which the shaft **22** and the disk **25** are latched in the position of FIG. **2**, with the cam follower **29** urged by a spring **33** against a low dwell of the disk. A pin **32** on lever arm **12** passes through a slot **30** of swing ring **27** and is normally held against the right-hand end of that slot (as viewed in FIGS. **2** and **3**) by the spring **34** acting through ring **9** and stud **10**; pin **32** and slot **30** thus constitute a yieldable lost-motion coupling between setting ring **9** and cam follower **29**. Shaft **22** is journaled in a housing wall **35**, omitted for the sake of clarity in FIG. **1** but shown in FIGS. **4** and **5**. An extension **22'** of this shaft beyond cam disk **25** ends in a pair of lugs **22''** by which it may be coupled to an unidirectional film-transport mechanism.

Upon the tripping of the shutter release, the nonillustrated control element coupled with shaft **22** is unlatched whereupon spring **26** rotates the shaft and cam disk **25** counterclockwise as viewed in FIGS. **2** and **3**. Cam follower **29**, riding on a ramp surface **25*b*** of disk **25**, is progressively displaced toward the right and eventually comes to rest on the high dwell of the cam after about half a revolution. At or before this point, depending upon the setting of preselector ring **13**, pin **18** contacts the edge **17** of that ring so that setting ring **9** is no longer entrained and iris leaves **4** occupy the selected position as diagrammatically illustrated for one of these leaves in FIG. **3**. Next, the nonillustrated camera shutter is briefly opened with stoppage of the rotation of shaft **22**, if necessary, to expose the film. Thereafter, as cam disk **25** continues its rotation beyond the position of FIG. **3** into substantially its starting position shown in FIG. **1**, as determined by the engagement of a web **25*c*** with a fixed stop **37** on housing wall **36**, cam follower **29** drops back onto the low dwell of disk **25** and restores the setting ring to normal, thereby returning the diaphragm to its wide-open position shown in FIG. **2**. Swing ring **27** also reverts to its normal position centered on axis **0**.

During the next windup stroke, which is clockwise in FIGS. **2** and **3** but counterclockwise in FIG. **4**, a beveled flank **25*a*** extending from the high dwell of cam disk **25** to its low dwell coacts with an oppositely beveled facet **29*a*** of cam follower **29** whereby extension **27*a*** of swing ring **27** is resiliently deflected in an axial direction indicated by an arrow A in FIG. **5**. The resiliency of ring **9** and the force of spring **33** now combine to hold the cam follower **29** against a face **25*d*** of cam disk **25** as well as against a contact surface constituted by the periphery of shaft extension **22'** which thus acts as an abutment limiting the displacement of ring extension **27*a*** of spring **33**. At the end of the windup stroke, with stop **37** contacted by the opposite side of web **25*c***, cam follower **29** confronts a zone **25*e*** of disk **25** in which the ramp surface **25*b*** is flush with the contact surface of shaft extension **22'** so that the cam follower is able to snap back into alignment with the coacting ramp surface to re-establish the initial starting position in which the associated control element is relatched. Thus, the assembly shown in FIGS. **4** and **5** constitutes a unidirectionally effective escapement mechanism as discussed above.

As in the prior German patent already referred to, an ancillary ring **19** also centered on axis **0** is provided with a handle **20** by which it may be rotated to reduce the diaphragm aperture independently of the shutter release within the limits set by preselector **13**, **14**. Ring **19** has an extension **21** engaging a pin **31** on ring extension **27*a*** whereby counterclockwise rotation of ring **19** separates the cam follower **29** from cam disk **25** within the limits established by curve **17** of ring **13**.

The compact preselection mechanism according to our invention links the setting ring **9** and the cam follower **29** through the intermediary of only two relatively movable members forming a lost-motion coupling therebetween, i.e. the oscillating ring **27** and the bell-crank lever **11**, **12** establishing a positive connection between ring **9** and pin **32**; there is no need for a biasing spring acting upon that lever. This minimizes the risk of malfunction due to spring fatigue or similar mechanical failures.

We claim:

1. In a reflex camera having an iris diaphragm centered on an optical axis and provided with a setting ring rotatable about said axis, biasing means engaging said settable ring for urging same into a wide-open diaphragm position, preselector means adjustable to a desired stop position, a spring-loaded cam disk manually rotatable in one direction against its spring force during a windup stroke and rotatable by its spring force in the opposite direction during a picture-taking operation, cam-follower means coacting with a radially effective ramp surface of said cam disk, and a linkage including a yieldable lost-motion coupling between said cam-follower means and said setting ring engageable with said preselector means for entraining said setting ring into the desired stop position,

the improvement wherein said linkage comprises a swingable resilient member having a fulcrum offset from said axis, said cam-follower means being rigid with an extremity of said member substantially diametrically opposite said fulcrum with reference to said axis, said cam disk and said cam-follower means being provided with coacting surfaces for axially deflecting said extremity at the beginning of each windup stroke with consequent disalignment of said cam-follower means and said ramp surface for the remainder of said windup stroke.

2. The improvement defined in claim **1** wherein said member is an oscillatable ring substantially centered on said axis in said wide-open position.

3. The improvement defined in claim **2** wherein said yieldable coupling includes a pin positively connected with said setting ring and urged by said biasing means against an edge of a slot in said oscillatable ring traversed by said pin.

4. The improvement defined in claim **1** wherein said ramp surface has a low dwell engaged by said cam-follower means in said wide-open position and a high dwell engaged by said cam-follower means at an intermediate point of said windup stroke, said high dwell being separated from said low dwell by a beveled flank forming one of said coacting surfaces.

5. The improvement defined in claim **4**, further comprising abutment means positioned for coaction with the axially deflected extremity of said member to enable a realignment of said cam-follower means with said ramp surface at the end of said windup stroke.

6. The improvement defined in claim **5** wherein said abutment means is rigid with said cam disk and forms a contact surface engageable by said cam-follower means.

7. The improvement defined in claim **6**, further comprising stationary stop means for arresting said cam disk at the end of said windup stroke in starting position in which said cam-follower means confronts a portion of said contact surface substantially flush with said ramp surface whereby said realignment is facilitated.

8. The improvement defined in claim **7** wherein said cam disk is provided with a shaft, said abutment means being part of said shaft.

9. The improvement defined in claim **1**, further comprising ancillary diaphragm-adjusting means linked with said extremity.

[57] **ABSTRACT**

An iris diaphragm of a reflex camera, spring-biased into a wide-open position, is settable to a preselectable stop position via a linkage including a cam follower on a swing ring oscillatable about an off-axial fulcrum. The cam follower coacts with a cam disk which is manually rotated against the force of a restoring spring during a windup operation and, upon subsequent release, displaces the cam follower and the swing ring which entrains the setting ring of the diaphragm through a yieldable coupling to the selected stop position and restores it to the wide-open position in the course of a revolution. During windup, a beveled flank on the high dwell of the cam disk oscillates the swing ring and entrains the setting ring for another brief but ineffectual reduction in the diaphragm aperture.

DIAPHRAGM PRESELECTOR FOR CAMERA OBJECTIVE

FIELD OF THE INVENTION

Our present invention relates to an iris diaphragm for a camera equipped with a reflex-type viewfinder.

BACKGROUND OF THE INVENTION

In such cameras, especially in those provided with interchangeable objectives in which the reflex mirror must be disposed behind an iris diaphragm, it is known to provide a preselector which is adjustable to a desired stop position, the diaphragm being normally biased into its wide-open position from which it is briefly displaced into the preselected position just before the tripping of a shutter by a release button or the like. This enables the operator to use full illumination when sighting and focusing upon an object to be photographed.

Such cameras are generally equipped with a windup handle which is manually operated to advance the film, cock the shutter and possibly carry out additional functions such as reactivating the viewfinder after its disablement upon the previous exposure. With the subsequent actuation of the shutter release, by which a control member coupled with the handle is returned to its original position by a restoring spring, the motion of this control member can be utilized to displace the iris diaphragm into its selected stop position and back to its wide-open position in timed relationship with the opening and closure of the shutter. Such an arrangement, which does not use the windup stroke itself for diaphragm control, has been disclosed in German Pat. No. 2,062,230. That system comprises a cam disk executing a full forward rotation during the windup stroke and a full reverse rotation during the return stroke, a coacting cam follower being connected with the setting ring of the diaphragm through a linkage including a yieldable coupling. The linkage further comprises a relatively complicated system of levers and springs designated to facilitate the escapement of the cam follower during the next windup stroke without entrainment of the setting ring.

OBJECT OF THE INVENTION

The object of our present invention is to provide an improved preselecting mechanism of this character which is of simplified construction and has a reduced number of relatively movable parts.

SUMMARY OF THE INVENTION

In accordance with our present improvement, the linkage between the cam follower and the setting ring of the iris diaphragm comprises a swingable member having a fulcrum offset from the diaphragm axis (which is also the axis of the associated objective), the cam follower being rigid with an extremity of this member which lies substantially diametrically opposite the fulcrum with reference to that axis.

In a preferred embodiment of our invention, the swingable member comprises an oscillating ring substantially centered on the diaphragm axis at least in the wide-open position in which the cam follower engages a low dwell of the coacting cam disk, the aforementioned extremity being an extension of this ring.

BRIEF DESCRIPTION OF THE DRAWING

The above and other features of our invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** is an exploded perspective view of an iris diaphragm and an associated preselecting mechanism according to our invention;

FIG. **2** is an axial view of part of the assembly, taken on the line II—II of FIG. **1**; and

FIG. **3** is a view similar to FIG. **2**, showing an alternate position.

SPECIFIC DESCRIPTION

In order to facilitate a comparison between the system of the aforementioned German Pat. No. 2,062,230 and our present improvement, the same reference numerals have been used wherever practical. The illustrated assembly comprises a mounting ring **1** of an iris diaphragm having lugs **3** with holes **2** for pins **5** of a set of iris leaves **4** having other pins **7** receivable in inclined guide slots **8** of a setting ring **9** rotatable with reference to ring **1** about a common axis O. A preselecting ring **13**, centered on the same axis, carries a lug **14** with a pointer **15** co-operating with a stationary diaphragm scale **16**. Ring **13** has a cutout **13***a* with an edge **17**, not centered on the diaphragm axis, engageable by a pin **18** on an arm **12** of a bell-crank lever having a fixed fulcrum **35**. A second arm **11** of this lever has a bifurcate end engaging a stud **10** which is rigid with setting ring **9**. Another stud **36** on ring **9** is connected to a coil spring **34** which is anchored to the objective housing and tends to rotate the ring **9** counterclockwise (as viewed in FIGS. **2** and **3**) into a wide-open position in which the iris leaves **4** are fully withdrawn as shown in FIGS. **1** and **2**. With pointer **15** confronting a selected mark on scale **16**, the curvature of edge **17** determines a point beyond which the ring **9** will not be able to rotate clockwise against the force of spring **34**.

In accordance with our present invention, an oscillating ring **27** is swingable about a fixed fulcrum **28** on one side of the objective axis O, i.e. at the top as shown in the drawing, and is provided at its opposite side (thus at the bottom) with an extension **27***a* rigidly connected with a cam follower **29**. The latter coacts with a cam disk **25** on a shaft **22** having a coupling head **23** provided with a slot **24** through which it is linked with a nonillustrated control element, such as a shaft of a pinion driven through approximately 360° upon the displacement of a windup handle coupled with a gear or rack in mesh with that pinion. A restoring spring **26** is tensioned during a clockwise windup stroke after which the shaft **22** and the disk **25** are latched in the position of FIG. **2**, with the cam follower **29** urged by a spring **33** against a low dwell of the disk. A pin **32** on lever arm **12** passes through a slot **30** of ring **27** and is normally held against the right-hand end of that slot (as viewed in FIGS. **2** and **3**) by the spring **34** acting through ring **9** and stud **10**; pin **32** and slot **30** thus constitute a yieldable lost-motion coupling between setting ring **9** and cam follower **29**.

Upon the tripping of the shutter release, the nonillustrated control element coupled with shaft **22** is unlatched whereupon spring **26** rotates the shaft and cam disk **25** counterclockwise. Cam follower **29**, riding on the surface of disk **25**, is progressively displaced toward the right and eventually comes to rest on the high dwell of the cam after about half a revolution. At or before

this point, depending upon the setting of preselector ring **13**, pin **18** contacts the edge **17** of that ring so that setting ring **9** is no longer entrained and iris leaves **4** occupy the selected position as diagrammatically illustrated for one of these leaves in FIG. **3**. Next, the nonillustrated camera shutter is briefly opened with stoppage of the return rotation of shaft **22**, if necessary, to expose the film. Thereafter, as cam disk **25** continues its rotation beyond the position of FIG. **3** into substantially its starting position in FIG. **1**, cam followr **29** drops back onto the low dwell of disk **25** and restores the setting ring to normal, thereby returning the diaphragm to its wide-open position shown in FIG. **2**. Swing ring **27** also reverts to its normal position centered on axis O.

During the next windup stroke, a beveled flank **25***a* extending from the high dwell of cam disk **25** to its low dwell coacts with an oppositely beveled edge **29***a* of cam follower **29** whereby setting ring **9** is again briefly rotated into and out of its preselected position; since the viewfinder is generally not used at this time, and may even be obstructed by the control mechanism, this brief reduction in the illumination of the reflex mirror is of no consequence.

As in the prior German patent referred to above, an ancillary ring **19** also centered on axis O is provided with a handle **20** by which it may be rotated to reduce the diaphragm aperture independently of the shutter release within the limits set by preselector **13**, **14**. Ring **19** has an extension **21** engaging a pin **31** on ring extension **27***a* whereby counterclockwise rotation of ring **19** separates the cam follower **29** from cam disk **25** within the limits established by curve **17** of ring **13**.

The compact preselection mechanism according to our invention links the setting ring **9** and the cam follower **29** through the intermediary of only two relatively movable members forming a lost-motion coupling therebetween, i.e. the oscillating ring **27** and the bell-crank lever **11**, **12** establishing a positive connection between ring **9** and pin **32**; there is no need for a biasing spring acting upon that lever. This minimizes the risk of malfunction due to spring fatigue or similar mechanical failures.

We claim:

1. In a reflex camera having an iris diaphragm centered on an optical axis and provided with a setting ring rotatable about said axis, biasing means engaging said settable ring for urging same into a wide-open diaphragm position, preselector means adjustable to a desired stop position, a spring-loaded cam disk manually rotatable in one direction against its spring force during a windup stroke and rotatable by its spring force in the opposite direction during a picture-taking operation, cam-follower means coacting with said cam disk, and a linkage including a yieldable lost-motion coupling between said cam-follower means and said setting ring engageable with said preselector means for entraining said setting ring into the desired stop position,

the improvement wherein said linkage comprises a swingable member having a fulcrum offset from said axis, said cam-follower means being rigid with an extremity of said member substantially diametrically opposite said fulcrum with reference to said axis.

2. The improvement defined in claim **1** wherein said member is an oscillatable ring substantially centered on said axis in said wide-open position.

3. The improvement defined in claim **2** wherein said yieldable coupling includes a pin positively connected with said setting ring and urged by said biasing means against an edge of a slot in said oscillatable ring traversed by said pin.

4. The improvement defined in claim **1** wherein said cam disk has a low dwell engaged by said cam-follower means in said wide-open position and a high dwell engaged by said cam-follower means at an intermediate point of a windup stroke, said high dwell being separated from said low dwell by a beveled flank momentarily repressing said cam-follower means during the windup stroke with subsequent re-establishment of the wide-open position at the end of said stroke.

5. The improvement defined in claim **1**, further comprising ancillary diaphragm-adjusting means linked with said extremity.

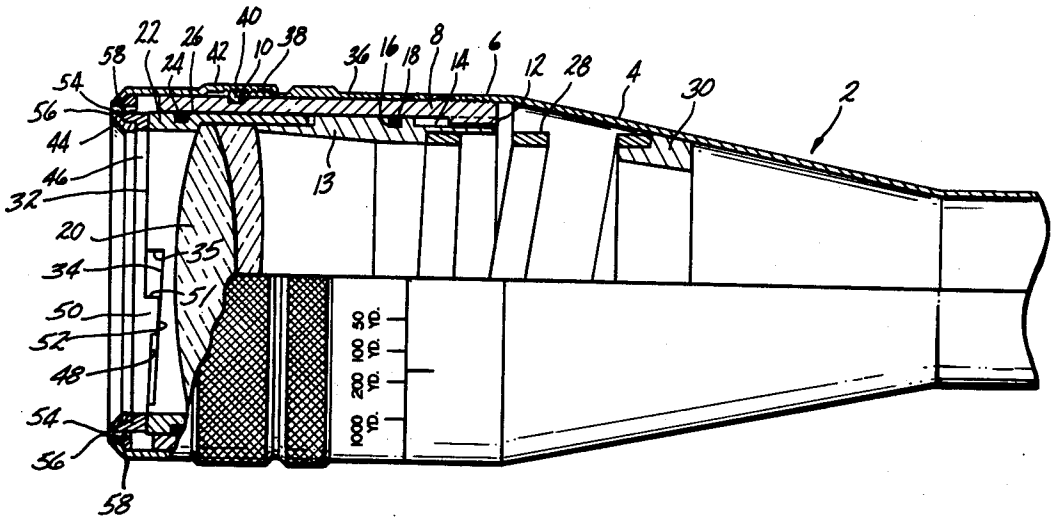
[57] **ABSTRACT**

A mechanism for focussing the objective lens assembly of a variable power telescopic rifle sight. A rotatable cam ring is used in conjunction with a coil spring which urges the lens assembly against the cam ring. A lens retainer portion of the lens assembly adjacent to the cam ring has formed thereon a camming ramp which is complimentary to a camming surface formed on the cam ring.

5 Claims, 3 Drawing Figures



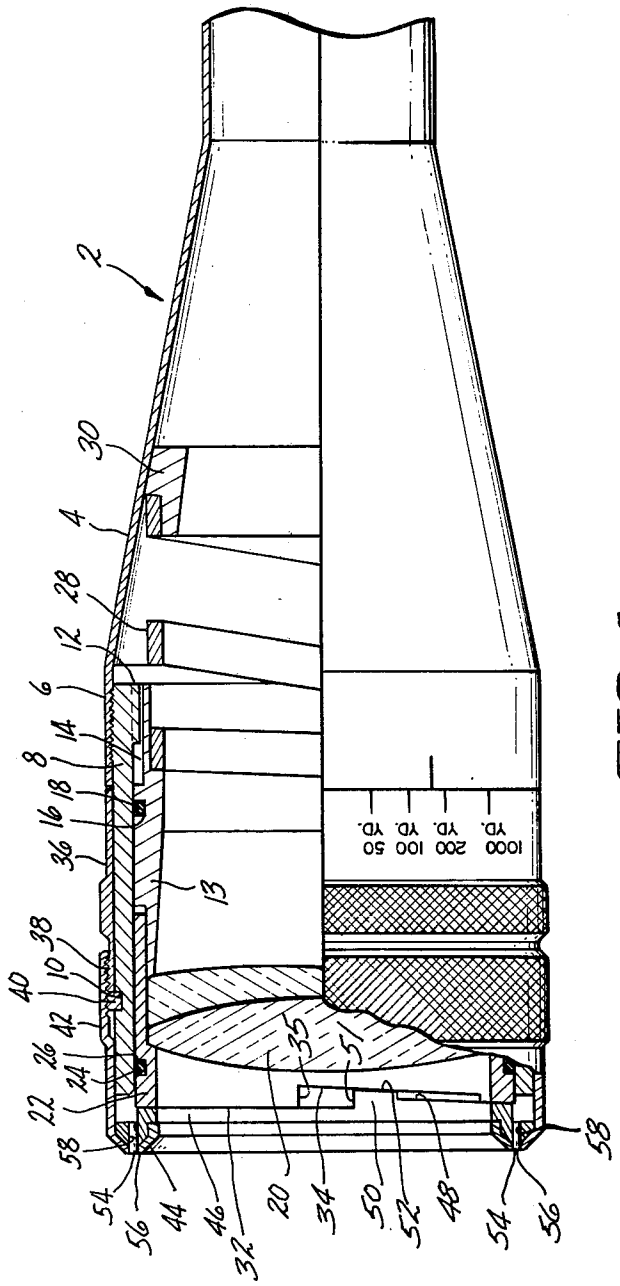


FIG-1

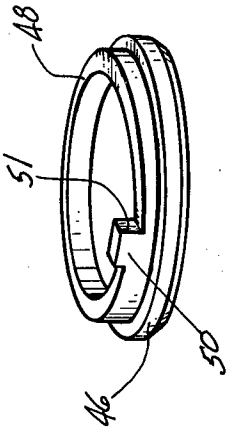

FIG-3

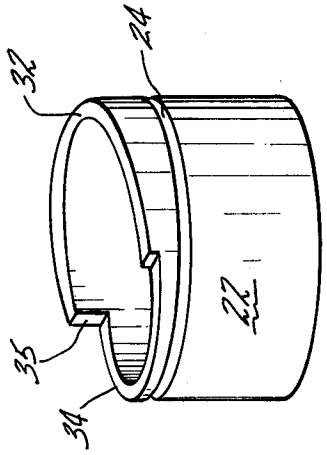

FIG-2

FOCUSSING OBJECTIVE MECHANISM FOR TELESCOPIC RIFLE SIGHTS

This invention relates to a mechanism used to focus the objective lens of a telescopic rifle sight. More particularly, the mechanism of this invention utilizes a rotatable cam ring and coil spring combination to move the objective lens cell for focussing, rather than a pin and cam slot or threaded collar.

The use of an objective lens which can be focussed on objects which are different distances from the viewer is an old concept in the optical instrument art. Such focussing arrangements can be preset as to distance so as to give a clear image as, for example, with a camera. They can also be used on other optical instruments, such as range finders, rifle scopes, and the like to bring a viewed object into focus, thereby determining the range or distance of the viewed object from the viewer from a vernier disposed on the instrument.

Optical instruments such as rifle scopes which have been equipped with focussing objective lens mechanisms have, for the most part, employed a pin and cam slot mechanism for moving the objective lens assembly during focussing. U.S. Pat. No. 3,336,831, issued Aug. 22, 1967 to J. Unertl, Jr. discloses a pin and cam slot focussing arrangement which is typical of the prior art. Another focussing arrangement disclosed in the prior art involves the use of a threaded end cap which, by reason of its threads, can be turned and moved longitudinally along the scope barrel. The threaded end cap bears against an objective lens cell assembly which is spring-biased and which follows the end cap for focussing. This structure is shown in U.S. Pat. No. 3,516,736, issued June 23, 1970 to W. R. Weaver.

The focussing assemblies for objective lenses which are found in the prior art have proved generally functional, but have presented problems relating to their ability to repeat proper focus at the predetermined ranges. These problems arise from wear on the pin and cam slot, and the presence of some degree of backlash when the focussing ring is rotated in opposite directions. The problem of wear and fouling of scope barrel threads also is found in connection with the threaded cap focussing system described above. The wearing problem is magnified in the prior art systems mainly because of the minimum surface contact area between the cam surface and the cam follower.

The focussing system of this invention involves the use of a rotating cam ring having a profiled cam surface in the form of an inclined ramp on one of its faces. The objective lens holder is formed with a similar or matching cam surface taking the form of an inclined ramp on one of its faces. The matching cam ramps are held in face-to-face contact by a coil spring engaging the objective lens assembly thus providing maximum area contact between the cam ring and the lens assembly. This maximum area contact provides for increased repeatability of focus at predetermined ranges and greatly reduces the deteriorating effects of wear on the several components of the system. The coil spring eliminates the problem of backlash found in the prior art camtype focussing systems.

It is, therefore, an object of this invention to provide an objective lens focussing system for a riflescope, which focussing system produces repeatable focussing on a target at different predetermined ranges.

It is a further object of this invention to provide a focussing system of the character described wherein minimum wear of the system components is encountered.

It is yet another object of this invention to provide a focussing system of the character described wherein backlash is minimized during focussing and re-focussing.

These and other objects and advantages of the focussing system of this invention will become more readily apparent to those skilled in the art from the following detailed description of an embodiment of the invention taken in conjunction with the accompanying drawings, in which:

FIG. **1** is an axial sectional view of the objective end of a riflescope formed in accordance with the invention;

FIG. **2** is a perspective view of the front objective lens cell part of FIG. **1** showing the cam ramp end thereof; and

FIG. **3** is a perspective view of the cam ring showing the cam ramp surface thereon.

Referring now to the drawings, there is shown in FIG. **1** the objective end portion of a telescopic rifle sight employing the objective lens focussing assembly of this invention. The barrel of the scope is denoted generally by the numeral **2** and includes an outwardly tapering portion **4** and an enlarged internally threaded terminal portion **6**. A tubular scope barrel extension **8** is threaded into the scope barrel terminal **6**. The extension **8** includes an external groove **10** and a longitudinally extending inwardly projecting key **12**.

Inside of the extension there is mounted an objective lens assembly which includes a rear tubular lens cell **13** having a longitudinally extending external slot **14** in which the extension key **12** is disposed. The rear lens cell includes an external groove **16** in which is mounted a gas-sealing O-ring **18**. The objective lens assembly also includes an objective lens doublet **20** and a forward tubular lens cell **22** which telescopes over the rear lens cell **12** and which includes an external groove **24** in which is mounted a gas-sealing O-ring **26**. A coil spring **28** is mounted within the scope barrel **2** and engages a fixed spring seat **30** on one end and the rear objective lens cell **12** on the other end. Thus the objective lens assembly is biased forwardly by the spring **28**. The forward end **32** of the front lens cell **22** takes the form of a helix of predetermined pitch. The helical lens cell end **32** also includes a slot **34** the bottom wall of which is also formed with the predetermined helical pitch.

An annular graduated collar **36** is mounted on the exterior of the barrel extension **8** and includes a forward externally threaded end **38**. The collar **36** is held on the extension **8** against forward movement with respect thereto by a snap-type retaining ring **40** which is mounted in the extension groove **10**. An annular shroud **42** is threaded onto the collar **36** and includes an inwardly turned U-shaped forward end part **44** which serves to retain a cam ring **46** in place forward of the front lens cell **22**. the cam ring **46** is formed with a rear end **48** which takes the form of a helix having the same predetermined pitch as the forward end **32** of the front objective lens cell **22**. The rear end **48** of the cam ring **46** is formed with a rearwardly projecting lug **50** which has a top wall **52** formed with the same predetermined helical pitch as the bottom wall of the front lens cell groove **34**.

While it is preferred to provide the entire ends **32** and **48** of the front lens cell **22** and cam ring **46** respectively,

as well as the bottom wall of the slot **34** and top wall **52** of the lub **50** with the helical pitch so as to maximize the area of contact of the cam actuator, it will be appreciated that only the top wall **52** of the lub **50** and the bottom wall of the slot **34** could be helically pitched, or alternatively, only the remainder of the ends **32** and **48** of the lens cell **22** and cam ring **46** could be pitched to provide the necessary camming action. It will also be appreciated that the lug **50** and slot **34** combine to limit the extent of rotational movement in both directions of the cam ring **46** with respect to the objective lens assembly.

A pair of pins **54** are inserted into aligned holes **56** and **58** drilled in the shroud **42** and cam ring **46** respectively to secure the shroud **42** and cam ring **46** together for concurrent rotation.

The device is assembled as follows. The graduated collar **36** is mounted on the barrel extension **8** and is retained thereon by the retainer ring **40**. Cement is applied to the internal threads of the scope barrel **2** and the barrel extension **8** is screwed into the barrel **2** to a depth that allows no loose linear movement of the graduated collar **36** but permits rotational movement thereof. The cement is then cured and must be free of gas leaks. The objective lens **20** is then cemented inside of the front lens cell **22** and the rear lens cell **13** is then cemented inside of the front lens cell **22**. The cement is cured and must be free of gas leaks. The O-rings **18** and **26** are then positioned on the outside of the objective lens assembly. The cam ring **46** is placed inside of the shroud **42** and both are then placed on an assembly arbor fixture for future adjustment. The coil spring **28** and spring seat **30** are then assembled to the objective lens assembly and then inserted into the scope barrel - barrel extension sub-assembly with the key **12** being inserted into the key slot **14** and the spring **28** is compressed after the spring seat **30** comes into contact with the tapered portion **4** of the scope barrel **2**. The fully compressed spring and lens assembly is held in place temporarily with the barrel and barrel extension by a test fixture. The shroud and cam ring sub-assembly is then moved into place over the barrel extension and then screwed fully onto the threads of the graduated collar **36**.

From FIG. **1**, it will be noted that a vernier scale is formed on the graduated collar **36** and an indicator mark is formed on the enlarged portion **6** of the scope barrel **2**. The partially assembled device is then mounted on a fixture and sighted in on an object which is a known, fixed distnce from the sighting fixture, for example 50 yards away. The proper distance graduation, in this instance, the "50 Yd." graduation is then rotated into alignment with the indicator mark stamped on the scope barrel and the graduated collar **36** is held fixed in this position. The adjustor then looks through the scope at the fixed range target and rotates the shroud **42** in a clockwise direction on its threads. This rotates the cam ring lug **50** until its longest side wall **51** contacts the longest side wall **35** of the front lens cell groove **34**, which is the builtin "low range" stop for the cam ring **46**. The cam ring **46** will then stop rotating but clockwise unscrewing of the shroud **42** is continued resulting in forward axial movement of the objective lens assembly resulting from pressure thereon by the spring **28**. The unscrewing action of the shroud **42** is continued until the scope focuses on the fixed range (50 yd.) target. The scope is then removed from the focussing fixture and cement is applied to the threads of the shroud **42** and graduated collar **36**, which cement is allowed to cure securing the shroud **42** to the collar **36** so that the two will thereafter rotate together. The holes **56–58** are then drilled in the shroud **42** and cam ring **46** and the pins **54** are inserted therein to lock the shroud **42** and cam ring **46** together for concurrent rotation. Assembly is then complete.

It will be readily appreciated that the mating helical cam surfaces on the cam ring and objective lens cell assembly will result in rotational movement of the graduated collar, shroud and cam ring (which rotate together as a unit) being translated into longitudinal movement of the objective lens assembly, aided by the coil spring. This longitudinal movement of the objective lens assembly results in focussing of the scope at predetermined different distances, which are marked on the graduated collar. The use of matched helical cam surfaces on the cam ring and lens cell provides maximum contact area for the focussing mechanism which results in a minimum of wear, and also permits the cam ring and lens cells to be made of molded plastic material, if desired. The coil spring acting in concert with the cam surfaces reduces focussing backlash to a minimum and increases the accuracy of the device. The use of a projecting lug and slot combination in the mating cam surfaces provides convenient high and low range focus stops for the device.

Since many changes and variations of the disclosed embodiment of the invention may be made without departing from the inventive concept, it is not intended to limit the invention otherwise than as required by the appended claims.

What is claimed is:

1. A focussing objective mechanism for a telescopic gun sight comprising in combination:

a. a sight barrel;

b. an objective lens assembly mounted in said barrel for axial reciprocal movement therein, said lens assembly having one end wall thereof formed with a predetermined helical pitch extending for substantially the entire duration of said one end wall;

c. a ring rotatably mounted on said barrel but fixed against axial movement thereon, said ring being adjacent to said lens assembly and having an end surface facing said lens assembly end wall, substantially the entire duration of said end surface which faces said lens assembly end wall being formed with the same predetermined helical pitch as said lens assembly end wall; and

d. spring means engaging said lens assembly to bias said end wall into engagement with said ring end surface.

2. The mechanism of claim **1**, wherein one of said end wall and said end surface is formed with a slot having a bottom wall formed with said predetermined helical pitch, and the other of said end wall and said end surface is formed with a projecting lug having an end wall formed with said predetermined helical pitch, said lug being disposed in said slot, and said slot and said lug having respective side walls forming stops governing the degree of rotation which said ring can undergo.

3. A focussing objective mechanism for a telescopic gun sight comprising in combination:

a. a sight barrel;

b. an objective lens assembly mounted in said barrel for axial reciprocal movement therein, said lens assembly having one end wall thereof formed with a predetermined helical pitch over substantially its entire extent, said end wall including a slot having

a bottom wall formed with said predetermined helical pitch, and said slot having side walls;

c. a ring rotatably mounted on said barrel but fixed against axial movement thereon, said ring being adjacent to said lens assembly and having an end surface formed with said predetermined helical pitch throughout substantially its entire extent, said end surface facing said lens assembly end wall, and said end surface including a projecting lug disposed within the confines of said slot and having an end wall formed with said predetermined helical pitch and side walls, the respective slot and lug side walls forming stops defining the rotational arc through which said ring can be turned; and

d. spring means biasing said lens assembly toward said ring to urge said lens assembly end wall into face-to-face contact with said ring end surface.

4. A focussing objective mechanism for a telescopic gun sight comprising in combination:

a. means forming a sight barrel;

b. an objective lens assembly mounted in said sight barrel for reciprocal axial sliding movement therein, said lens assembly including one end wall formed with a predetermined helical pitch;

c. means fixing said lens assembly against rotational movement in said sight barrel;

d. a focussing collar mounted on said sight barrel for rotational movement thereon, said collar having one end thereof which is threaded;

e. means for preventing said collar from moving axially of said sight barrel;

f. a shroud screwed onto said collar;

g. a camming ring carried by said shroud, said camming ring having an end surface facing said lens assembly end wall, said end surface being formed with the same predetermined helical pitch;

h. spring means engaging said lens assembly to bias said end wall thereof into face-to-face contact with said end surface of said camming ring;

i. means securing said camming ring to said shroud; and

j. means securing said shroud to said collar to prevent said shroud from being unscrewed from said collar and to enable said collar, said shroud and said camming ring to be concurrently rotated to focus said lens assembly at a plurality of different distances from the sight.

5. The mechanism of claim 4, further comprising cooperating slot means and lug means formed on said contacting end wall and end surface of said lens assembly and camming ring, said lug means being disposed in said slot means to form rotational stops for the focussing mechanism.

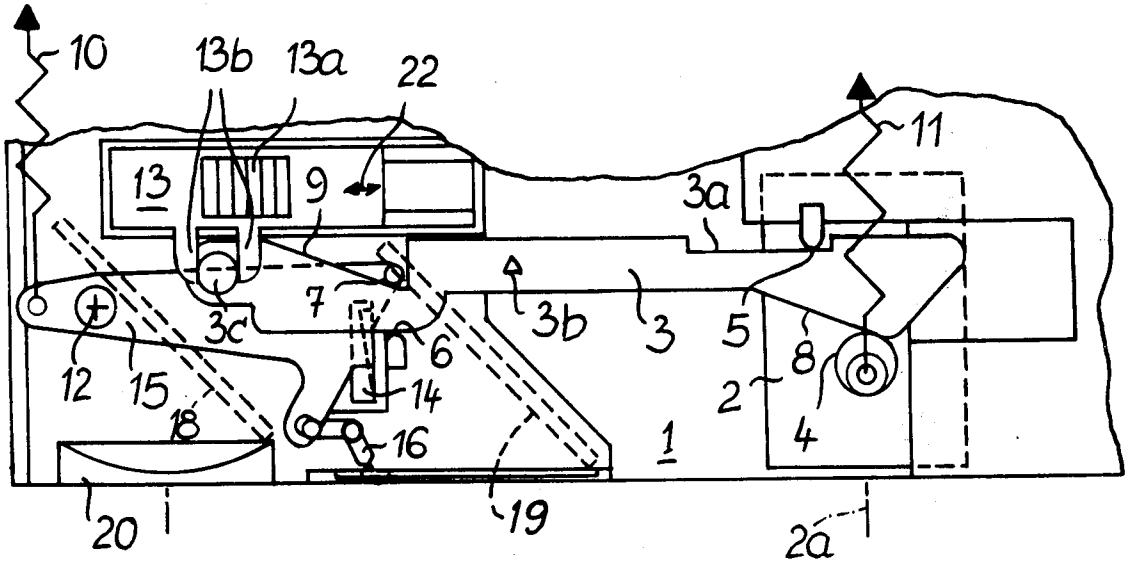
[57] **ABSTRACT**

A camera is provided with an objective supported by a housing of the camera for movement along its optical axis. A movable member is guided by the camera housing for movement transversely with respect to the optical axis, and this movable member has a pair of inclined surfaces. These inclined surfaces are inclined both with respect to the optical axis and with respect to the direction of movement of the movable member. A pair of pressing members respectively press against the inclined surfaces of the movable member, a pair of springs acting on the pair of pressing members for urging them against the inclined surfaces, respectively, so that the latter surfaces are slidable with respect to the pressing members engaging the same. One of these pressing members is fixed to the objective so that when the movable member is moved transversely with respect to the optical axis this one pressing member in cooperation with the inclined surface engaging the same will bring about adjustment of the objective along its optical axis. The arrangement of the pair of inclined surfaces of the movable member is such that at all times, irrespective of the position of the movable member, the spring-pressed pressing members provide equal and opposite forces in the direction of movement of the movable member.

6 Claims, 3 Drawing Figures



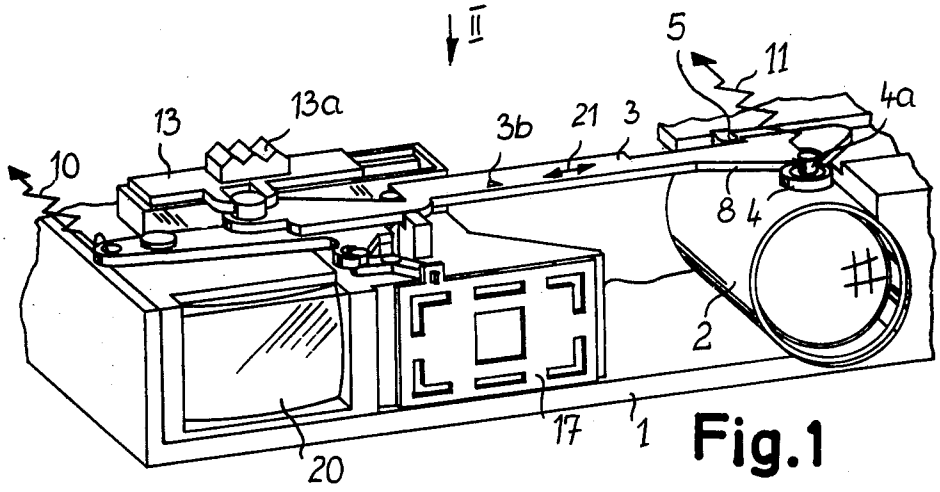


Fig.1

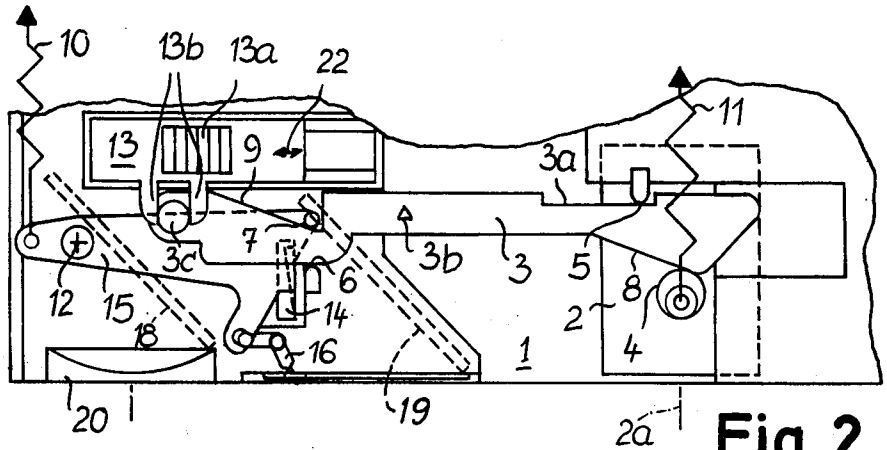

Fig. 2

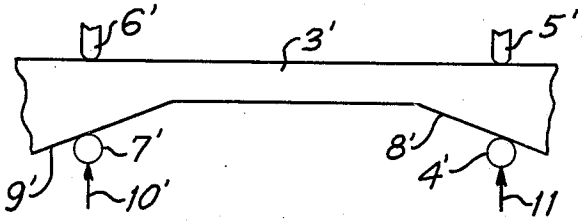
Fig. 3



CAMERA WITH ADJUSTABLE OBJECTIVE

BACKGROUND OF THE INVENTION

The present invention relates to cameras.

In particular, the present invention relates to cameras having adjustable objectives.

The present invention relates to that type of device according to which an objective can be moved along its optical axis without play upon movement of an adjusting member which extends transversely with respect to the optical axis and which can be moved with respect to the objective, this movable adjusting member having an inclined surface engaged by a member which is fixed to the objective and which is urged against the inclined surface by a spring.

With a known construction of the above type the pressure with which the member fixed to the objective acts against the inclined surface of the transversely movable member can be resolved into a pair of vectors, one of which acts in the direction of the optical axis and the other of which is perpendicular thereto. The component of this force which is perpendicular to the optical axis seeks to overcome the frictional forces which are encountered and to return the movable objective-adjusting member toward a position where this movable adjusting member is free of forces acting on the same. Such movement is prevented by mounting the movable member in such a way that it is difficult to move so as to assure the presence of sufficiently great forces of friction to hold the movable member in its adjusted position. This requirement of a relatively great friction for the member which is moved to adjust the objective has a considerable disadvantage in that the adjustment of this movable member under certain circumstances can only be carried out in a non-uniform manner because the so-called stick-slip effect is encountered. In other words this movable member in a conventional construction does not slide smoothly and instead tends at one time to stick and then at another time to slip easily, rendering it difficult to provide a precise adjustment of the objective.

SUMMARY OF THE INVENTION

A primary object of the present invention is to provide a construction which will avoid the above drawbacks.

In particular, it is an object of the present invention to provide a structure which is capable of moving an objective smoothly and uniformly back and forth along its optical axis while also providing a smooth uniform movement for the movable member which adjusts the objective.

Also, it is an object of the present invention to provide a construction according to which this movable member which adjusts the objective is at all times acted upon by forces which are substantially in equilibrium.

Thus, it is an object of the present invention to provide for a camera objective the possibility of play-free movement thereof completely without any possibility of sudden, jerking movements, especially by providing at the member which adjusts the objective equal and opposite forces which cancel each other.

It is also an object of the present invention to provide a construction which can achieve the above advantages irrespective of whether the objective-adjusting member is in the region of a central position thereof or in the region of one of its end positions.

Furthermore, it is an object of the present invention to provide a construction according to which part of the structure of the invention can be combined with other camera structure such as, for example, range-finder structure, paralax-compensating structure, or automatic flash-control structure.

According to the invention the camera has an objective means which is provided with an optical axis and which is guided for movement along its optical axis by a housing means of the camera, this housing means also guiding a movable means for movement transversely with respect to the optical axis. A pair of inclined surface means are connected to and form part of the movable means and a pair of pressing means respectively press against and slidably engage the pair of inclined surface means. A pair of spring means cooperate with the pair of pressing means for pressing the latter against the pair of inclined surface means. One of the pressing means is fixed with the objective means so that when the movable means is moved transversely of the optical axis one of the inclined surface means cooperates with the pressing means fixed to the objective means for adjusting the objective along its optical axis. The pair of inclined surface means cooperate with the pressing means for providing at all positions of the movable means equal and opposite forces in the direction of movement of the movable means, so that the latter is maintained in equilibrium at all of its positions.

BRIEF DESCRIPTION OF DRAWINGS

The invention is illustrated by way of example in the accompanying drawings which form part of this application and in which:

FIG. 1 is a schematic fragmentary perspective illustration of part of a camera provided with the structure of the invention;

FIG. 2 is a fragmentary schematic top plan view of the structure of FIG. 1 as seen in the direction of the arrow II of FIG. 1; and

FIG. 3 is a schematic illustration of another embodiment of the invention.

DESCRIPTION OF PREFERRED EMBODIMENTS

Referring to FIGS. 1 and 2, the camera illustrated therein includes a housing means 1 which carries an objective means 2 and which guides the objective means for movement along its optical axis 2*a*. The objective means 2 carries a pressing means 4 in the form of a circular member which is eccentrically mounted for angular adjustment so as to have its eccentricity adjusted in a known way, this pressing means 4 being formed with an opening through which a pin 4*a* extends, this pin 4*a* being fixed to and projecting from the objective means 2. A spring means 11 is operatively connected with the pin 4*a*, this spring being fixed distant from the pin 4*a* to a stationary part of the housing 1, so that the spring means 11 acts on the pressing means 4, 4*a* to urge the objective means 2 rearwardly along its optical axis. Through the spring means 11 the pressing means 4, 4*a* is urged against an inclined surface means 8 which forms part of a movable means 3 which is guided by the housing means 1 for movement, as shown by the double-headed arrow 21, in opposite directions transversely with respect to the optical axis. Thus, the movable means 3 is guided by the housing means 1 for movement in a direction parallel to the film plane and perpendicular with respect to the optical axis 2*a*. For the pur-

pose of guiding the movable means **3** the housing means **1** carries a stationary bearing member **5** which has a convex end surface engaging a longitudinal side surface **3***a* of the movable means **3**, this side surface **3***a* being formed by the inner surface of a notch which is formed along the rear longitudinal edge of the transversely movable objective-adjusting means **3**. Thus the member **5** forms a bearing member for the movable means **3** and has a substantially line-contact therewith.

The movable means **3** has a longitudinal side surface opposed to the side surface **3***a* and engaged by a second bearing member **6** fixedly carried by the housing means **1**, and forming a part thereof, this bearing member **6** also having a convex surface engaging a longitudinal side surface of the member **3** so as to have a substantially line-contact therewith. At the side of member **3** which is opposite from the bearing member **6**, the member **3** has a second inclined surface means **9** which it will be noted is inclined in the same direction as the inclined surface means **8**. A pressing means **7** presses against the inclined surface means **9**, this pressing means **7** being in the form of a pin carried by a lever **15** which is supported for turning movement about a stationary pivot pin **12** carried by the camera housing **1**, and through the lever **15** a spring means **10** acts on the pressing means **7** to urge the latter into engagement with the inclined surface means **9**. This spring means **10** is fixed distant from the lever **15** to a stationary part of the housing **1**. Thus, the pair of pressing means **4** and **7** are respectively urged by the pair of spring means **11** and **10** against the pair of inclined surface means **8** and **9** so as to press against the same, while the pair of inclined surface means **8** and **9** are respectively slidable with respect to the pair of pressing means **4** and **7**.

The camera housing **1** carries a manually shiftable member **13** having a portion **13***a* capable of being conveniently engaged by the operator. This member **13** can be moved back and forth by the operator on suitable guides in the directions indicated by the double-headed arrow **22**. This manually shiftable member **13** has a pair of fingers **13***b* defining between themselves a space which receives a pin **3***c* which is fixed to and projects upwardly from the transversely movable means **3**. Thus, when the operator moves the member **13** by engaging the portion **13***a* thereof, in the direction indicated by the arrow **22**, the movable means **3** is moved by engagement of one or the other of the fingers **13***b* with the pin **3***c*, so that in this way the movable means **3** is moved to the right or left, as viewed in FIGS. **1** and **2**. Thus, the member **13** receives the force exerted by the operator and transmits this force only in one or the other of the directions indicated by the double-headed arrow **22**, so that only horizontal forces are transmitted from the member **13** to the movable means **3**.

Of course, the movable means **3** is urged against the bearing member **5** by the spring-pressed pin **4**, and since the pin **4** is out of line with the bearing member **5** it seeks to turn the member **3** about the member **5** in a counterclockwise direction, as viewed in FIG. **2**, thus pressing the movable means **3** against the guide member **6**. This force with which the movable means **3** is urged against the bearing member **6** by way of the action of members **4** and **5** is augmented by the force of the spring **10** acting on the pin or pressing member **7**. Thus this member **7** also seeks to press the member **3** against both of the bearing members **5** and **6**.

As a result of the force provided at the pressing means **4** by way of the spring **11**, this pressing means **4** cooperates with the inclined surface means **8** to tend to urge the movable means **3** toward the right, as viewed in FIGS. **1** and **2**. However, the spring **10** acts through the lever **15**, swingable on the pivot pin **12**, to provide at the pressing means **7** on the inclined surface means **9** a force which urges the movable means **3** toward the left, as viewed in FIGS. **1** and **2**. Because the pair of inclined surface means **8** and **9** have the same inclination, being parallel to each other, by suitable selection of the spring forces, the components of force which are opposite to each other and which are perpendicular to the optical axis **2***a* are equal to each other. Thus, the movable means **3** will be in equilibrium in all of its positions.

In the example illustrated the lever **15** is operatively connected with a wedge-shaped lens **14** utilized for range-finder purposes. Moreover, the lever **15** acts through a lever **16** on a framing member **17** which has openings shaped as shown in FIG. **1** to provide in a known way in the field of the viewfinder an image of the frame in which the viewed image will be photographed. The viewfinder lens **20** is also shown in FIGS. **1** and **2** as well as the mirror or reflector **19** and the semi-transparent reflector or mirror **18**.

It will be noted that the movable means **3** carries an index **3***b*. This index is movable along an unillustrated scale indicating the distance between the object to be photographed and the camera.

Of course, certain variations are possible. Thus there is schematically shown in FIG. **3** an embodiment according to which the movable means **3'** corresponding to the means **3** has one longitudinal side surface engaging a pair of bearing members **5'** and **6'** respectively corresponding to the bearing members **5** and **6**. At its opposite longitudinal side surface the movable means **3'** of FIG. **3** is provided with a pair of inclined surface means **8'** and **9'** which it will be noted are oppositely inclined. The pair of pressing means **4'** and **7'**, corresponding respectively to the pair of pressing means **4** and **7**, press against the pair of inclined surface means **8'** and **9'**. FIG. **3** schematically illustrates a spring means **10'** acting on the pressing means **7'** for urging the latter against the inclined surface means **9'** as well as a spring means **11'** acting on the pin means **4'** for urging the latter against the inclined surface means **8'**. Of course, the pin means **4'** of FIG. **3** is fixed to the objective while the pin means **7'** can be carried by a swingable lever which is acted upon by a spring in the same way as in FIG. **2**. Thus it will be seen that the embodiment of FIG. **3** also can achieve the results of the invention inasmuch as the forces with which the members **7'** and **4'** are urged against the inclined surfaces **9'** and **8'** can be resolved into components which include components directed respectively to the left and right as viewed in FIG. **3**, the arrangement being such that these latter oppositely directed components are equal to each other at all times, thus achieving in this way the results set forth above.

It is thus apparent that with the structure of the invention it is possible to achieve for the objective a smooth movement free of any play. With the known construction having only one inclined surface and only one spring urging a pin into engagement with this one inclined surface, the force required to adjust the objective will vary with different adjusting directions. In one direction of adjustment it is necessary to tension the spring as well as to overcome the forces of friction. In the opposite direction of adjustment the force stored in

the spring will itself contribute to overcoming the friction force, so that uniformity in both directions of adjustment cannot be achieved with a conventional construction, whereas such uniformity is indeed achieved with the structure of the invention.

Thus, in contrast with the above conventional construction, with the structure of the invention the movable means is in all of its positions in a condition of equilibrium. The same force is required to move the movable means in one direction as in the opposite direction. Moreover the magnitude of the adjusting force remains practically the same at all positions of adjustment. It is immaterial whether the movable means **3** is at a central position or at the region of one of its end positions.

Of course, it is of advantage to utilize the lever **15** not only for transmitting the spring force of the spring **10** to the pressing means **7** but also to actuate other components such as those utilized in connection with range-finding, parallax compensation, or operation of a component such as the diaphragm of a flash device.

What is claimed is:

1. In a camera, objective means having an optical axis, housing means guiding said objective means for movement along said optical axis thereof, movable means guided by said housing means transversely with respect to said optical axis, a pair of inclined surface means connected with and forming part of said movable means and each being inclined both with respect to the direction of movement of said movable means and with respect to said optical axis, a pair of pressing means respectively pressing against and slidably engaging said pair of inclined surface means, one of said pressing means being fixed to said objective means, and a pair of spring means respectively connected operatively with said pair of pressing means for respectively urging the latter against said pair of inclined surface means, said movable means when moved transversely with respect to said optical axis acting through one of said inclined surface means on said one pressing means which is fixed to said objective means for moving the latter along said optical axis, and said pair of inclined surface means respectively cooperating with said pair of pressing means for providing at all positions of said movable means equal and opposite forces in the direction of movement of said movable means.

2. The combination of claim **1** and wherein, for guiding said movable means, said housing means carries a pair of bearing members which are stationary with respect to said housing means and with respect to said movable means, said movable means slidably engaging said bearing members to be guided thereby.

3. The combination of claim **2** and wherein said movable means is of an elongated configuration and in its longitudinal direction extends transversely with respect to said optical axis, said movable means having a pair of opposed longitudinal side surfaces, and said pair of bearing members respectively engaging said pair of opposed longitudinal side surfaces of said movable means, said pair of inclined surface means being inclined in the same direction and also being respectively situated in the region of said opposed longitudinal side surfaces of said movable means.

4. The combination of claim **2** and wherein said movable means is of an elongated configuration and in its longitudinal direction extends transversely with respect to said optical axis, said movable means having a pair of opposed longitudinal side surfaces, and said pair of bearing members both engaging one of said longitudinal side surfaces of said movable means, said pair of inclined surface means respectively being oppositely inclined and both being situated at the region of the other of said longitudinal side surfaces of said movable means.

5. The combination of claim **1** and wherein a lever is swingably carried by said housing means, said lever carrying the other of said pressing means.

6. The combination of claim **5** and wherein said lever forms part of said spring means which acts on said other pressing means, the latter spring means including a spring connected directly to said lever for acting through the latter on said other pressing means.

[57] **ABSTRACT**

A telephoto type objective comprising a front lens group and a rear lens group axially spaced apart from each other. The front lens group has a positive refracting power and which remains stationary during focusing. The rear lens group has a negative refracting power and is comprised of two movable lens members for focusing. When the two movable lens members are moved along the optical axis toward an image plane, the telephoto type objective is caused to focus an object at a near distance from its focusing on an object at a far distance with the resulting amount of movement of the rear lens member being larger than that of movement of the front movable lens group.

TELEPHOTO TYPE OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to a telephoto type objective comprising a front lens group and a rear lens group which includes at least two members movable for focusing.

It is known to provide a symmetrical lens or triplet lens of which the rearmost lens element is movable for focusing, as disclosed in U.S. Pat. Nos. 2,503,789 and 3,020,804. In these patents, however, no account is taken of the fact that the image quality will be deteriorated when only one lens element is moved for focusing.

It is also known to provide a telephoto lens composed of convergent front and divergent rear lens groups, both of which are made movable as a unit for focusing purposes. In the course of development of new types of telephoto lens, however, it is considered possible to achieve the focusing by moving either the front lens group or the rear lens group.

If the telephoto lens is made bodily movable for focusing, as the amount of axial movement of the entire lens system through the focusing range is far larger than that of axial movement of the ordinary lens, and the weight and bulk of the telephoto lens are relatively large, it is proven that the focusing mechanism such as those employing helicoid structure requires not only large constructional dimensions with high production cost thereof but also a large driving torque with difficult management thereof.

In the case of focusing provision made at the rear lens group, it is possible to minimize the dimensions of the focusing mechanism with improved management thereof. Another advantage of this type telephoto lens is that the front lens group may be supported in fixedly secured relation to a camera body as the physical length between the front lens vertex and the image plane within the camera housing is maintained constant, thereby minimizing the probability of producing a jiggle or oscillation of the image at the focal plane by small accidental motion of the lens-and-camera assembly which is otherwise encountered particularly when the objective lens of the camera is telephoto in nature. With this type of telephoto lens, however, it is made more difficult to prevent deterioration of image quality resulting from variation of aberrations with focusing.

This difficulty can be overcome by employing an additional lens member arranged to be movable along with the focusing member to compensate for variation of aberrations caused by the focusing member. An example of such method is described in U.S. Pat. No. 3,854,797 assigned to the same assignee as the patent application, in which the rear lens group is divided into at least two sub-groups of which the image side one has a negative refracting power and is arranged to be moved toward the rear as the entire lens system is focused for shorter object distances, and another subgroup on the object side which has a strong divergent surface and is arranged to be moved toward the front in the same focusing as above. This arrangement, however, leads to an increase in the diameter of the front sub-group, or otherwise those of the axial rays which are to pass through the marginal portion of the rear sub-group are blocked by the lens cell holding the front sub-group when the entire system is focused for shorter object distances.

SUMMARY OF THE INVENTION

Accordingly, it is a primary object of the present invention to provide a new type of focusing lens arrangement which, though requiring no undue increase in the diameter of the front lens sub-group, will avoid the eclipse or shading which would occur when the front and rear lens sub-groups of the rear lens group are arranged to move in the opposite directions to each other for focusing purposes.

Thus, it is an object of the invention to provide a telephoto type objective which, while maintaining a high standard of aberration correction throughout the entire focusing range, is also capable of avoiding any undue increase in the diameter of the focusing members as well as in the complexity of the focusing mechanism.

To achieve this, the telephoto type objective of the invention is constructed as comprising a stationary front lens group and a rear lens group which includes at least two movable members arranged to be moved in the same direction with variation of the axial separation therebetween, for example, toward the image plane when the objective is focused for shorter object distances. In this case, the prerequisite is that the amount of axial movement of the member adapted to the focusing purpose be larger than that of axial movement of the member adapted to the compensation for variation of aberrations. On this account, these movable lens members are arranged so that when the objective is infinitely focused, the axial separation between the members is minimum, and also in such a manner as to be moved toward the image plane in differential relation as the object distance is decreased.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram of an embodiment of the telephoto type objective according to the present invention in two different focusing positions designated I and II with object at infinity and at a distance of 5 meters respectively.

FIG. 2 is aberration curves of FIG. 1 embodiment, wherein FIGS. 2A to 2D show various aberrations occurring when the objective is focused for object at infinity, and FIGS. 2E to 2H show various aberrations occurring when focused for object at a distance of 5 meters.

FIG. 3 is a block diagram of another embodiment of the telephoto type objective according to the present invention in two different focusing positions I and II with object at infinity and at a distance of 5 meters respectively.

FIG. 4 is aberration curves of FIG. 3 embodiment, wherein FIGS. 4A to 4D show various aberrations occurring when the objective is focused for object at infinity, and FIGS. 4E to 4H show various aberrations occurring when focused for object at a distance of 5 meters.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIG. 1, a preferred embodiment of a telephoto type objective is shown comprising a stationary front lens group having a positive refracting power and a rear lens group having a negative refracting power and comprised of two achromatic doublets A and B having positive and negative refracting powers respectively. The doublets A and B are arranged in this order with respect to incident light to be moved from

their positions I to their positions II when the object distance is changed in focusing from infinity to 5 meters. The rear doublet B is adapted to effect the focusing, and therefore will be hereinafter referred to as "focusing member B", while the front doublet A is adapted to compensate for aberration variation caused by the movement of focusing member B, and therefore will be hereinafter referred to as "compensating member A".

For facilitating the achievement of good stabilization of aberrations throughout the focusing range, it is preferred that focusing member B is configured with the strongest diverging surface of rearward concavity. If otherwise configured with the strongest diverging surface of forward concavity, remarkable spherical aberrations are produced at the close focusing region. The aforesaid preferred condition when satisfied, however, leads to the production of inward coma and positive astigmatism. In order to facilitate the compensation for these aberrations, it is preferred that compensating member A is configured with the strongest converging surface of forward convexity.

In practice, the following relationships must be satisfied to assist the achievement of a high standard of aberration correction which is a further object of the invention.

$$Sa < Sb \tag{1}$$

$$0.8f < fa < 2f \tag{2}$$

$$1.6 < (Ra/Rb) < 1.8 \tag{3}$$

$$Vb_1 - Vb_2 > 8 \tag{4}$$

wherein Sa and Sb are the amounts of axial movement of the members A and B respectively, f is the focal length of the entire lens system, fa is the focal length of the member A, Ra is the radius of curvature of the strongest converging surface in the member A, Rb is the radius of curvature of the strongest diverging surface in the member B, Vb_1 is the mean value of the Abbe numbers of the positive lens elements in the member B, and Vb_2 is the mean value of the Abbe numbers of the negative lens elements in the member B.

The function of each of the above relationships will be explained below.

The type of objective of the invention is characterized in that when the object distance is changed in focusing from infinity to a close range, the movable members A and B are moved in the same direction toward the image plane, while permitting the compensation for variation of aberrations with focusing. For this reason, inequality (1) must be satisfied.

The positive lens member A is adapted to have a function of compensating for spherical aberrations, but results in an adverse effect on the focusing function. On this account, inequality (2) is set forth. When the upper limit is violated, the spherical aberrations are under-corrected in the short distance region, while when the lower limit is violated, the amount of movement of the focusing member B is increased to such an extent that fabricating difficulties are introduced to the focusing mechanism as incorporated in the lens barrel.

As excessive movement of the compensating member A causes serious increase in variation of spherical aberrations, inequality (1) is also effective in avoiding remarkable under-correction of spherical aberrations.

In equality (3) is set forth for achieving the minimization of variation of coma under the conditions of inequalities (1) and (2). When the upper limit is violated, unacceptable inward coma is produced in the short distance region, while the lower limit is violated, under-correction of shperical aberrations are resulted in the short distance region.

In order to achieve good stabilization of chromatic aberrations over the focusing range, it is required to employ positive and negative lens elements in constructing the focusing member B, and further that these elements satisfy inequality (4). If not so, variation of chromatic aberrations becomes excessive. In the practical embodiments of FIGS. 1 and 3, the focusing member B is shown as constructed from only one positive and only one negative lens elements, but it may be constructed from two or more lens elements in the same sign.

The telephoto type objective of the invention having a rear lens group R characterized by the above described relationships makes it more difficult as compared with the known type telephoto lens to perform correction of spherical aberration due to the divergent lens elements. On this account, the front lens group F must be well corrected in itself for various aberrations, thereby creating a difficult problem of correcting coma. In order to provide for the objective of the invention a large relative aperture, therefore, it is desired to set forth specific requirements for construction and arrangement of the various elements of the front lens groups F.

Thus, in the preferred embodiments of FIGS. 1 and 3, the front lens group F is constructed in the form of the so-called Taylor triplet, namely, a positive lens member, a negative lens member and a positive lens member arranged in this order from the front to increase the capabilities of correcting chromatic aberrations as well as other various aberrations, and is characterized by the following relationships:

$$-0.95 < (R_1R_2) < -0.8 \tag{5}$$

$$-0.45f < R_3 < -0.38 \tag{6}$$

$$0.15f < l < 0.2f \tag{7}$$

wherein R_1 and R_2 are the radii of curvature of the front and rear surfaces of the first lens member counting from the front, R_3 is the radius of curvature of the front surface of the second lens member, and l is the axial separation between the second and third lens members.

When the upper limit of inequality (5) and the lower limit of inequality (6) are violated, coma is deteriorated, while when the lower limit of (5) and the upper limit of (6) are violated, spherical aberration is deteriorated.

In order to minimize variation of astigmatism with focusing at the widest aperture, it is required to satisfy inequality (7). When the upper limit is violated, spherical aberration becomes large at the intermediate height region of light incidence, while when the lower limit is violated, unacceptable negative astigmatism is produced.

The two embodiments of the telephoto type objective of the invention represented in FIGS. 1 and 3 may be constructed in accordance with the numerical data given in Tables 1 and 3 respectively, in which the radii of curvature, R, and the axial separations between the successive surfaces, D, along with the indices of refraction Nd for the spectral D line of sodium and the Abbe numbers Vd for the various lens elements are all expressed with the corresponding numbers counted from

the front to the rear. The minus values of the radii, R, indicate surfaces concave toward the front. The aberration coefficients of the telephoto type objective of FIGS. 1 and 3 with object at infinity are given in Tables 2 and 4 respectively, in which L: axial chromatic aberration; T: lateral chromatic aberration; LS: axial chromatic aberration of pupil; Sa: spherical aberration; CM: coma, AS astigmatism; PT: Petzval sum; and DS: distortion. Aberration correction attained in the objective according to the data of Table 1 when focused for object at infinity or at a distance of 5 meters measured from the image plane is shown respectively in FIG. 2A or 2E for spherical aberration and sine condition, FIG. 2B or 2F for astigmatism, FIG. 2C or 2G for distortion, and FIG. 2D or 2H for coma. In the case of the objective according to Table 3, aberration correction for object at infinity or at a 5 meters distance is shown respectively in FIG. 4A or 3E for spherical aberration and sine condition, FIG. 4B or 4F for astigmatism, FIG. 4C or 4G for distortion and FIG. 4D or 4H for coma.

What is claimed is:

1. A telephoto type objective comprising:

a front lens group having a positive refracting power and which remains stationary during focusing, said front lens group being comprised of a plurality of lens members, and

a rear lens group having a negative refracting power and positioned on the image side of said front lens group in axial alignment therewith, said rear lens group including at least two movable lens members arranged to be moved in the same direction along the common optical axis toward the image plane when the object distance is changed in focusing from infinitely distant object to close object with the resulting speed of movement of the front one of said two movable lens members being different from that speed of movement of the rear one.

2. A telephoto type objective according to claim 1, wherein said front lens member of said rear lens group moves at a slower speed than said rear lens member.

3. A telephoto type objective according to claim 2, wherein said rear movable lens member has at least one positive lens element and at least one negative lens element.

4. A telephoto type objective according to claim 2, wherein said front movable lens member has a front lens surface convex toward the front.

5. A telephoto type objective according to claim 1, wherein said front movable lens member of said rear lens group has a positive refracting power, and said rear movable lens member has a negative refracting power.

6. A telephoto type objective according to claim 5, wherein said front movable lens member has a plurality of surfaces including a strongest converging surface convex toward the front, and said rear movable lens member has a plurality of surfaces including a strongest diverging surface concave toward the rear, and wherein the focusing is effected with the resulting speed of movement of said front movable lens member being slower than that of movement of said rear movable lens member.

7. A telephoto type objective according to claim 6, wherein the mean value of the Abbe numbers of the positive lens elements in said rear movable lens member is larger than the mean value of the Abbe numbers of the negative lens elements therein.

8. A telephoto type objective according to claim 1, wherein said front lens group is comprised of a positive lens, a negative lens and a positive lens arranged in this order.

9. A telephoto type objective comprising:

a primary lens group having a positive refracting power and which remains stationary during focusing, said primary lens group being comprised of a plurality of lens member, and

two movable sub-groups positioned on the image side of said primary lens group in axial alignment therewith to be movable for focusing in such a manner that the image side one of said two sub-groups moves at a faster speed than the object side sub-group.

10. A telephoto type objective according to claim 9, wherein said image side sub-group has a negative refracting power, and said object side sub-group has a positive refracting power.

11. A telephoto type objective according to claim 9, wherein said image side sub-group has at least one positive and at least one negative lenses, and said object side sub-group is meniscus-shaped.

12. A telephoto type objective according to claim 9, wherein the axial separation between said primary lens group and said object side sub-group is larger than that between said two sub-groups.

13. A telephoto type objective according to claim 9, wherein said primary lens group is comprised of a positive lens, a negative lens and a positive lens arranged in this order.

[57] **ABSTRACT**

An apparatus for measuring and evaluating a subject's visual field presents a target image, consisting of a spot of light, at a series of selected locations within the subject's visual field. Means are provided to monitor his resulting eye movement and positions in response to each target presentation. A projection apparatus presents the target images at various locations and in a programmed sequence. The apparatus also includes means for making a photographic plot of those presented targets which the subject has seen or missed, as desired. Determination of whether subject has seen or missed a particular target is evaluated by logic systems which discriminate between eye movement and positions displaying characteristics indicative of whether the subject has seen or missed the target. The logic discriminates between blinks, hunting eye movements and other characteristic positions and movements which are indicative of the subject having seen the target. Means also are provided to enable selective coarse or fine mapping of selected regions of the subject's visual field.

OBJECTIVE PLOTTING OF VISUAL FIELDS BY EYE MOVEMENT MONITORING

This is a division of application Ser. No. 505,339, filed Sept. 12, 1974 now U.S. Pat. No. 3,984,156.

BACKGROUND OF THE INVENTION

Measurement of one's visual field is important for a variety of reasons including the diagnosis of glaucoma as well as other human visual system diseases or impairments. In general, the prior techniques for determining one's visual field and any blind spots have been quite slow and tedious and require a definite subjective response from the person being tested in order to determine whether he has sighted the target at a particular location in his visual field. Additionally, the previously employed tests require administration by one having relatively high degree of skill such as an ophthalmic technician, optometrist or ophthalmologist. For example, in the most common type of visual field test, a hand held target such as a small disc at the end of a wand, is moved about the subject's visual field by the examiner while the subject fixates on a central point. During movement of the hand held target through the subject's field, the examiner asks the subject repeatedly whether he can see the movable target as it is passing from location to location. The examiner may plot, manually, the location of each point which is seen by the subject, or alternatively, he may plot those locations which the subject is unable to see, and which, therefore, define his blind spot.

In order to overcome the uncertainties and difficulties in the foregoing testing techniques some attempts have been made to automate partly the foregoing visual field test, such as employing an arrangement for automatically presenting a series of targets to the subject. Although these devices are somewhat faster than the completely manual test described above, they still are relatively slow and require that the subject respond consciously and intentionally when he sees the target. For example, the response may be verbal or may be indicated by the subjective manipulation of a lever or a button.

Also among the primary difficulties in obtaining fast and accurate plots of the subject's visual field is that the examiner must be assured that the subject's line of sight is directed toward a central fixation point or other known reference point before the target is presented to him. In some instances this may be quite difficult when problems of communication exist between the subject and the examiner as, for example, when testing the young, the aged, or persons whose native language is different than that of the examiner. Furthermore, any such difficulties render efficient and accurate testing still more complicated because it may confuse the results of the test.

A further difficulty in conducting visual field tests with prior techniques is that an indication by the subject that he has seen the target may be the result of hunting eye movements in which, he did not at first actually see the target but moved his eyes about slightly, in a searching motion, and then having seen the target, then moved his eyes directly to it. The present invention employs means for discriminating between such hunting movements and movements in which the presented target was initially seen by the subject.

It is among the primary objects of the invention to provide an apparatus for determining a subject's visual field which avoids the foregoing and other difficulties.

SUMMARY OF THE INVENTION

The invention takes advantage of the natural voluntary or involuntary eye movements which result when a target is presented suddenly to a subject within his visual field. Measurement of the eye movement or change in eye position in response to presentation of the target is employed to determine whether the subject has seen the target. The eye movements may be detected and monitored by a technique described in U.S. Pat. No. 3,473,868 in which the direction and magnitude of the eye movements are translated into electrical signals. Electronic logic means are provided for discriminating between signals which represent eye movements characteristic of the subject having actually seen the target from other types of eye movements such as blinks, hunting or searching movements or the like which produce electrical impulses unrelated to the subject's actual initial detection of the target image. The logic means includes a decision logic circuit which evaluates whether the subject actually visually detected the target by reference to the number and magnitude of the subject's eye movements within an extended time interval which includes the interval during which the target image is presented and a short period thereafter.

The invention employs a target image projector which develops a narrow collimated light beam and directs the beam sequentially toward selected locations on a screen which is within the subject's expected visual field. The position of the intermittent light beam and target image on the screen is determined by reflecting the beam, from its source, off one surface of a double faced mirror toward the screen. The attitude of the mirror is controllable to selectively direct the beam in the desired direction by stepping motors which are positioned in accordance with preprogrammed digital information. The location of the target imge on the screen, as presented to the subject, may be recorded permanently and automatically on photographic film incorporated into the projector. In the preferred embodiment, the photographic film is of the Polaroid type which enables immediate inspection after the test has been completed. The photographic recording is made by employing a second light beam which is reflected off the opposite face of the controlled mirror toward the photographic film. The second, reflected beam is directed along the same axis as the first projection beam, but from the opposite direction and impinges on the film at a location which is dependent on the angle of incidence of the beam to the mirror which corresponds to the direction of the light beam which impinges on the target screen. Shutters are provided in association with each of the first and second light beams, the first shutter being employed to control the timing and duration of presentation of the target light and the second shutter means being employed to expose the photographic film to the second beam. In another mode of operation only those points which are not observed are photographically recorded to provide a plot of the subject's blind spot or spots. The second shutter is controlled automatically in response to the logic circuitry which evaluates whether the subject has seen or missed a particular target.

The stepping motor arrangement for changing the attitude of the mirror also enables the device to be pro-

grammed to present a sequence of targets on the screen in close proximity to each other rather than more widely spaced locations about the screen. This enables more precise plotting and evaluation of an area of the subject's blind spot or spots after the more coarse presentation of the target spots has indicated the general location of the blind spot or spots. The device may be operated in a mode in which the more precise evaluation is effected automatically when a subject has missed a presented target.

It is among the primary objects of the invention to provide an improved technique for determining and plotting a subject's visual field.

Another object of the invention is to provide an improved technique in which the subject's response to a series of targets presented at various locations in his visual field is determined objectively without subjective response on his part.

A further object of the invention is to provide an arrangement for making a permanent record of the subject's visual field.

Still another object of the invention is to provide an improved technique for plotting and measuring a subject's visual field without requiring that the test be administered by highly skilled personnel.

Another object of the invention is to provide an improved technique by which eye movements characteristic of a subject's actual sighting of a target presented within his visual field may be discriminated from other types of eye movements automatically.

DESCRIPTION OF THE DRAWINGS

The foregoing and other objects and advantages of the invention will be understood more fully from the following further description thereof, with reference to the accompanying drawings wherein:

FIG. **1** is an illustration of the invention set up in readiness for use;

FIG. **2** is a sectional plan illustration of the mirror positioning mechanism as seen from line **2—2** of FIG. **1** and showing portions of the mechanism broken away;

FIG. **3** is a sectional elevation as seen along the line **3—3** of FIG. **2**;

FIG. **4** is a side elevation of the mirror positioning mechanism as seen along the line **4—4** of FIG. **2**;

FIG. **5** is a sectional view of the mirror positioning mechanism as seen along the line **5—5** of FIG. **4**;

FIG. **6** is a sectional elevation of the mirror positioning mechanism as seen along the line **6—6** of FIG. **5**;

FIG. **7** is an enlarged illustration of the low friction bearing by which the mirror is mounted;

FIG. **8A** and **8B** illustrate a schematic of the control logic electronics of the invention;

FIG. **9** is an illustration of the relative locations of the vernier target images with respect to each other and to the location of the primary target image on the presentation screen;

FIG. **9A** is an illustration of an alternative configuration of vernier target locations;

FIG. **10** is a schematic illustration of the electronic logic circuitry for controlling the positioning of the mirror mechanism;

FIG. **11** is a schematic illustration of the electronic logic system for controlling presentation of the vernier target images;

FIG. **12A** is a DC plot of a subject's response when an actually presented target has been missed;

FIG. **12B** is a DC plot of an ideal "target seen" response;

FIGS. **12C** and **12D** are DC plots of a three saccade response in which the subject initially detected the target but required a minor correctional saccade to focus directly on the target;

FIG. **12E** is a DC plot of a subject's response where the target was detected but where his eyes returned to the central fixation point before the target light was switched off;

FIGS. **12F** and **12G** are DC plots of the subject's eye movement where he did not see the target image and moved his eyes to hunt or search for the target;

FIG. **12H** is a DC plot representative of a blink;

FIG. **13** is a schematic diagram of the decision logic circuitry; and

FIG. **14** is a block diagram illustrating diagrammatically the relationship between the various functions of the logic circuits.

DESCRIPTION OF THE PREFERRED EMBODIMENT

FIGS. **1-3** shows generally the apparatus employed in the invention which includes a projector-camera housing **10** in which is mounted the mirror mechanism **12**. The housing **10** includes a front wall **14** and a rear wall **16**, having apertures **18, 20** respectively which can be opened or closed by a projection shutter **22** and film shutter **24**. The mirror mechanism **12** includes a double faced mirror **26** having a front face **28** and a rear face **30**. The mirror **26** is arranged so that it will reflect the light beam **32** from a projection light **34**, mounted to a sidewall **36** of the housing, **10** through the projection shutter **22** and onto the projection screen **38**. The opposite sidewall **40** of the housing **10** supports a second light source **42** which directs a beam of light **44** toward the rear face **30** of the mirror **26** along the same axis as that of the light beam from the projection light **34**. The beam from the second light source **42** is reflected from the mirror surface **30** in a direction which is opposite that of the reflected projection beam **32** from the front face **28** of the mirror **26**. The recording light beam **44** is directed toward a film plane, indicated diagrammatically at **46** and disposed at the rear of the housing **10** by any of a variety of well-known film holding devices **48**. The double faced mirror **26** thus directs the projection beam **32** to a selected location on the screen and simultaneously directs the recording beam **44** (when it is operated) to a corresponding location in the film plane **46**, as controlled by the attitude of the mirror **26**.

The mirror **26** is mounted for adjustable movement by the mirror mechanism **12**. The mirror mechanism is mounted to a support block **50** which is secured to the interior of the housing **10**. As shown more fully in FIGS. **2-7**, the mirror mechanism **12** includes a driven bevel gear segment **52**. The mirror **26** is secured to and across the diameter of gear **52** by a bracket **54** and lies in a plane perpendicular to that of the gear **52**. The mirror **26** and gear **52** are supported for rotation in unison about the central axis of the gear **52** by means of a yoke **56** having a low friction bearing **58** which supports the upper edge of the mirror, by bracket **62**, and a low friction bearing **60** which supports the opposite face of the gear **52**, by bracket **54**, to enable the mirror **26** and gear **52** to rotate in unison about a common axis defined by the bearings **58, 60**. The yoke **56** is mounted for rotation about a horizontal axis to rotate the mirror **26** and gear **52** bodily about that horizontal axis. To this

end the yoke **56** is secured to the end of an outer cylinder **64** which is mounted for rotation to the block **50** by bearings **63**. The cylinder **64** has a gear **66** secured thereto which is rotated by a worm gear **68** which is driven, in turn, by a stepping motor **80** mounted to the block **50**. The mirror **26** and gear **52** are rotatable with respect to the yoke **56** by means of an inner cylinder **72** which extends through and is rotatable within the outer cylinder **64**. One end of the inner cylinder **72** extends into and is supported at the yoke by bearing **73** and has a bevel gear **74** secured thereto which meshes with driven bevel gear **52**. The opposite end of the inner cylinder **72** extends outwardly beyond the end of the outer cylinder **64** and has a collar **75** secured thereto. The collar **75**, in turn, is rotatably mounted to the block **50** by bearing **77**. The inner cylinder **64** is driven by a gear **76** secured thereto which is driven by the worm gear as described above. The worm gear is secured to shaft **78** of stepping motor **70**. The stepping motors **70**, **80** of the mirror mechanism **12** are operated by the position logic system which, in turn, is controlled by the digital information on the program card or the vernier positioning system to orient the mirror **26** to present the target image at any desired location within the subject's visual field and also direct the recording light beam (when operated) to a corresponding location in the film plane. The second light source **42** is mounted to a sidewall of the housing in alignment with the axis of rotation of the innerwall and outer cylinders **72**, **64**. The inner cylinder **72** is hollow along its length to enable the light beam from the second light source to impinge on and be reflected by the mirror **26**.

For convenience in the further description herein, the mirror axis of rotation extending through the bearings **58**, **60** will be referred to as the "X" axis and the axis of rotation of the mirror by means of the yoke **56** will be considered as the "Y" axis. Similarly, step motor **70** will be referred to as the "X" step motor and step motor **80** will be referred to as the "Y" step motor.

In order to monitor the position and eye movements of the subject during the test, the device may include a partially reflective plate **82** mounted above and forwardly of the housing **10** so as to be directly in front of the subject's view when his head is properly placed in the head rest and chin support **84**. Plate **82** is adapted to enable the subject to view the screen **38** and is disposed at an angle to his general line of sight to enable a light source **86**, preferably infrared, to reflect from the plate **82** and illuminate the subject's eyes. The image from the subject's eyes is, in turn, reflected from the plate **82** toward an imaging arrangement **88** which includes a ground glass screen **90** on which the reflected image of the subject's eye may be focused, employing the technique described in the aforementioned U.S. patent. As described in that patent a pair of vertically spaced photoelectric cells **92** and horizontally spaced photoelectric cells **94** are located on or adjacent the screen **90** and are aligned with selected regions of the image of the subject's eye on the screen **90**. Variations in the output signals from the photocells **42**, **94** are dependent on the direction and magnitude of the subject's eye movements and their signals are processed in the logic circuitry as described more fully herein. Imaging arrangement **88** preferably is mounted for adjustment to the housing **10** to facilitate initial alignment of the photocells **92**, **94** with the subject's eye image on the screen **90**. This may include a bracket **96** pivoted for horizontal movement to the housing **10** and a vertical elevation screw **98** carried by the bracket **96** and in engagement with the end of the barrel **100**, the other end of the barrel **100** being pivoted to the bracket at trunnions **102**.

GENERAL DESCRIPTON OF OPERATION

The invention employs a number of electronic logic systems which are interrelated as shown diagrammatically in FIG. **14**. The primary logic systems include a control logic circuit, a positioning logic circuit, a decision logic circuit and a vernier logic circuit. A typical cycle might begin by an output from the control logic circuit to step a card reader and read the card bearing digital information corresponding to an intended location of the target image. The digital information is fed into the position logic circuitry which controls the mirror positioning mechanism **12** and positions the mirror in the intended attitude. In the embodiment of the invention described, digital data is included in the card for the positions of each of the X and Y motors with the Y motor being positioned first and then the X motor. When the Y motor has been driven to its intended position, a "Y position ready" signal is fed into the control logic to cause the card reader to advance to the next column of X positioning information on the digital information card. This is fed into the position logic and the X motor is driven to its intended position. During the stepping of the motors **70**, **80** the position of the X or Y step motor being driven is fed back to the position logic circuit for comparison with the intended position corresponding to the digital positioning input. The control logic includes means for delaying operation of the other elements of the invention during positioning of the mirror. After that delay has elapsed and the mirror has been positioned the control logic resumes operation to open the projector shutter and turn on the projector light to present the target image on the projection screen while simultaneously turning off the central, reference fixation target light. The target image will be located at a predetermined angular distance, within approximately 40°, from the central reference fixation target. The position and movement of the subject's eyes, during and slightly after presentation of the target image, is monitored by the photocells **92**, **94** and their output is fed into the decision logic which evaluates whether the subject has seen or missed the presented target. The seen/missed decision from the decision logic is fed back into the control logic and, depending on whether the manual inputs to the control logic were set to record seen or missed targets, the control logic will operate the camera shutter and the camera light to make, or not to make, a photographic plot of that target image.

Means are also incorporated in the invention for checking the subject's cooperation in the test by enabling "dummy" targets (those in which there is no target presented) to be "presented" to the subject. In the event that the output from the photocells indicates eye movement indicating that the subject did "see" the dummy target, the control logic causes a "dummy seen" indicator light on the operator's control panel to turn on thus advising the operator of the subject's uncooperativeness.

It should be noted that the shutter mechanisms are opened and closed whether a real target or a dummy target is presented. This is desirable when the shutter mechanism selected makes audible operating sounds which might be heard by the subject. By operating the

shutters for each mode the subject cannot tell audibly whether the target is real or a dummy.

The invention also includes means for evaluating the subject's visual field closely about the region in which he missed an actually presented target. For this purpose the vernier logic circuit may be employed. The vernier logic circuit is set into operation when the control logic receives a signal from the decision logic indicating that the subject missed an actual target. When the vernier logic circuit is initiated, the control logic is disabled from operating the card reading mechanism and the positioning of the mirror, to present the vernier target images, is controlled entirely by the vernier logic circuit. When the vernier target images have been presented the vernier logic causes the position logic to return the mirror to the attitude which it was in before the vernier sequence and the positioning logic is then enabled to be responsive to the digital positioning information from the card reader. The control logic causes the card reader to be advanced to the next informational word corresponding to the next intended target location and the sequence is begun anew.

The electronic logic systems may be housed conveniently in a control module **110** which houses the card advancing and reading mechanism which includes an exposed slot **112** to receive the card. The module **110** may also house a strip chart recorder **464** to provide a supplemental record of subject's eye test. The module **110** also includes a control panel which includes a manual target positioning means **112**, a start switch **114**, a stop switch **116**, a "dummy seen" indicator light **118**, a record seen/missed selector switch **120**, a vernier in/out switch **122**, a manually controllable switch **124** for turning the reference fixation target on or off, a "disable double saccade" switch **126** and a number of intensity controls **128** for the target light, recording light and reference fixation light.

DESCRIPTION OF CONTROL LOGIC

FIGS. **8A** and **8B** show the circuitry controlling and coordinating the operation of the machine. The sequence of operation is begun by applying a pulse to line **150** through flip-flop **152** and through OR gate **154** to trigger monostable multivibrator **156**. When first starting the sequence of operation the starting pulse may be applied to line **150** through manual start switch **114**. Succeeding pulses are applied to line **150** through flip-flop **152** which is operated in a manner described herein. The high output pulse from multivibrator **156** is amplified and fed through line **160** to initiate operation of a card advancing and reading device **162** which may be of any of a variety of commercially available designs. It should be noted that while the present embodiment of the invention is described as employing digital programming information in the form of a machine readable card, other information, storage and reading techniques may be employed such as tape or the like as is well known in the art. The pulse from multivibrator **156** is also applied to multivibrator **164** through OR gate **166**. Multivibrator **164** has a delay constant (will remain at a high output) sufficient to delay presentation of the target image long enough to enable the card advancing and reading mechanism **162** to position the card so that its digital information may be read as well as to provide sufficient delay for the stepping motors of mirror mechanism **12** to position the mirror, as for example, a delay of approximately one second. The output from multivibrator **164** also is directed through line **168** to a gating circuit **170** (FIG. **8A**) which has an AND function. The output from gate circuit **170** is fed through NAND gate **172** and inverter **174** to apply a high input to monostable multivibrator **176**. The other inputs to the gating circuit **170** are from the positioning logic circuitry, described below, which is effective to apply a high input to gating circuit **170** when the mirror has been positioned in accordance with the digital information on the input card, as described herein. With the mirror properly positioned, monostable multivibrator **176** is triggered and its output is directed, through line **178** to actuate the driving mechanism for the projection shutter **22** to open the projection shutter. In the embodiment shown this may be achieved by applying the output from the multivibrator **176** to the input of an enabled NAND gate **180**, inverting the low output from gate **180** to a high state through inverter **182** and applying the high pulse to the shutter mechanism to open the shutter. Multivibrator **176** has a time delay sufficient to maintain the projection shutter open while the target light is being presented. For example, the delay may be of the order of 2.75 seconds.

It is desirable to delay the operation of the target light until the projection shutter **22** has been opened fully. To this end simultaneously with actuation of monostable multivibrator **176**, the pulsed output from inverter **174** is also applied to monostable multivibrator **184** which has a delay constant of the order of 55 milliseconds, depending on the time required to open the shutter fully. The high output pulse from multivibrator **184** is fed into monostable multivibrator **186** which, in turn, controls operation of the target light. The output from multivibrator **186** causes the target light **34** to turn on through line **188** to NAND gate **190** and inverter **192** to the switch mechanism (not shown) for the target light. Gate **190** is normally enabled because of the normally high state of line **236** as will be described. Multivibrator **186** has a delay constant sufficient to remain in a high output state and present the target image for a predetermined time interval long enough to afford the subject a sufficient opportunity to detect and respond to the target. By way of example, a delay constant of the order of 2.2 seconds would be typical. It is desirable to switch the central reference fixation target light **193** off when the target image is presented. This may be accomplished automatically by connecting line **188** through an inverter **189** to the central fixation light. When multivibrator **186** switches high to present the target light, the output from inverter **189** switches low to extinguish the central fixation light **193**. When multivibrator **186** returns to its stable state, turning off target light **134**, the output from inverter **189** will return to its high state to re-present the central reference fixation target. In an alternative mode of operation the central fixation light **193** may be maintained on at all times, including the time in which the target is presented, by line **191** which is connected to the panel switch **124**.

The subject's eye movements and positions are monitored during an extended time interval which includes the predetermined time interval of the presentation of the target image. As described, the output from the photocells **92, 94** is evaluated by the decision logic circuitry to determine whether the subject actually visually detected the target image. In order to provide ample opportunity for the decision logic to perform its function the output from multivibrator **186** is applied concurrently to monostable multivibrator **194** which has a delay constant sufficient for the subject's eye posi-

tions and movements to be monitored by the photocells **92, 94** and the resulting signals processed through the decision logic circuitry. The delay constant of multivibrator **194** preferably is somewhat longer than the time constant of multivibrator **186** to enable the decision logic to evaluate eye movements after the target image has been extinguished, for the full extended time interval. The delay may be, for example, of the order of three seconds. This is desirable because the subject's eyes may move after the target light has been extinguished, as when returning his vision to the central fixation point as described herein.

When the decision logic has evaluated whether a subject actually visually detected the presented target image, it then remains for the photographic recording system to make, or not make, a photographic plot of the target image location, as determined by the mode of operation which the examiner has selected. To this end as multivibrator **194** returns to its stable, low output state, the pulse triggers multivibrator **196**, and the output of multivibrator **196** is directed through line **198** to the camera shutter mechanism to open the camera shutter **24**. At the same time, the output from multivibrator **196** is directed through line **200** through inverter **202** to apply a low signal at NAND gate **180** which will insure that the projector shutter is closed. This precludes ambient light from reaching the film plane as might occur if the projection shutter **22** remained opened at the same time as the camera shutter. Simultaneously with the actuation of multivibrator **196**, the output from multivibrator **194** is applied to monostable multivibrator **204** which is effective to delay further sequencing of the photographic recording functions until the camera shutter **24** is open fully. The delay will depend on the characteristics of the shutter mechanism and may for example, be of the order of 55 milliseconds. It may be noted that monostable multivibrator **196** has a time delay constant sufficient for the logic and control circuits to "decide" whether or not to make a photographic plot of the relative location of the target image as described below. By way of example, the delay may be of the order of 1.2 seconds. When the camera shutter **24** has been opened fully, the return to its stable, low output state of multivibrator **204** triggers multivibrator **206**. Multivibrator **206** sets the control logic circuitry in readiness to cause a photographic record of the position of the target to be made, depending on whether the target light was actually presented, whether it was a "dummy" in which case no target would have been presented, whether the subject "saw" or "missed" the target or dummy and whether the intended mode of operation, as controlled by a suitable selector switch on the panel of the control box, is set to record "seen" or "missed" points.

As shown in FIGS. **8A** and **8B** the output from multivibrator **206** is directed through line **208** to one of the inputs "*a*" of each of the NAND gates **210, 212, 214, 216**. Each of gates **210, 212, 214** and **216** also has an input "*b*" which is controlled by the decision output front the decision logic circuitry. As described more fully herein, the output from the decision logic circuitry is a signal which is indicative of whether the subject's eye positions and movements where characteristic of his having "seen" the target. As shown in FIG. **8B** the output from the decision logic circuitry is applied to monostable multivibrator **218** and the output from multivibrator **218** is directly connected to input "*b*" of each of NAND gates **210** and **214.** The output from multivibrator **218** is also connected, through inverter **220** to input "*b*" of each of NAND gates **212** and **216**. Each of the gates **210, 212, 214, 216** also includes an input "*c*", as through line **222**, which controls gates **210, 212, 214, 216** in the event that a "dummy" target was presented. The state of line **222** may indicate a "dummy" either by a manual dummy presentation switch on the control panel or from appropriate digital information programmed into the card. Line **222** is connected directly to input "*c*" of each of the NAND gates **210, 212** and is applied, in an inverted form, through inverter **224** to input "*c*" of each of the NAND gates **214, 216**.

Gates **210, 212** are effective to detect, respectively, whether a dummy signal was "seen" or whether it was "missed", as it should have been. Gates **214, 216** discriminate between actually presented targets which were "seen" or "missed". For example, assuming that an actually presented target was seen and that the manually controlled panel switch (which controls the output of flip-flop arrangement **230**), to selectively record points seen or points missed, is in the "record seen" configuration. Where the target was actually presented, line **222** is at a low state which applies low inputs to terminals "*c*" of gates **210** and **212** and high inputs to terminals "*c*" of gates **214, 216**. Inputs "*a*" of each of gates **210, 212, 214, 216** are high at this time, from the output of multivibrator **206** through line **208**. A target which was actually seen will result in an output pulse from the decision logic to pulse multivibrator **218**. This will result in a high input to terminal "*b*" of NAND gate **214** and a low input to terminal "*b*" of NAND gate **216**. The resulting high output of gate **214** is passed through OR gate **226** and the high output from OR gate **226** is applied to NAND gate **228**. The other input to NAND gate **228** is high because of its connection to the output of OR gate **229**, which was high because of the high output from NAND gate **216**. This results in a pulse at the output from NAND gate **228** which triggers the recording light source. Had the subject under test missed the presented target, input "*a*" to NAND gate **216** would have remained in its inverted high state thus maintaining its output low which, through OR gate **229**, would maintain NAND gate **228** in its previous state. The result would be no output pulse from NAND gate **228** and the record light source would not be triggered.

If it is desired to record the missed targets, thus providing a photographic plot of only the missed points, the panel controlled record seen/missed selector **230** may be set manually to switch the state at line **232** from high to low which sets one of the input terminals of NAND gate **228** at a high state through inverter **234** and OR gate **229**. The low state of line **232** is applied directly to one of the inputs to OR gate **226**. When the presented target is missed, there will be no pulse from multivibrator **218** and its output will remain low, resulting in a high output from gate **216** which, through OR gate **226**, will generate a low output pulse from NAND gate **228**, thus triggering the recording light source and making a photographic plot of that missed point. If, however, the target is seen, the output pulse from multivibrator **218** will be applied to input "*b*" of NAND gate **214** which will switch gate **156** to a low output state with a corresponding low output state from OR gate **226**. NAND gate **228** will not be triggered and no photographic recording will be made.

In those instances where it is desired to spot check the subject's response by providing a "dummy" target, the state of line **222** may be changed from low to high either by a manually operable switch on the face of the control

panel or by preprogrammed digital instruction on the program card. In either event, when the state of line **222** is switched to high, the high state is applied to inputs "*c*" of NAND gates **210, 212**, respectively. Inputs "*a*" of gates **210, 212** are also at a high state. Gates **214, 216** are disabled from operating the recording light during this mode of operation by means of the low output of the inverter **224**. The low output from inverter **224** also is applied, through line **236** to an input of NAND gate **190**, thus disabling gate **190** (FIG. 8A) and precluding operation of the target light.

When a "dummy target" is presented and "missed" input "*b*" to gate **210** will be low, resulting in a high output from gate **210** which, is inverted through inverter **238**. The output from inverter **238** is employed to control the operation of an indicator light **240** on the panel which, when lit, indicates that the subject moved his eyes when there was no target presented. Here, however, where the "dummy target" was missed, the output from inverter is low and the indicator **240** is not lit. The "dummy missed" indication also results in a high input at terminal "*b*" of gate **212**, thus switching the output of gate **212** to a low state which, in turn, is applied at the input terminal "*b*" of NAND gate **242**. This maintains a high output state from gate **242** which is passed through OR gate **154** and is employed to actuate multivibrator **156**, to step the card reading mechanism and begin a new cycle of operation.

Where the dummy target has been "seen" the high output from multivibrator **218** is applied to input terminal "*b*" of gate **210** resulting in a low output from that gate. This actuates the "dummy seen" indicator light on the panel which advises the operator that the subject is moving his eyes in a search for the target or is otherwise being uncooperative in the test. It also switches AND gate **242** through line **241** to pulse multivibrator **156** and advance the card reading mechanism.

After the foregoing arrangement has completed its cycle of evaluating whether the subject detected or missed a real or dummy target and a photographic plot of the seen or missed points has been made, the card reader is sequenced to its next position to read the next column of digital information from the preprogrammed card and begin a new cycle of operation.

When the target image is presented, the inputs to terminals "*c*" of gates **210, 212** will be low resulting in a high output from these gates into NAND gate **242**. If the real target was seen the low output from gate **214** will be inverted at inverter **244** and the resulting high signal will be applied to an input of NAND gate **246**. In most instances (except as described below in connection with operation of the vernier logic circuitry) the other input to gate **246** will also be at a high state, resulting in a low output from gate **246** which applied into terminal "*c*" of gate **242** thus causing a high output pulse to be applied to multivibrator **156** through OR gate **154** to advance the card reader and begin a new cycle as described above.

Where an actually presented target has been missed (assuming that the device is not being operated in its vernier mode) gate **242** is switched by switching its input "*d*" low. This results from the low output of NAND gate **254** when an actual target has been missed. Input "*b*" to gate **254** is set high when not operating in vernier (as will be described). Input "*a*" to gate **254** is controlled by the output from gate **260**. NAND gate **260**, in turn, has one input "*a*" set high when not operating in the vernier mode through the high state in line **413** which is inverted, at inverter **261** to a low output state which, in turn, is applied to input "*b*" of gate **263** maintaining the output of gate **263** high which is applied to input "*a*" of NAND gate **260**. When an actual target has been missed, output of gate **216** switches low resulting in a high output pulse from NAND gate **260** which switches gate **254** low and in turn switches NAND gate **242**.

As will be described more fully with regard to the vernier logic circuitry, when in the vernier mode, a series of targets are presented in a programmed sequence which is incorporated into the logic circuitry itself and is not embodied in the preprogrammed digital input information. For this reason, the card reading and stepping mechanism must be disabled while the vernier sequence is being performed. Whether the vernier cycle is to be employed in a given test is controlled manually by the operator at a switch at the control panel. Once the switch has been set by the operator, the vernier circuit will operate automatically in response to a subject having missed a real target and the card reading mechanism will be disabled. The card reading mechanism is disabled by maintaining a low output from gate **242**. Inputs "*a*" and "*b*" of gate **242** are maintained at a high state when the target image is actually presented and missed. This results from the high output of gate **246** which, in turn, results from the low output of inverter **244** which, in turn, results from the high output of gate **214** when an actual target has been missed. Input "*d*" of gate **242** also is maintained at a high state when an actual target is missed and when operating in the vernier mode. To this end, the manual vernier switch operates a flip-flop **248** which, when the vernier is "in", is at a high output state. The high state from flip-flop **248** is applied to line **250** and is inverted through inverter **252** and the resulting low state is applied to input "*b*" of NAND gate **254**. The resulting high output from gate **254** is applied at input "*d*" of gate **242** thus disabling that gate. After the device operation of the vernier mode, inputs "*c*" and "*d*" to gate **242** are maintained at a high state, thus maintaining the card stepping and reading mechanism **162** disabled throughout the vernier operation, which results from line **413** being switched to a low state. This maintains the output from gate **246** into input "*c*" of gate **242** high. The output from gate **254**, which is applied to input "*b*" of gate **242** also is maintained high as a result of the low output from inverter **252** which occurs when operating in the "vernier in" mode.

With the card advancing and reading mechanism disabled the presentation of the vernier target images is initiated by an output pulse from monostable multivibrator **256** as will be described more fully herein. The input to multivibrator **256** is dependent on whether the device is being operated in a "vernier in" mode and also whether a real target has been missed. When operating in the "vernier in" mode, the high state in line **250** is fed into input "*b*" of NAND gate **258** to enable that gate. When an actually presented target is missed, the output from gate **216** switches low which, in turn, switches the output from NAND gate **260** high thus switching gate **258** to its low output state. This is inverted at inverter **262** and the resulting pulse is employed to trigger multivibrator **256** and pulse line **266** to begin the functioning of the vernier control logic as will be described.

Should it be desired to stop the machine at any time this may be done by operating panel stop switch **116**

which controls a flip-flop **171** to the disable gate **172** and preclude further sequencing of the control logic.

DESCRIPTION OF POSITIONING LOGIC

The circuitry for controlling the position of the mirror **26** includes means for both manually and automatically feeding digital information into the machine regarding the desired attitude of the mirror and/or whether a particular target is to be a real or dummy target. The mirror positioning logic receives inputs, selectively, from the vernier control circuitry as well as from the programmed digital information card or tape. As mentioned above, when operating in the vernier mode the sequential positioning of the mirror is a function of the circuitry incorporated into the vernier circuit itself. However, when the position of the mirror is to be controlled by the digital information on the program card or tape, a separate input to the positioning logic is employed. For this purpose, and as shown in FIG. **10**, the card reader indicated generally at **300** includes a plurality of output gates **301** which are set to a state corresponding to the information read by the card reader and which corresponds to the target coordinates. This data is transferred to a seven bit register **304** which stores the digital information regarding the particular coordinates of the intended target location. The register **304** feeds a comparator **306**. The comparator **306** also receives feedback input corresponding to the actual position of the X and Y stepping motors **70, 80** at any given time. To this end, step motors include follower potentiometers **308, 310** which step with the motors **70, 80** and are employed to feed back, in analog form, a signal corresponding to the position of their respective step motors **70, 80**. The analog information is fed through an analog-to-digital converter **312** and the output from the A/D converter is fed into the comparator **306**. As will be described below, the X and Y step motors **70, 80** are driven by the output pulses from a system clock in incremental steps which, in cooperation with the gearing selected, will cause the target image on the screen to shift one degree (1°). The output from comparator **306** is employed to terminate driving of the step motors when they have reached a position corresponding to that which was fed into register **304** in digital form.

It may be noted that in the described embodiment of the invention the digital information for a particular intended mirror position is stored on a conventional card having rows and columns of digital data and in a manner in which each column has information relating to either the X or Y position. Whether a particular seven bit digital word read by the target coordinate portion of the card reader relates to an X or Y coordinates is so identified by a bit in the column being read. Thus, card reader **300** also includes a section including output gates **302** which are set, alternatively, to a high or low state depending whether the information which relates to X or Y coordinates. It may be noted that the invention also includes manual means for positioning the target location, indicated generally at **303** and having controls at the control panel.

When operating automatically the card reader will first read a data column relating to the intended position of one of the step motors (the Y motor) and then, after that function has been carried out, the card reader will be advanced to read the next column and carry out the positioning instructions with regard to the other step motor (the X motor).

When a column of digital information is read at reader **300** or fed in at manual input **302**, it is entered into the register **304** when the register **304** is pulsed through line **314**. Line **314**, in turn, carries the output from flip-flop **316** which, in turn, is pulsed by the system clock **318** through line **320**, flip-flop **316** having been previously set by multivibrator **322**. The starting pulse from the system clock **318** is also applied, through inverter **324** to A/D converter **312** to initiate its operation. The A/D converter **312** is selectively fed with analog information from either of the following pots **308, 310** as controlled by a switch **326**. The position of switch **326** is in turn controlled by the digital input information which also includes in each column data indicative of whether the particular column or manual input relates to positioning of X motor **80** or Y motor **90**. The "X" or "Y" motor identification data is applied to a pair of flip-flops **328, 330**. Digital information indicating a column of "X" information relating to the intended position of motor **80** will actuate X flip-flop **328** which, through line **332** operates switch **326** to connect the A/D converter **312** to the "X" motor follower pot **308**. In the absence of an output pulse from X flip-flop **328**, switch **326** will normally be in a position which connects the output from the "Y" follower pot **310** to the A/D converter **312**.

The direction in which the step motors **70, 80** are driven is controlled by output **334** of comparator **306**. Comparator output **334** controls the state of lines **340** and **342** which are connected to the X and Y step motors **80, 90**, respectively to switch the polarity of each motor in accordance with the desired drive direction. Thus, comparator output **334** is low at all times except when the digital information in register **304** is greater than that indicated by the output A/D coverter **312**. The number of incremental steps which the motors **70, 80** are driven is controlled by comparator output **336** which, in turn, controls the outputs of NAND gates **344** and **346** respectively. Gates **344** and **346** are connected to the motors to drive them one increment for each output pulse. Output **336** of comparator **306** remains low at all times except when the outputs from storage register **304** and A/D converter **312** are equal, in which case comparator **306** produces a high output pulse in line **336**.

Assuming that the digital input data in register **304** relates to a Y position coordinate, switch **326** will direct the feedback of analog motor position information from the Y follower pot **310** to the A/D converter **312**. This will be compared at comparator **306** with the position data in register **304** which will be entered into the register **304** in response to the output pulse from flip-flop **316**, the A/D converter **312** being simultaneously pulsed through line **320** to begin its operation. When the "Y" information in register **304** is greater than the output from A/D converter **312**, the output **334** from comparator **306** will be high, which will result in a low pulse from NAND gate **338**. The other inputs to gate **338** also are high, line **413** being high when the system is not operating in vernier and line **386** being pulsed high in response to switching of Y flip-flop **330** as is the case when the digital data relates to "Y" positioning information. The low output from gate **338** is employed to maintain the polarity of the drive pulse applied to Y step motor **80** to drive it in one direction as will be described. Conversely, if the digital position information in register **304** is not greater than the output from A/D converter **312**, output **334** from comparator **306** will switch

low which, in turn, will switch the output of gate **338** to high, thus reversing the polarity of the pulse applied to Y step motor **80** and, therefore, reversing its direction of rotation.

The number of drive pulses received by the Y step motor **80** from the system clock is controlled by NAND gate **346**. One input to gate **346** is a function of whether the machine is in a vernier sequence, and, when not, line **348** is low which, when inverted through inverter **350**, is applied as a high input to gate **346**. The other input to gate **346** is controlled by NAND gates **352, 344** and **354**. As long as the outputs from register **304** and A/D converter **312** are not equal, line **336** will be at a low state which, when inverted through inverter **346** will apply a high input to gate **354**. The other input to gate **354** is pulsed high by the system clock **318**, through line **320** and through a delay circuit **358** to cause a low output from gate **354**. This, in turn, results in a high output from gate **344** which produces a low output from gate **352**. The low output of gate **352** results in a high output pulse from gate **346** to drive the Y step motor **80** one increment. Delay circuit **358** is of conventional design and permits the analog feedback information from the follower pots **308, 310** to be fed through A/D converter **312** and converted to digital information usable in the circuit.

In the foregoing manner a high output pulse will result from gate **346** each time the clock **316** pulses to step the Y motor **90** until the information in register **304** is equal to the output from A/D converter **312**. When that occurs, the output **336** will switch to a high state, switching NAND gate **344** to a low output and thus terminating further stepping of the Y step motor **80**. In addition, when line **336** is pulsed to its high state, this pulse is applied to NAND gate **360** which then switches low, triggering monostable multivibrator **362**. The output pulse from multivibrator **362** is connected through line **364** to multivibrator **156** of the control circuitry to step the card reader to the next column of digital information which will bear data corresponding to the other (X) coordinate of the intended target image.

It may be noted that when the Y step motor **80** is stepped to its intended position in response to each high output pulse from gate **344**, that high output pulse also is directed through line **366** to the X step motor **70** to drive it simultaneously with the Y motor **80**. This mode of operation is employed because of the special construction of the mirror positioning mechanism shown in FIGS. **2–7**. The construction of that mechanism is such that operation of the Y step motor **80** alone will cause the yoke **56** to rotate which will move the mirror **26** to a position in which the reflected light beam would shift horizontally as well as vertically on the target screen. For example, rotation of the Y step motor **80** in a direction indicated by the arrow +Y in FIGS. **5** and **6** would cause the yoke to rotate in the direction indicated by the arrow +Y in FIG. **4**. Because the surface of the mirror lies at an angle to the axis of rotation of the yoke, rotation of the yoke in the +Y direction will also cause the mirror to pivot to an attitude to cause the target image to be shifted not only in the +Y direction but also to the left in a −X direction on the projection screen **38** as indicated by the corresponding ±X, ±Y arrows in FIGS. **1** and **2**. By simultaneously operating the X step motor **70** in a direction opposite to that which is caused by the Y step motor (here +X), the X component of Y step motor movement can be compensated for. The positioning logic circuitry is arranged so that if the Y step motor **80** is driven a direction to shift the target location up (+Y) and to the left (−X) the X motor **70** is also driven in a direction which will shift the target image to the right (+X). As will be described, a high output in line **340** will switch the polarity of the X step motor **70** to shift the target image to the left (−X) and a high output in line **342** is effective to switch the Y step motor **80** to shift the target image up (+Y) and to the left (−X), the outputs at lines **340** and **342** would be opposite when the mirror is being positioned to a Y coordinate. The opposite polarity at lines **340, 342** will cause the X step motor **70** to be driven in a +X or −X direction which is opposite to that component of the −Y or +Y direction of the mirror movement which would cause shifting of the target image along an X direction as the yoke is rotated.

The polarity of the pulse applied to Y step motor **80** is controlled by AND gate **368** and the polarity of the pulse applied to X step motor **70** is controlled by NAND gates **370, 372, 374**. The outputs from NAND gates **370, 372, 374** are connected in common to a termination resistor **376** which provides an OR function for that combination of gates. When not operating in the vernier mode, line **413**, which is connected to the vernier control circuitry in a manner described below, is at a high state. The high state of line **413** is inverted at inverter **382** and the resultant low state is applied to gate **374** thus maintaining its output high at all times when the system is not in vernier and the mirror attitude is being determined by the digital input data. The high state of line **413** is also applied to an input of each of gates **370, 372** to enable them to be switched to high or low outputs depending on the state of the other inputs to those gates as will be described below. The high state at line **413**, when not in the vernier mode, is also applied to an input of AND gate **368** which enables that gate to be switched, depending on the output from NAND gate **338**. Switching of gates **370, 372** and **368** are dependent on the output **334** from comparator **306** and on whether the mirror mechanism **12** is being positioned to a Y coordinate or an X coordinate. When positioning the mirror to a Y coordinate and assuming that the output **334** from comparator **306** is high, all the inputs to gate **338** will be high, switching the output of gate **338** low to maintain a low output from gate **368** to set the polarity of the Y step motor **80** in a direction which will shift the target image down (−Y) and to the right (+X). The X step motor **70** is driven in a compensating direction (−X), to shift the target image to the left, because the high state at line **334** will result in a high output from each of NAND gates **370** and **372**. Conversely, if the intended Y coordinate were such that the state of line **334** was low, the output from NAND gate **338** would be high, thus switching AND gate **368** high and directing the Y step motor thus switching AND gate **368** high and directing the Y step motor **80** to shift the target image up (+Y) and to the left (−X). The X step motor **70** would be driven in a compensating direction (+X), to shift the target image to the right, by a low output in line **340** which results from all high inputs to NAND gate **72**, switching its output low with a resultant low signal at line **340**.

After the mirror has been shifted to the new Y coordinate and the card reader as been advanced as a result of the pulse in line **364**, the next columm on the card will include data relating to "X" positioning information and will trigger flip-flop **330**. This switches switch **326** to connect A/D converter **312** with the X follower

pot **308**. In the manner similar to that described above, the gates **370, 372** and **374** result in an output at line **340** which is dependent on comparator output **334**. However, when processing X positioning information the high output from flip-flop **328** is applied through lines **384** to an input of gate **370**. A second input to gate **370** is maintained high by line **413**. The output of gate **370** this depends on the input **334** from comparator **306**. Gate **372** which, during the positioning of "X" data, has a low input from Y flip-flop **330** will remain in a high output state at all times as will gate **338** which is also connected through line **386** to the output from Y flip-flop **330**. Thus, when the output from comparator **306**, in line **334**, is high, the outputs from each of the gates **370, 372, 374** will be high which will direct the X step motor **70** to shift the target image to the left (−X). When the comparator output **334** is low, however, all the inputs to gate **370** will be high, switching its output low and resulting in a low state in line **340** which sets the polarity of the X step motor **70** to shift the target image to the right (+X).

With the polarity for the X step motor **70** set, regular pulses from the system clock will result in high output pulses from gate **344**. When the feedback from the X step motor **70** indicates that the motor **70** has reached the intended position, the output from comparator **306** at line **336**, switches high which will switch the output of gate **344** low thus terminating further stepping of the X step motor **70**. It should be noted that when the mirror **26** is being positioned with respect to X coordinate information, the Y step motor **80** is disabled because of the low output from gate **346**. This results from high input to gate **346** from inverter **350** (when not operating in vernier) and a high input to gate **346** from gate **352**. The output from gate **352** is maintained high during the X coordinate positioning because of the low input to that gate by line **386** from Y flip-flop **330** which has a low output state during the processing of X coordinate information.

Where a dummy target is to be presented neither of the X or Y flip-flops **328, 330** are actuated and the positioning system remains inactive.

It may be noted that X and Y flip-flops **348, 330** are self-resetting. When the A/D converter **312** has cycled, its "busy" output at line **388** switches low which, when inverted through inverter **390** switches gate **392** which, in turn, actuates multivibrator **394**. The output from multivibrator **394** operates gates **396, 398** which are effective to reset the Y flip-flop **330** and X flip-flop **332**, respectively.

The foregoing description of the positioning control has related to its operation when the system is not within a vernier cycle. When in a vernier cycle the number and direction of steps for each stepper motor is controlled entirely and independently by the vernier control circuitry.

DESCRIPTION OF VERNIER LOGIC

As mentioned above when it is desired to examine more closely the regions of the subject's visual field about actually presented targets which were missed by the subject, the panel switch **122** is set to the "vernier in" mode of operation. This enables automatic operation of the vernier cycle in response to the subject having missed an actual target and disables the card reading and advancing system until the vernier target presentation has been completed. When operating in the "vernier in" mode, a signal from the decision logic indicating that the subject has missed a real target image will cause automatic actuation of the vernier control logic to automatically present a plurality of target images in a predetermined array and sequence and in close proximity to and surrounding the location of the target image which was missed. FIG. **9A** shows the relative location of the vernier target images with respect to the primary target image which was missed. In the preferred embodiment, three vernier targets are presented in a triangular configuration about the primary target image location located at **400** in FIG. **9**. The first of the three vernier points to be presented in the sequence **V1** is located 1° directly above the primary target location **400**. After vernier image **V1** has been presented and the subject's eye position and movements evaluated the vernier control circuitry causes the mirror to be repositioned to present vernier point **V2** which is also spaced 1° from primary target location **400** but below and to the left of location **400** as indicated. The procedure of evaluating the subject's eye movements with respect to vernier target image **V2** is performed and the vernier control logic then causes repositioning of the mirror to present vernier target image **V3**. Vernier image **V3** is spaced 1° from the primary target image **400** and is downwardly and to the right of that location to define the triangular spacing of the three vernier points **V1, V2, V3**.

By presenting a plurality of vernier targets in sequence, fine mapping of the subject'visual field about the region of a missed point is achieved and may show a general boundary line of the subject'scotoma. For example, if the vernier presentation indicates that the subject missed vernier points **V1** and **V2** but saw vernier point **V3**, this would indicate that the boundary line of the particular scotoma in question would extend somewhere between vernier point **V3** and a line drawn between vernier points **V1** and **V2** as indicated in phantom by the line **402** in FIG. **9**. If the subject missed all three of the vernier targets **V1, V2** and **V3** this would indicate that the boundary of the scotoma was somewhere outside all of the vernier points. Conversely, if the subject saw all three vernier points this might indicate that the scotoma is quite small and is located closely about the primary target image location **400**. It may be noted that while the illustrative embodiment of the invention shows a vernier pattern of only three points, a more fine mapping of the scotoma boundary could be achieved by employing more than three vernier points, as suggested in FIG. **9A** in which there are six vernier points presented which would provide still further fine mapping of the scotomic boundary. However, three vernier points are adequate for most testing purposes.

The vernier sequence is begun in response to a missed target by an output pulse from multivibrator **256** (FIG. **8B**) which is applied to pulse flip-flop **404** (FIG. **11**) through line **266**. The other input to flip-flop **404** is synchronously controlled by the system clock **318** to produce an output pulse from flip-flop **404** synchronously with the timing of the vernier system as controlled by the system clock. The output pulse from flip-flop **404** is fed into a three bit digital counter **408** having both positive and inverted outputs. It may be noted that counter **408** is rezeroed through line **409** at the beginning of each operational sequence by its connection to line **150** through gate **411**. The inverted outputs are connected to the three inputs of NAND gate **410**, the output of which is connected to line **413** of the

control logic and position logic circuits described above. Thus, where the system is not operating in vernier or, if an in vernier and a target was seen, there is no output pulse from multivibrator **256** and the flip-flop **404** remains in the low output state. As a result each of the three counter outputs *a, b, c* will be at a low state (000) which, when inverted and fed into NAND gate **410** will result in a low output which may be inverted through inverter **412** to a high state which is applied to line **413**. As described above, when line **413** is high gates **246** and **254** are disabled and cannot control switching of gate **242**.

When a target is missed the first vernier pulse from multivibrator **256** is applied to flip-flop **404**. The counter **408** switches to a (001) digital state which results in input "*a*" to gate **410** being switched low. This results in a high output from gate **410** which is inverted to a low state through inverter **412** to switch line **413** to a low state. As described above, when line **413** is switched low, gate **246** is switched to produce a high output which further precludes operation of the step card reader multivibrator **156** during the vernier sequence. Similarly, because the panel switch and flip-flop **248** is set to the vernier position, the output from gate **254** is high. In addition, line **413** is connected to an input of each of NAND gates **370**. **372** and **338** of the position logic (FIG. **10**) to maintain their high outputs and disabling them from switching to low output during the vernier cycle. The high output from NAND gate **338** enables AND gate **368** to be controlled directly by the vernier circuitry through line **380** as will be described below. Line **380** is also connected through line **381** to an input of gate **374** to control its output in response to the vernier circuit. It should be noted that the other input to NAND gate **374** is enabled by a high signal from an inverted input, through inverter **382** from line **413**. It may be noted that during operation of a vernier cycle one of the inputs "*a*", "*b*" or "*c*" to gate **410** will be low, which maintains the low state in line **413**.

When counter **408** has received its first pulse from flip-flop **404** and has been switched to a (001) digital configuration the X and Y step motors **70, 80** are driven to a position which will orient the mirror **26** to reflect the light target at the first vernier position V1 which, in the illustrative embodiment, is 1° above the location of the missed target **400**. This requires the Y step motor **80** to be advanced to move the mirror to reposition the image one step upwardly (+Y) and to the left (−X) and the X motor **70** to compensate one step to the right (+X). The number of pulses applied to the step motors is controlled by switching X NAND gate **414** and Y NAND gate **416** to develop output pulses in response to and for the desired number of output pulses from the system clock **318**. For example, with the counter **408** set to a (001) output all but input terminal "*a*" of NAND gate **418** will be high. When the system clock **316** pulses input "*a*", through line **420**, the output from gate **418** will be switched to low which will result in an output pulse from X NAND gate **414** and, through line **424**, a high output pulse from gate **416**. The output of gate **414** is connected through line **422** to the position logic circuit. As shown in FIG. **10**, a high output in line **422** will be inverted to low at inverter **426** and that low signal switches the output of gate **344** high to pulse the X step motor **70**. The high output from gate **416** is connected through line **348**, through inverter **350** (FIG. **10**) to pulse NAND gate **346** high and drive the Y step motor **80** one increment.

The direction in which each of the step motors is driven for the first vernier point is controlled by the state of line **380**. Line **380** is connected to the output of NAND gate **428** and its state is dependent on the output from counter **408**. When counter **408** receives its first pulse to begin positioning of the first vernier point the input to gate **428** from output "*b*" of counter **408** will be low thus maintaining line **380** at a high state. This, in turn, results in a high output pulse from gate **368** to direct the Y step motor to drive the mirror in a +Y, −X direction (up and to the left as seen on the screen) and results also in switching of gate **374** resulting in a low output which will direct the X step motor **70** to drive the mirror in a compensating +X direction to shift the target image location to the right.

The output pulse from gate **418** also is applied to NAND gate **430** which, in turn, drives a two-bit counter **432**. When the output from gate **418** switches low in response to termination of the clock pulse, output from NAND gate **430** switches high, pulsing counter **432**. The output from counter **432** switches NAND gate **434** so that its resultant low output will be applied to an input of gate **418** through line **436** thus switching gate **418** back to its high output state which, in turn, switches vernier control gates **414, 416** back to their low output state and terminates the positioning of the mirror at the first vernier point. With the mirror having been positioned to the first vernier point V1 within the delay of multivibrator **164**, the resetting of multivibrator **164** to its low output state pulses gating circuit **170** through line **168** (FIG. **8A**) to control the projection shutter, projection light, the camera shutter, record light in the same manner and sequence described previously. The subject's response to the presentation of the first vernier point V1 is monitored by the photocells **92, 94** and the decision logic circuitry determines whether the subject saw or missed the first vernier point. Depending on whether the photographic recording system is set to record seen/record missed points, a photographic plot of the subject's response to the presentation of the first vernier target image may be recorded. Whether the subject saw or missed the first vernier point, after his response has been evaluated multivibrator **256** is then pulsed to continue the vernier sequence. This results from the output pulse from gate **258** each time either of gates **214** or **216** are switched. It should be noted that each time counter **408** is advanced from the output from flip-flop **404**, counter **432** is reset to a (00) state through line **444**, flip-flop **445**, inverter **446** and line **447**.

The foregoing sequence of automatically entering into the vernier mode and positioning the mirror to direct the target image to the first vernier location all takes place within the delay constant of multivibrator **164** which may be of the order of slightly over one second.

After the first vernier target image V1 has been presented, and it has been determined whether the subject has seen or missed it, and whether the response should be photographed, the second vernier point is presented. As can be seen from FIG. **9**, this requires movement of the Y step motor **80** to shift the target image two increments downwardly (−Y) and to the right (+X) and three incremental steps of the X step motor to the left (−X). When multivibrator **256** is again pulsed to cause the output from flip-flop **404** to advance counter **408** to the next digital state (010), the output from counter **408**

switches NAND gates **438, 428, 440** to each produce low output pulses which, in turn, switches X and Y gates **414, 416** to produce high output pulses synchronously with system clock **316**. The switching of NAND gate **328** produces a low pulse in line **380** which is effective to reverse the polarity of the pulses applied to the step motors thus reversing the direction of the X and Y step motors. By switching the state of line **380** low, the output from AND gate **368** will switch low causing the of the X and Y step motors. By switching the state of line **380** low, the output from AND gate **368** will switch low causing the polarity of the drive pulses which are directed to the Y step motor to shift the target image location downwardly (−Y) and to the right (+X). The low pulse in line **380** also is applied through line **381** to gate **374** switching its output high which, in combination with the high outputs from gates **370** and **372** result in a high state in line **340** which will direct the X step motor **70** to shift the target image location to the left (−X). The X and Y motors are pulsed in the manner described above with counter **432** being advanced for each pulse from the system clock. When the counter **432** has been pulsed twice and advanced to a **(10)** digital state NAND gate **442** switches from its high state to produce a low output pulse which is applied to an input of gate **440** thus switching that gate to a high output which in turn switches gate **416** low and terminates further operation of the Y step motor **80** after two incremental steps. The X drive gate **414**, however, is driven one more time until counter **432** registers the third digital state **(11)** which causes NAND gate **448** to switch to a low output, causing a high output from gate **438** which, in turn, disables X gate **414** to terminate operation of the X step motor **70**. The target is then presented at the second vernier point V2 and the decision and control logic run through their respective sequences as described above. It may be noted that when presenting the second vernier target the operation of multivibrator **164** is controlled by the output of multivibrator **256** through line **257** and not by multivibrator **156** which is disabled during vernier operation.

In order then to present the third vernier point it may be seen (FIG. **9**) that the mirror must be moved to shift the target image location two increment to the right (+X). In the illustrative emebodiment this requires operation of the X step motor alone. Thus, when the counter **408** has been pulsed to its next digital state **(011)** gate **428** will switch to a high output again reversing the polarity of the pulse which is applied to the step motors through line **380**. The Y drive gate **416** remains in a low output state as all of its inputs are high. X drive gate **414** is switched through line **445** to produce a high output pulse as the output from gate **441** switches to low in response to all high inputs to gate **441**, thus stepping the X motor. When counter **432** has been pulsed twice, the output from gate **442** switches to low, the switching gate **441** to a high output which switches X drive gate **414** low and terminates further stepping of the X drive motor. With the mirror positioned to show the third vernier point, the third vernier target image is presented and the control and decision logic perform their respective functions.

After the three vernier points have been presented, it then remains for the mirror to be repositioned to the location of the original target image which was missed and which initiated the vernier sequence. This, in turn, requires that the Y motor be stepped one increment up (+Y) and to the left (−X) while the X motor is maintained inoperative. When counter **408** is pulsed, for the fourth time, and is advanced to the **(100)** state, the inputs to X gate **414** remain high thus maintaining X step motor inoperative. The Y drive gate **416**, however, is switched to a high output state because of the low input in response to the low input from fate **450**. Gate **450** is switched to a low output by reason of the high input to it from counter **408**. After NAND gate **430** has pulsed counter **432** to indicate one pulse, NAND gate **452** is switched high and, through line **454** resets counter **408** to its initial digital state **(000)**. Resetting of counter **408** to the **(000)** digital state, returns line **413** to a high state. The **(100)** state of counter **408** also causes gate **453** to be pulsed and which passes through OR gate **154** switches multivibrator **156** to advance the card reader and resume the presentation of the primary targets.

DESCRIPTION OF THE DECISION LOGIC

The position and movement of the subject's eyes are monitored by the eye imaging techniques described in U.S. Pat. Nos. 3,583,794 and 3,689,135 in which the image of the subject's eye is projected onto a screen and in which photocells **92, 94** are located on the screen to be responsive to the position and movement of the eye image. The vertically spaced photocells **92** detects variations in the vertical position of the subject's eye (including movements of the eye lid) and the horizontally spaced photocells **94** detects changes in the subject's horizontal eye position. The outputs from the horizontal and vertical photocell pairs results in a single which is indicative of both magnitude and direction of the subject's eye movement. The decision logic circuitry is designed to discriminate between photocell outputs which are characteristic of the subject having actually seen or missed the presented target, hunting eye movements and blinks.

FIG. **12A** is a DC representation illustrating the relationship between the presentation of the target image and a subject's target missed response as indicated by the output from the photocells. Where the subject's eye does not move during presentation of the target there is no change in output from the photocells.

FIG. **12B** illustrates an ideal response in which the subject has actually seen the target image. Typically, there will be a slight delay from the time in which the target is presented to the time in which the subject's eyes actually move and the response may be delayed, for example 200–500, milliseconds. Also, when the slighted target image is turned off a similar delay will occur in the subject's returning his eyes to the central fixation target. It may be noted that the photocell output may be positive or negative depending on the direction of movement of the subject's eyes. As will be described in connection with the decision logic circuitry, the direction of eye movement is not critical in the particular embodiment shown, the magnitude being the primary consideration.

FIG. **12C** illustrates the photocell output in a situation where the subject has sighted the target but was unable to control his eye movement to direct it precisely to the target image in a single saccade. The photocell output indicates a first substantial eye movement to the general vicinity of the presented target image and a second, minor correctional movement. For example, the first sccade may be of the order of 5° or more, depending on how far the target image is from the central fixation point and the second correctional saccade may be of the order of 3° or less. FIG. **12C** shows a minor

correctional saccade in the same direction as the first saccade and FIG. 12D shows a minor correctional saccade in an at least partly reversed direction. Both responses indicate an actually seen target.

FIG. 12E shows a further response which is indicative of the subject having actually seen the target. This response may be considered as an "early return" in which the subject returned his eyes to the central fixation position before the target light was extinguished. This response also is considered as an actually seen target.

FIG. 12F illustrates a hunting or searching eye movement in which the difference in magnitude of the photocell outputs between the first and second saccades is substantial, for example, of the order of more than 5°. This may result from a first saccade in a direction which is away from the location of the target image, as shown in FIG. 12F or may result from an eye movement shown in FIG. 12G in which, while the searching saccade and second saccade are in the same general direction, the second saccade is substantial, of the order of more than 5°.

FIG. 12H shows a typical output from the vertically spaced photocells which results from a blink. The duration of a typical blink is of the order of 30–50 milliseconds and results in a relatively short duration pulse. Of course, a blink may occur at any time, whether the target is being presented or not.

The decision logic circuitry is effective first to determine whether an output from the photocells is the result of a blink. If so, the remaining portions of the decision logic are disabled from further evaluating that photocell output.

As shown in FIG. **13** the outputs from the horizontal and vertical photocell pairs are amplified at amplifiers **460, 462** respectively. The amplified signals may be coupled to a strip chart recorder **464** if desired to provide a permanent charted D.C. record of the subject's eye movements. The outputs from amplifiers **460, 462** are fed through buffer amplifiers **466, 468** and these signals are coupled to an absolute value adder **470** through AC couple **472**. Where the amplified signals from the photocell pairs are DC, the AC couple is effective to overcome the effect of any long term drift which might be inherent in the system as well as to overcome the effect of any slight head shift of the subject during the test. The absolute value adder insures that a positive output from one pair of photocells will not be negated by a negative output from the other pair of photocells but, instead, results in an output which is the sum of the magnitude of the photocell outputs regardless of their sense. The output from absolute value adder **470** is coupled to a first sense amplifier **474** and also to a second sense amplifier **476**. Sense amplifier **474** is selected so that it will pulse line **478** when the amplitude of the input to amplifier **474** corresponds to an eye movement of more than a first predetermined magnitude, for example, 3°. Sense amplifier **476** is effective to produce an output pulse in line **480** in response to an input from adder **470** having an amplitude corresponding to a change in the direction of eye movement of more than a second predetermined magnitude, for example, 5°. **The outputs at lines** 478 **and** 480 **are employed in the decision logic circuitry to discriminate between the various saccadic movements illustrated in FIGS.** 12A-12H **in a manner described below.**

The decision logic includes three channels including a primary saccade detection channel **479**, a secondary saccade detection channel **481** and a link detection channel **493**. Each signal resulting from the output of either or both of the photocell pairs **92, 94** is applied to each of the three channels simultaneously. If the photocell output was the result of a blink the blink detection channel **493** disables the primary and secondary channels **479, 481** from further operation thus disregarding the effect of the blink. If the resulting signal from the photocells **92, 94** was caused by a genuine saccade this is detected by the primary channel **479** which, in turn, is connected to the secondary channel **481** to enable the secondary channel to thereafter detect existence of a second saccade within a predetermined time interval after the first saccade. The output from the first channel is also connected to an output decision gate **506** (as will be described) in a manner which causes that gate to be enabled at a fixed, predetermined time interval after the detection of the first saccade. The state of the other input to decision out gate **506** is dependent on whether the primary and secondary channels **479, 481** have detected the existence of only two or more saccades and the timed relationship of the saccades with respect to the presentation of the target image as well as their magnitude.

More particularly in order to discriminate blinks from other eye movements, the signal from the vertical photocells is connected through buffer amplifier **468** to a sample and hold circuit **482** and also to a comparator **484**, the output from the sample and hold circuit **482** also being fed into comparator **484**. Comparator **484**, in turn, drives a pair of sense amplifiers **486, 488** which produce an output pulse when the output from the comparator is positive and negative respectfully. When an output signal results from the photocells, the decision logic circuit first evaluates whether the output was the result of a blink. If so, the decision logic circuitry is disabled and there is no change in its output. The blink detection circuitry includes a NAND gate **490** having its inputs fed by sense amplifiers **485, 488**. The output from NAND gate **490** is inverted at inverter **492**. The inputs to NAND gate **474** are normally high which results in a normally high output from inverter **492**. The output from inverter **492** thus may be switched by any change of state to either input to gate **490** resulting from a pulse from either of sense amplifiers **486, 488**. The output from the inverter **492** is connected directly to an input of NAND gate **494** and also to the other input of gate **494** through a multivibrator **496** having a delay constant of, for example, approximately **330** milliseconds. When either input to NAND gate **490** is low as a result of a signal from the vertical photocells input of gate **494** will remain low, to preclude switching of gate **494** while monostable multivibrator **496** will switch to a high output state.

If the triggering input to NAND gate **490** was the result of a blink, which typically lasts between 30–50-milliseconds, the low output of inverter **492** and input "*a*" of gate **494** will switch back to high before multivibrator **496** has returned to its low output state. The all high inputs switch gate **494** to a low output which triggers monostable multivibrator **498**, switching it to a high output state and switching the output of NAND gate **500** to low. A low state at the output of NAND gate **500** indicates the presence of a blink and disables NAND gate **502** and **504** which, in turn, precludes any change in output of the decision out gate **506** as will be apparent from the further following description. If, on the other hand, the input to NAND gate **490** was the

result of a genuine saccade in which the subject's eye remain fixated for considerably more than 30–50 milliseconds, the direct input to gate **494** will remain low at all times during and after the delay of multivibrator **496** thus leaving gate **94** unactuated and maintaining the output from gate **500** in its normally high state which, in turn, maintains the inputs to gates **502, 504** high and in an enabled state.

If the blink detection channel **493** has detected that the input pulse was the result of a genuine saccade, the remaining primary and secondary channels **479, 481** evaluate whether the saccade was the result of the subject's actual perception of the target image or whether it was the result of "hunting" of searching eye movements. When an added pulse from one or both pairs of photocells is fed into sense amplifiers **474, 476** those amplifiers, respectively, evaluate whether the saccade (here the first saccade) was of a magnitude of more than 3° and whether the saccade was a change in eye movement of more than 5°. For example, assuming that a target was presented and was seen, the subject's eye movement of more than 3° results in an input pulse to monostable multivibrator **505** switching its output high. Multivibrator **505** has a 330 delay function and serves to delay further operation of the portions of the primary channel **479** for a time sufficient to enable the blink detection channel **493** to evaluate whether the pulse resulted from an eye movement or a blink. When multivibrator **505** switches back to its low, stable state, that actuates monostable multivibrator **508** switching its output momentarily to a high state. If the target light was on at the time of the saccade then all three inputs to NAND gate **502** are switched to high. This is accomplished by applying a pulse in line **510** indicating that the target light is on and passing it through inverter **512** and NAND gate **514** to produce a high pulse at input of gate **502**, thus enabling that gate as long as the target light is on. It may be noted that while the first saccade may have been of a magnitude which would have also switched the output from sense amplifier **476** to a high state, gate **524** is, at that time, in a disabled state because of the low input, through line **518** from the monostable multivibrator **522** as will be described.

In order to evaluate whether the first saccade was the first of a series of eye movements indicating true perception of the target or whether it was a "hunting" saccade, the decision logic awaits subsequent signals from the photocells to determine whether only a second saccade follows or whether both a second and third saccade follows. Also, where there are three saccades, their relative magnitudes must be evaluated to discriminate between hunting movements (FIGS. **12F, 12G**) and acceptable correctional movements (FIGS. **12C, 12D**). As described above, saccadic movements of less than a predetermined magnitude for example, 3°, are considered to be mere correctional movements. Thus, a pulse resulting from photocells **92, 94** which corresponds to an eye movement of less than 3° will be isolated from the primary and secondary channel, **479, 481** by the sense amplifiers **474, 476** respectively. There being no signal applied to the primary and secondary channels, an eye movement of less than 3° has the same effect as if there had been no eye movement at all thus completely disregarding mere correctional movements.

As indicated at FIGS. **12A–12B**, where there has been a first saccade there will always be a second saccade. The second saccade may result from the subject's returning his eyes to the central fixation target (FIGS. **12B, 12E**) in which case the second saccade is a final saccade indicating that the subject actually saw the target. However, the second saccade may have been the result of the first time that the subject actually saw the target, in which case the second saccade would be only an intermediate saccade which would indicate that the first saccade would have been a hunting or searching movement (FIGS. **12F, 12G**). In order to discriminate between these saccadic movements the invention employs a technique in which the subject's eyes are monitored to detect the existence and magnitude of at least three saccades in which the intermediate saccade or saccades was more than 5° which would indicate that the first saccade was a hunting movement and that the subject did not actually see the presented target.

The foregoing functions are enabled by the switching of gate **502** to a low output state which is the case when the first saccade is not a blink, as described above. The low output from gate **502** is inverted to a high state through inverter **520** and that pulse is applied to monostable multivibrator **522**. Multivibrator **522** is switched to its high output state when the output from multivibrator **508** returns to its low state after generating its short pulse. When multivibrator **522** is switched, its high output is applied to the input of NAND gate **524** which enables that gate and, consequently, the secondary channel **481** to be actuated when the remaining low input of gate **524** receives a high pulse from sense amplifier **476**. Multivibrator **522** has a time delay which will maintain its high output state, thus maintaining the secondary channel **481** in an enabled state for a time sufficient to include that in which a second, intermediate saccade would be made. For example, the delay of multivibrator **522** may be of the order to 450 milliseconds. Thus, if the photocells **92, 94** produce a signal indicating a saccade which was a change of more than 5° and during the enabled interval of secondary channel **481**, gate **524** will be actuated to switch its output low to low thus actuating blink delay monostable multivibrator **526** which also has time delay constant of **330** milliseconds. This enables the blink detection logic to again evaluate whether the second input signal to gate **524** was the result of a blink or a genuine second saccade. If a blink, the low output at gate **500** of the blink detection logic is applied to an input of gate **504** thus disabling that gate and the secondary channel **481**. However, if the signal was not a blink gate **504** will be enabled. When multivibrator **526** switches back to low state, after its **330** millisecond delay, and that pulse triggers monostable multivibrator **528** to produce a short output pulse switching gate **504** low which triggers monostable multivibrator **530** switching its output high. This high output is applied to an input of NAND gate **532** which enables that gate. Multivibrator **530** has a delay constant sufficient to maintain gate **532** in an enabled state for an extended interval ending shortly after the target light has been extinguished. By way of example the delay may be of the order of 2.75 seconds. As described below the other input to gate **533** depends on whether or not there was a third saccade which, in turn, controls the output of gate **532** and the input to decision out gate **506**.

The detection of a third saccade is effected by the primary channel **479**. After the **450** millisecond delay of multivibrator **522**, its output switches low which switches multivibrator **536** to a high output state. This, in turn, enables one of the inputs to gate **534**. Multivibrator **536** has a delay constant which also extends

beyond the time that the target lights is extinguished in order to be able to detect return eye movements which often occur after the extinguishment of the target light. It may be noted that multivibrator **530** has a delay slightly longer than multivibrator **536** so that gate **532** may remain enabled and be switchable in the event that gate **534** is switched. If a third pulse is emitted from the photocells, it will, as in the case for each such pulse, be directed to the sense amplifiers **474, 476** as well as to the blink detection circuitry. Multivibrator **505** delays functioning of the primary channel **479** stages until the blink detection channel **493** has an opportunity to evaluate whether the photocell output was the result of a saccade or a blink. Assuming that it was not a blink and that a third saccade was made by the subject, the signal resulting from the third saccade switches the output from inverter **520** high which is applied through lines **538** to the other input of gate **534** switching its output low which, is inverted at inverter **540** and is fed as high pulse into an input of NAND gate **532**. This results in a low output from gate **532** which switches multivibrator **542** to produce a high output which is inverted at inverter **544** and is fed into decision out gate **506**. This will not switch multivibrator **164** in the control logic and its output will remain low thus indicating a "missed target".

When there is no third saccade during the delay of multivibrator **536**, this indicates that the second saccade was in fact a final saccade to the central fixation point and was thus an actually seen target. When there is no third saccade the input to decision out gate **506** from inverter **544** is high thus enabling that gate. When multivibrator **536** switches back to its low stable output this switches multivibrator **546** and the high output pulse from multivibrator **546** switches decision out gate **506** to a low output which, in turn, actuates multivibrator **164** and indicates a target seen.

In some mass testing situations it may be desirable to make a more coarse test, for example, to detect only whether the subject responded at all to presentation of the target image. This may be accomplished by disabling the second channel **481** so that the output from inverter **544** will remain high at all times thus maintaining decision out gate **506** enabled continuously. Any non-blinking eye movement during presentation of the target image will result, ultimately, in a pulse from multivibrator **546** which will switch decision out gate **506** low indicating a response by the subject during presentation of the target image. While this mode of operation does not discriminate between hunting eye movements and true perceptions, it does not give a rapid more coarse testing procedure. The second channel may be disabled by switch **126** on the control panel which switches flip-flop **550** to enable or disable gate **524** as desired.

When the subject has actually perceived the target and makes a "normal" response (FIG. **12B**) his eyes will fixate on it as long as it is presented (approximately 2.2 seconds). In this event there will be no detected eye movement during the **450** milliseconds that the multivibrator **522** is in its high state. Thus, even though gate **522** is in readiness to be actuated in response to sensed eye movement during the **450** millisecond interval, there is no movement and the input to gate **532** remains low. When the subject's eyes do not return to the reference fixation target shortly after the target light has been extinguished from the subject's view the pulse resulting from that saccade, which is channeled to gate **502** causes multivibrator **522** to be pulsed. The high output from multivibrator **522** is inconsequential at this time because the multivibrator **536** already is in its high state. When the multivibrator **536** switches back to its low state multivibrator **546** is pulsed to apply a high input to decision out gate **506**. The other input of the deecision out gate **506** is also high at this time because as multivibrator **536** was switched to its low state, gate **534** switched to a high state which is inverted to low through inverter **540** which maintains gate **532** at a high state thus precluding actuation of multivibrator **542** whose normally low output is inverted at **544** to a high state which is applied to the decision out gate **506**. The resulting low pulse from gate **506** is applied through line **470** to the control logic as previously described.

As described previously, there may be some instances in which the subject has perceived the target but returns his gaze to the general region of the central fixation target before the target light has been extinguished. Such early return is detected by the foregoing decision logic as a perceived target. Here, the subject's eye movement usually will be after the **450** millisecond delay of multivibrator **522** but before multivibrator **536** has switched back to its low state. This has the same effect as a "seen" response described above.

In order to insure that gate **502** is enabled through line **516** during the extended time interval which includes the interval during which the target is actually presented and a short time thereafter, the output from multivibrator **522** is connected through inverter **548** to an input of gate **514** and the output from multivibrator **536** is connected through inverter **550** to the other input of gate **514** thus insuring a high state in line **516** at all times during operation of the decision logic.

The foregoing mode of operation of the decision logic may be considered as employing a technique in which the extended time interval during which the subject's eye positions and movements are monitored may be considered as divided into successive portions in which each portion begins with eye movement. The number and duration of each such portion of the extended time interval will, of course, depend on the time in which the subject moves his eyes. In addition, an initial segment of each portion of the extended time interval is employed to evaluate whether the particular eye movement was a blink, in which case the eye movement is disregarded as described above.

It should be understood that the foregoing description of the invention is intended merely to the illustrate thereof and that other modifications and embodiments of the invention may be apparent to those skilled in the art without departing from its spirit.

Having thus described the invention what I desire to claim and secure by Letters Patent is:

1. An apparatus for presenting a target image at various selected locations within a subject's visual field comprising:

a light source adapted to emit a beam of light;

a mirror:

means mounting said mirror with respect to said light source to reflect said beam, said means mounting said mirror being constructed and arranged to enable said mirror to be oriented in various selected attitudes with respect to said beam of light to selectively reflect said beam of light to said various locations;

electrically operable drive means connected to said means for mounting said mirror to effect said movement thereof;

circuit means having its output connected to said drive means for operating said drive means;

said circuit means including storage register means for storing digital information corresponding to a selected intended position of said drive means:

feedback means operatively associated with said drive means for developing a signal corresponding to the position of said drive means;

said circuit means including a comparator having inputs from each of said storage register means and said feedback means;

said circuit means including means responsive to the output of said comparator to operate said drive means when said input to said comparator are unequal thereby to move said mirror toward a selected attitude and for thereafter terminating operation of said drive means when said inputs to said comparator are equal.

2. An apparatus as defined in claim **1** wherein said drive means comprises a reversible step motor constructed and arranged as to be driven a selected angular increment in response to a pulse applied thereto, the polarity of the pulse applied thereto determining the direction in which said step motor is driven;

said circuit means including means responsive to the sense of said output from said comparator for controlling the polarity of the signal applied to said step motor thereby to control the direction of drive of said step motor.

3. An apparatus as defined in claim **1** further comprising:

said mirror being mounted for rotational movement about each of a pair of perpendicular axis;

said drive means including a pair of step motors, each connected to said mirror mounting means to effect rotation of said mirror about said axes;

said storage register means being constructed and arranged to receive digital information corresponding to an intended position of one of said step motors;

means for selectively connecting the feedback means associated with one of said step motors to said comparator to correspond with the step motor with which said digital information in said storage register means corresponds to, whereby said selected step motor may be driven to the position corresponding to that represented by the digital information in said storage register means; and

means responsive to positioning of said step motor to said intended position for resetting said storage register means with digital information corresponding to the intended position position of the other of said step motors and for switching said feedback means to said comparator means into connection with the other of said step motors whereby the other of said step motors may be advanced to its intended position corresponding to that represented by said reset digital information whereby said step motors may be positioned sequentially.

4. An apparatus as defined in claim **3** further comprising:

said mirror mounting means being constructed and arranged so that one of said axes is rotatable about the other of said axes whereby, when one of said step motors is operated it will cause the mirror to rotate simultaneously about both of said axes;

means for operating that step motor which controls rotation of said mirror about the other of said axes to drive said step motor in a direction opposite to that which is caused by operation of said first mentioned step motor.

5. An apparatus as defined in claim **1** further comprising:

control means for operating said light source;

means for applying digital information to said storage register means to set said storage register means;

said control means including means for delaying operation of said light source for a predetermined time interval sufficient to enable said drive means to move said mirror to a selected attitude.

6. An apparatus as defined in claim **1** further comprising:

means for monitoring the subject's eye positions and movements;

means for detecting those of the subject's eye positions and movements which display at least one characteristic indicative of whether the subject actually visually detected said presented target image;

circuit means responsive to the detection, by said detection means, of the subject's having failed to visually detect said presented target, for disabling the input from said storage register means to said comparator means, said second circuit including means connected to said drive means to move said mirror to an attitude which may direct said light beam to a predetermined location within the subject's visual field and with respect to the location of said first presented target image.

7. An apparatus for presenting a target image to a subject and for recording the position of said target image comprising:

a housing having front and rear walls;

projection shutter means mounted to said front wall;

camera shutter means mounted to said rear wall.

a double faced mirror mounted within said housing between said projection shutter means and said camera shutter means;

projection light means supported within the housing and located with respect to said mirror to direct a first narrow beam of light along an axis toward one surface of said mirror and to reflect said first beam toward said projection shutter;

recording light means supported in said housing on the other side thereof for directing a second narrow beam of light along said axis and toward the opposite surface of said mirror to enable said second beam to be reflected toward said camera shutter means and in a direction which is opposite to that at which said light beam is reflected from said one surface of said mirror;

film mounting means disposed on said rear wall and on the other side of said camera shutter means;

means for orienting said mirror in selected attitudes thereby to vary the direction of each of said reflected first and second beams;

means for operating said projection light means and said recording light means independently of each other; and

means for operating each of said projection shutter means and camera shutter means.

8. An apparatus as defined in claim 7 further comprising:

means for delaying operation of said projection light means until after said projection shutter has opened fully.

9. An apparatus as defined in claim 8 further comprising:

means for precluding operation of said projection light means after said projection shutter has opened thereby to preclude presentation of an actual target image but without varying the character of audible sound from the operation of said projection shutter means.

10. An apparatus as defined in claim 8 further comprising:

means for delaying operation of said recording light until said camera shutter has opened fully;

means delaying opening of said camera shutter until said projection shutter has closed fully.

11. An apparatus as defined in claim 8 further comprising:

means for operating said camera shutter after each operation of said projection shutter means; and

means for selectively enabling or disabling operation of said recording light source independently of operation of said camera shutter means.

[57] **ABSTRACT**

A varifocal objective with a four-component front lens group, including axially shiftable second and third components, is provided with a focusing mechanism for the joint displacement of these second and third components as well as a further lens member relatively to the axially fixed first component, that further lens member being either the fourth component of the front lens group or part of an otherwise fixed rear lens group. In the case of an afocal front lens group the last three components thereof are displaced in unison by the focusing mechanism. The lens shifts can be co-ordinated by electric servomotors under the control of stored data.

FOCUSING MECHANISM FOR VARIFOCAL OBJECTIVE

FIELD OF THE INVENTION

My present invention relates to a focusable varifocal objective.

BACKGROUND OF THE INVENTION

Conventional varifocal objectives usually comprise an adjustable front group and a fixed rear group of coaxial lens members, the front group being constituted by an object-side first component considered stationary for the purpose of focal-length adjustment, axially shiftable second and third components, and an axially fixed fourth component. The first and fourth components are usually of positive refractivity whereas the shiftable second and third components are negatively refracting. The third component, sometimes termed compensator, moves in a manner designed to keep the image plane of the objective stationary during displacement of the second component or variator. Reference in this connection may be made, for example, to commonly owned U.S. Pat. No. 3,827,786 in the name of Karl Macher.

For focusing purposes, the quasi-stationary first component (or just a front lens thereof) is limitedly axially displaceable to an extent which does not significantly alter the selected overall focal length but shifts the rear focal plane of the objective relatively to the image plane. This axial displaceability of the first component or at least its front lens increases the physical axial length of the objective and also tends to cut off slanting incident rays, thus causing vignetting, unless the front lens is correspondingly enlarged. The presence of a large mobile front lens, however, makes the correction of aberrations more difficult; moreover, in a camera equipped with servofocusing the motor is burdened by the weight of this front lens. Finally, the air volume trapped behind the front lens within the camera housing impedes its movements unless fairly large vent openings are provided which, however, could make the optical system sensitive to atmospheric conditions.

OBJECT OF THE INVENTION

The object of my present invention, therefore, is to provide a focusing system for a varifocal objective which obviates the aforestated drawbacks without materially changing the selected focal-length setting.

SUMMARY OF THE INVENTION

I realize this object, in accordance with my present invention, by the provision of focusing means operatively coupled with the second and third components of the varifocal front group for jointly shifting same to vary the distance at which objects can be sharply focused on the image plane, the focusing means also being operatively coupled with a lens member disposed on the image side of the third component for axially shifting that lens member concurrently with the second and third components to maintain the preselected focal length of the objective. The joint shifting of the second and third components is, of course, independent of their separate shifting by the zooming means designed to vary that overall focal length.

The lens member chosen for the compensatory focusing displacement may be the normally fixed fourth component (or part thereof) of the varifocal front group but could also be one of the constituents of the normally fixed rear group, especially the first — usually positive — lens member of the latter group.

The zooming and focusing shifts of these various lens members can be carried out mechanically, as by means of lens barrels provided with the usual camming grooves or slots, or electronically with the aid of data stores and position sensors controlling the operation of the respective servomotors.

BRIEF DESCRIPTION OF THE DRAWINGS

The above and other features of my invention will now be described in detail with reference to the accompanying drawing in which:

FIG. **1** is a diagram schematically illustrating the focusing displacement of certain components in a five-component varifocal objective according to the invention;

FIG. **1***a* is a similar diagram relating to a modified varifocal objective;

FIG. **2** is a diagram similar to FIG. **1**, schematically illustrating the zooming displacement of certain components of the objective represented in FIG. **1**;

FIG. **3** diagrammatically illustrates an objective with an afocal front group focused upon infinity;

FIG. **3***a* is a view similar to FIG. **3**, showing the objective focused upon a finite object distance;

FIG. **4** is an exploded isometric side view of a zooming and focusing mechanism for an objective of the type represented by the diagrams of FIGS. **1** and **1***a*;

FIG. **5** is a similar view of a zooming and focusing mechanism for an objective of the type shown in FIGS. **3** and **3***a*; and

FIG. **6** is a block diagram of an electronic zooming and focusing circuit for use with an objective as represented in FIGS. **1** and **1***a*.

SPECIFIC DESCRIPTION

In FIGS. **1**, **1***a* and **2** the several objective components have been illustrated schematically as thin lenses even though at least some of these components will generally consist of more than one lens. In all embodiments described hereinafter, the objective comprises an axially fixed positive first component **1**, an axially shiftable negative second component **2**, an axially shiftable third component **3**, a positive fourth component **4** and a positive rear component **5** usually constituted by a multilens group. A diaphragm B is inserted between front group **1–4** and rear group **5**.

The conventional focal-length adjustment, schematically illustrated in FIG. **2**, involves only the negative components **2** and **3**, with component **3** moving first forwardly and then rearwardly while component **2** is shifted toward the rear from a position of minimum focal length to a position of maximum focal length (top and bottom graphs in FIG. **2**). During this displacement along the optical axis A, the position of the image plane O' remains fixed.

In FIG. **1** I have shown how, from the starting position similar to that illustrated in the upper graph of FIG. **2**, the two negative components **2** and **3** are jointly displaced at the same rate toward the rear with reference to the axially fixed first positive component **1**. As far as these three components **1–3** are concerned, such a displacement is equivalent to a forward shifting of the first component as is conventionally done for focusing purposes. In the present instance, however, such a movement — if unaccompanied by a compensatory adjustment of some other lens member — could not

bring about the desired shift of the secondary focal point of the system with reference to the image plane O' without significantly altering the preselected focal length. Thus, a compensatory movement is simultaneously imparted to component **4** at a rate nonlinearly related to that of components **2** and **3** whereby the overall focal length is kept constant on passing from the position of the upper graph to that of the lower graph with focusing of the objective upon closer objects.

Let us consider, by way of example, a conventional varifocal objective with a back-focal length *s* (FIG. **1**) of **12** mm having a relative aperture of 1:2.1 and an overall focal length variable between f_{min} = 20 mm and f_{max} = 300 mm by a shifting of its negative components **2** and **3** in the manner indicated in FIG. **2**. The following values represent the focusing displacement of lens members **2** and **3** on the one hand and lens member **4** on the other hand from the position shown in the upper graph of FIG. **1** to that shown in the lower graph.

TABLE

Rightward shift of components 2 and 3 (mm)	Rightward shift of component 4 (mm)	Focusing distance (meters)
0	0	∞
5	5.93	4.42
10	11.94	2.46
15	18.06	1.81
20	24.30	1.48

As illustrated in FIG. **1***a*, the lens member undergoing a compensatory shifting need not be the component **4** of the front group but could be a positive lens **5***a* (preferably the one nearest the diaphragm space) forming part of rear group **5**, that group also comprising one or more axially fixed lenses **5***b*.

If lens members **2–4** are designed to complement the front member **1** to an afocal system, there will be a field of parallel rays **6** in the diaphragm space between the varifocal front group **1–4** and the rear group **5**. In that instance the spacing between components **4** and **5** becomes noncritical whereby the three movable members **2–4** can be shifted as a unit, relatively to components **1** and **5**, between the position shown in FIG. **3** (with focus on infinity) and the closeup position of FIG. **3***a* in which the objective is focused on a nearby object. An intermediate image is formed in both positions (and in all intervening ones) between components **1** and **2**. The amount of shift required for focusing purposes depends on the individual focal length of component **1** and corresponds to that conventionally imparted to the front lens, yet in the present instance no increase occurs in the total axial length of the objective.

Reference will now be made to FIG. **4** showing a lens barrel **7** centered on the optical axis of the system, this lens barrel being provided with conventional camming slots **22** and **23** for displacing the lens members **2** and **3** in the manner indicated in FIG. **2** upon rotation of that barrel about its axis (arrow B). Such rotation can be brought about by a zooming mechanism including a setting ring **16** from which an arm **17** extends into a slot **15** or lens barrel **7**. This lens barrel is also axially reciprocable (arrow C) with the aid of a focusing ring **10** having threads **11** meshing with a rack **12**, a bifurcated extremity **13** of this rack straddling an annular flange **14** of the lens barrel; rack **12** is guided for movement parallel to the barrel axis by mounting means not shown. An arm **10***a* extending from focusing ring **10** is rigid with another, shorter lens barrel **8** surrounding the positive lens member **4** which is guided therein by a camming slot **24**. All these lens members are, of course, held against rotation by conventional means such as stops engaging the pins which traverse the camming slots **22–24**.

A change in the overall focal length (zoom effect) with the aid of ring **16** does not affect the lens member **4** since only the lens barrel **7** rotates in one or the other sense as indicated by arrow B. On the other hand, a rotation of focusing ring **10** causes this lens barrel to slide axially, as indicated by arrow C, together with lens members **2** and **3** while lens barrel **8** rotates (arrow D) and axially shifts the lens member **4**. Thus, the mechanism of FIG. **4** brings about the lens displacements diagrammatically shown in FIGS. **1** and **2**.

In FIG. **5**, in which lens members **2–4** are assumed to be part of an afocal group as described with reference to FIGS. **3** and **3***a*, component **4** is fixedly held in lens barrel **7** which is rotatable and slidable in the aforedescribed manner under the control of rings **16** and **10**, respectively. A rotation of the lens barrel under the control of zooming ring **16** has no effect upon the axial position of component **4** whereas an axial shift under the control of focusing eing **10** displaces all three lens members concurrently.

In FIG. **6** I have shown an electronic control system for shifting the components **2, 3** and **4** without a slotted lens barrel. A zooming-control switch ZC, when closed, connects a voltage source E_1 to a reversible servomotor M_1 for axially shifting the negative lens member **2**; switch ZC actually has two working positions for energizing the motor M_1 in one sense or the other, e.g. as described in commonly owned U.S. Pat. No. 3,165,044 in the name of Paul Himmelsbach. A motion feeler or position sensor MF_1, coupled with lens member **2**, reports the position of that lens member to a data store S_1 such as a read-only memory which is activated upon closure of switch ZC to deliver a signal representative of the corresponding zooming position of lens member **3** to one input of a comparator C_1 also having another input connected to a position sensor MF_2 which is coupled with lens member **3**. Comparator C_1 thereupon energizes a servomotor M_2 which displaces the lens member **3** until its position conforms to that of lens member **2** in accordance with the schematic showing of FIG. **2**. The position information available from sensor MF_2 is also fed to a comparator C_2 which, however, is inhibited at this time by a blocking voltage on another lead from switch ZC.

A third servomotor M_3, controlling the displacement of lens member **4**, is unaffected by closure of switch ZC but is energizable from a voltage source E_2, in one sense or the other, by a similarly constructed focusing-control switch FC which also activates a data store S_2 receiving the output of a position sensor MF_3 coupled with lens members **4**.

Data store S_2 works into comparator C_2 which, with comparator C_1 blocked upon closure of switch FC, controls the two servomotors M_1 and M_2 to correlate the position of lens members **2** and **3** with that of lens member **4** as indicated schematically in FIG. **1**.

If lens group **1–4** is afocal, as discussed with reference to FIGS. **3** and **3***a*, data store S_2 will be omitted along with comparator C_2 and position sensor MF_3; servomotors M_1, M_2 and M_3 are then energizable in parallel from source E_2 through the closed switch FC.

The provision of a fixed front lens, made possible by the present improvement, allows the camera to be

equipped with stable holders for filter and lens attachments as well as devices for the insertion of film titles or the like. The normally unavoidable decentering effect due to rotation of the front lens for focusing purposes is eliminated.

I claim:

1. In a varifocal objective comprising a plurality of coaxial lens members constituting an axially fixed object-side first component, an axially shiftable second component following said first component, an axially shiftable third component following said second component, a fourth component following said third component and an image-side fifth component following said fourth component, the combination therewith of:

zooming means operatively coupled with said second and third components for axially shifting same at different rates to selectively vary the overall focal length of the objective while maintaining a stationary image plane beyond said further lens members; and

focusing means operatively coupled with said second and third components for jointly shifting same to vary the distance at which objects can be sharply focused on said image plane, one of said lens members disposed on the image side of said third component being axially shiftable and operatively coupled with said focusing means for displacement thereby concurrently with said second and third components to maintain the selected overall focal length.

2. The combination defined in claim **1** wherein said second and third components are mounted in a first lens barrel provided with camming slots for the axial shifting thereof and coupled with said zooming means for rotation thereby, said one of said lens members being mounted in a second lens barrel provided with a camming slot for the axial shifting thereof, said focusing means being directly connected with said second lens barrel for rotating same and being threadedly coupled with said first lens barrel for axially displacing the latter.

3. The combination defined in claim **1** wherein said one of said lens members constitutes said fourth component.

4. The combination defined in claim **3** wherein said second, third and fourth components complement said first component to an afocal group, said focusing means maintaining said second, third and fourth components at an invariable relative distance selected by said zooming means.

5. The combination defined in claim **4** wherein said second, third and fourth components are mounted in a common lens barrel provided with camming slots for the axial displacement of said second and third components, said lens barrel being coupled with said zooming means for rotation thereby and with said focusing means for axial displacement thereby, said second, third and fourth components complementing said first component to an afocal group.

6. The combination defined in claim **1** wherein said one of said lens members is a part of said fifth component.

7. The combination defined in claim **1**, further comprising a pair of servomotors for respectively shifting said second and third components and a further servomotor for shifting said one of said lens members, said zooming means including a first control circuit for the energization of said pair of servomotors, said focusing means including a second control circuit for the energization of all said servomotors.

8. The combination defined in claim **7** wherein said first control circuit includes a position sensor of one of the axially shiftable components and a data store addressable by said position sensor for determining the displacement of the other axially shiftable component.

RETROFOCUS WIDE ANGLE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a compact retrofocus wide angle objective lens system of a long back-focal length adapted for use with a single lens reflex camera.

2. Description of the Prior Art

In general, retrofocus objective lenses are configured to have a negatively refracting front lens assembly and a positively refracting rear lens assembly for the purpose of facilitating increase in the back-focal length thereof. This type of retrofocus objectives has been characterized by the difficulty of achieving a good standard of aberration correction because of the asymmetric configuration of the complete lens system. Further, in this type of objective, an increase in the overall physical length resulting from, for example, decreasing the number of lens components constituting the complete lens system, or the diameter of the front lens component, makes it more difficult to compensate for various aberrations.

SUMMARY OF THE INVENTION

The general object of the present invention is to provide an improved retrofocus lens system of the above-described character yielding a back focal length as high as 1.28 times the overall focal length of the complete system with as small as seven air-spaced lens components and having a relative aperture 1 : 2.8 with a field angle of at least 75° with limitation of the overall length of the lens system to less than 1.83 times the overall focal length thereof, while nevertheless achieving a very high standard of correction of various aberrations otherwise encountered by limitation of the overall dimensions of the lens system to such a minimum.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is an axial sectional view of a retrofocus wide angle objective lens according to one embodiment of the invention.

FIGS. **2, 3** and **4** are curves of the spherical aberration, astigmatism and distortion respectively for the lens of FIG. **1.**

FIG. **5** is an axial sectional view of a lens according to a second embodiment of the invention.

FIGS. **6, 7** and **8** are curves of the spherical aberration, astigmatism and distortion respectively for the lens of FIG. **5.**

FIG. **9** is an axial sectional view of a lens according to a third embodiment of the invention.

FIGS. **10, 11** and **12** are curves of the spherical aberration, astigmatism and distortion respectively for the lens of FIG. **9.**

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

As shown in FIGS. **1, 5** and **9,** a retrofocus wide angle objective lens system of the present invention is characterized in comprising seven optically aligned lens elements, the first and second lens elements counting in the order of the entrant light beam being negative meniscus singlet lenses of forward convexity, the third lens element being a positive singlet lens, the fourth lens element being a bi-convex singlet lens, the fifth lens element being a bi-concave singlet lens, and the sixth and seventh lens elements being positive singlet lenses. If desired, the fourth, fifth and sixth lenses may be individual cemented lenses. For facilitating minimization of the overall dimensions of the lens system, the third and fourth lens elements are separated by a large axial air space as will be described in more detail later, and, accordingly, the diameter of the third lens element is considerably larger than that of the fourth lens element.

A conventionally well-accepted technique for reducing the bulk and size of a complete objective lens is to increase the powers of the individual lens components with decrease in axial air spaces between the successive lens components. When this technique is employed in designing such retrofocus objectives as comprising a divergent front lens assembly and a convergent rear lens assembly, an important problem arising therein is to compensate residual aberrations introduced by the front lens assembly in a manner to achieve a high standard of correction of the image aberrations without involving any great increase in the overall dimensions of the complete objective.

The present invention provides a retrofocus wide angle objective lens with seven lens elements of which the first and second lens elements constitute a divergent front lens assembly and with limitation of the overall dimensions of the complete objective to a minimum by utilizing the above mentioned size reduction technique, whereas residual spherical aberration and field curvature introduced by the front lens assembly are well compensated for. As is known in the art, good compensation for residual aberration is more effectively made at a lens located nearer the lens which contributes to the lens system the residual aberrations. For this reason, the third lens element following the divergent front lens assembly to compensate residual aberrations introduced thereby is required to be located as near to the second lens element as possible. It is desirable to separate the third and fourth lens elements from each other by an axial air space d_6 larger than the axial thickness d_5 of the third lens element, as the second and lens elements are separated from each other by a small axial space.

While the above mentioned feature is generally applicable to any retrofocus objective lens comprising divergent front and convergent rear lens assemblies, the objective is characterized, for purposes of assisting towards improvement of various aberrations otherwise encountered with such size limitation by the following features in combination:

a. $0.6 < d_6/d_4 < 1.0$
b. $0.68f < \gamma_4 < 0.9f$
c. $7.0f < |\gamma_6|$
d. $N_3 > 1.72$; $V_3 < 40$
e. $0.95f < |\gamma_8| < 1.5f$; $\gamma_8 < 0$

wherein f is the overall focal length of the complete objective; d_4 and d_6 are the axial air separations between the second and third lens elements and between the third and fourth lens elements respectively; γ_4, γ_6 and γ_8 are the radii of curvature of the rear refracting surfaces of the second, third and fourth lens elements respectively; and N_3 and V_3 are the refractive index and Abbe number of a glass respectively from which the third lens element is made.

Condition (a) is a compromise between the requirements of limiting to a minimum the dimensions of the complete objective both in the axial and in the radial directions, and of compensating the residual spherical aberration and field curvature introduced by the first

and second lens elements to a modest degree under the situation that the third lens element is located as far from the fourth lens element as possible for the purpose of effecting the limitation of the dimensions. When the lower limit namely, 0.6 is violated, residual spherical aberration and field curvature ascribable to the third lens element become so serious that various residual aberrations ascribable to the first and second lens elements can not be compensated for with the result of a low standard of correction of the image aberrations. When the upper limit, namely, 1.0 is violated, the diverging function of the first and second lens elements is weakened by the converging function of the third lens element. Consequently, the diverging powers of the first and second lens elements must be increased, or otherwise the desired back focal length could not be retained. As the powers of the first and second lens elements are increased, various aberrations ascribable thereto are increased in a non-linear manner to such values as cannot be balanced out by the suitable design of the remaining lens elements.

Condition (b) assists in adjusting the balance in this respect. When the lower limit is violated, this refracting surface γ_4 produces large aberrations which can not be balanced out by the suitable design of the remaining lens elements. When the upper limit, namely, 0.94 is violated, residual aberration ascribable to this surface is decreased with decrease in the diverging effect. In order to obtain an equivalent diverging effect, therefore, the axial air separation d_4 between the second and third lens elements must be increased with sacrificing an increase in the size of the complete objective and permitting an adverse effect on the balance of the nature described above.

Conditions (c) and (d) are concerned particularly with lateral chromatic aberration correction. When the absolute value of the radius of curvature of the rear surface γ_6 of the third lens element is smaller than $7.0f$, the lateral chromatic aberration is over-corrected when $\gamma_6 < 0$, and is under-corrected when $\gamma_6 > 0$. Condition (d) facilitates correction of lateral chromatic aberration along with spherical aberration and field curvature.

Condition (e) assists towards correction of spherical aberration, coma and distortion. When the lower limit, namely $0.95f$ is violated, the rear surface of the fourth lens element contributes to the system large aberration with the result of over-compensated coma and distortion. When the upper limit, namely, $1.5f$ is violated, effective compensation cannot be made because of the production of small aberration. Particularly in the spherical aberration and distortion, under-compensation will be resulted. In other words, condition (e) provides a compromise in respect of the good balance of the image aberrations.

According to a further feature of the present invention, the objective may be constructed from a forwardly convex lens as the third lens element of positive power either independently of or in combination with a rearwardly convex lens as the seventh lens element of positive power. In addition to this feature, the objective is characterized in that the axial thickness d_9 of the fifth lens element is related to the axial air separation d_{10} between the fifth and sixth lens elements as $d_9 < d_{10}$.

Numerical date for three preferred embodiments of the retrofocus wide angle objective lens system according to the present invention are given in Tables 1, 3 and 5 in which γ_1, γ_2 . . . designate the radii of curvature of the individual surfaces counting from the front, the negative sign indicating that the surface is concave to the front; d_1, d_2 . . . designate the axial thicknesses or air separations between the successive two surfaces; N_1, N_2 . . . designate the refractive indices for the sodium d-line of the spectrum of the materials from which the various elements of the objective are made; and ν_1, ν_2 . . . designate the Abbe numbers of the corresponding materials. Seidel aberration coefficients for the lens systems of Tables 1, 3 and 5 are given in Tables 2, 4 and 6 respectively, in which SA designates the spherical aberration coefficients for the individual surfaces; CM designates the coma coefficients; AS designates the astigmatism coefficients; PT designates the Petzval sums; and DS designates the distortion coefficients.

What is claimed is:

1. A retrofocus wide angle objective lens system comprising seven axially aligned lenses including, in the order of the entrant light beam:

negative meniscus first and second lenses of forward convexity;

a positive third lens;

a bi-convex fourth lens;

a bi-concave fifth lens; and

positive sixth and seventh lenses; and

wherein axial air space between said third lens and said fourth lens is larger than the axial thickness of said third lens, said third lens having a diameter larger than the fourth lens.

2. A retrofocus wide angle objective lens system according to claim **1**, wherein said third lens of positive power has a front surface convex to the front.

3. A retrofocus wide angle objective lens system according to claim **2**, wherein said seventh lens is a positive meniscus lens of rearward convexity.

4. A retrofocus wide angle objective lens system according to claim **3**, wherein said fifth lens has an axial thickness smaller than the axial air space between said fifth and sixth lenses.

5. A retrofocus wide angle objective lens system according to claim **1**, wherein

a. $0.6 < d_6/d_4 < 1.0$

b. $0.68f < \gamma_4 < 0.9f$

c. $7.0f < |\gamma_6|$

d. $N_3 > 1.72$; $V_3 < 40$

e. $0.95f < |\gamma_8| < 1.5f$; $\gamma_8 < 0$

wherein f is the overall focal length of the complete objective lens system; d_4 and d_6 are the axial air separations between said second and third lenses and between said third and fourth lenses respectively; γ_4, γ_6 and γ_8 are the radii of curvature of the rear refracting surfaces of said second, third and fourth lenses respectively; and N_3 and V_3 are the refractive index and Abbe number of a glass respectively from which said third lens is made.

6. A retrofocus wide angle objective lens system having the following characteristics of the various lens elements thereof with their spatial relationships from each other as related to a focal length of unity:

f = 1; F 2.8; $\omega = 38°$

[57] **ABSTRACT**

A telephoto objective comprising a stationary convergent front lens group and a rear lens group which includes a lens member axially movable for focusing behind a front lens member which remains stationary during focusing, and an operating mechanism therefor. In order to achieve excellent stability of the various aberrations and particularly spherical aberration throughout the focusing range, compensation for the residual aberrations introduced by the front lens group is concentrated in the stationary front member of the rear lens group, while the movable rear member is configured to provide minimized variation of aberrations by constructing these two members as being divergent with their front surfaces convex to the object. In this particular arrangement, the movable member is moved toward the image plane as the objective is focused from the position for an object at infinity to the position for a close object.

TELEPHOTO OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to optical objectives for photographic devices, and more particularly to a telephoto objective comprising a stationary front lens group and a rear lens group which includes a member axially movable to focus while still maintaining improved stabilization of the aberrations throughout the focusing range.

In general, the focusing of an optical objective is effected by axially moving the objective bodily with reference to the image plane. But this may be otherwise achieved by axial movement of a part of the objective, for example, either the front, or the rear lens group thereof with reference to the other part which remains stationary during focusing. In telephoto objectives, if made bodily movable for focusing purposes, the amount of movement of the objective throughout the focusing range tends to increase, and this in turn calls for increases in the weight and bulk of the objective and the driving torque of its focusing mechanism as well as in the production cost thereof, thus it being made more difficult to keep the weight and bulk of the complete objective including its mechanical mounting and focusing mechanism within easily manageable proportion.

With a telephoto objective having the provision for focusing made at a rear part of the lens system, it is possible to minimize the movement of the focusing part and to employ a focusing mechanism of small size and weaker driving torque, because the focusing part comprises only a fraction of the weight and bulk of the complete objective, thereby giving an advantage of facilitating high-speed focus adjustment of the objective. Another advantage deriving from the selection of the rear lens group of the objective for employment as the movable part for focusing purposes is that the front lens group which is of a relatively large weight and bulk may be supported in fixedly secured relation with a camera body to minimize the probability of producing a jiggle or oscillation of the image at the focal plane by small accidental motions of the objective and camera assembly which is otherwise encountered particularly when the objective is telephoto in nature. However, this system has a disadvantage that variation of the aberration particularly variation of the spherical aberration due to the movement of the lens is large, and the image forming ability is low. Further, in order for an objective to embody an advantageously small overall length, a convergent lens group is usually selected for employment as the front part thereof in combination with a divergent rear lens group having design parameters determined so as to cancell out the residual spherical aberration introduced by the front lens group in a focusing position for an object at infinity. However, as the objective is focused from this position to a position for a close object, the axial separation between the front and rear lens groups is increased with decrease in the hight of incidence of an axial ray upon the rear lens group, so that occurrence of the positive spherical aberration is less, while varying the value of the spherical aberration to a remarkable extent. In this respect, it is well known that this arrangement is disadvantageous for stabilization of the image aberrations throughout the focusing range.

SUMMARY OF THE INVENTION

The present invention has for a general object to provide the above-mentioned advantages in the case of a telephoto objective having the provision for focusing made at the rear part thereof, while still proving improved stabilization of the aberrations throughout the focusing range.

A concomitant object of the invention is to provide a focusing mechanism for use with an telephoto objective of the character described which assists in high-speed focus adjustment thereof.

In order to avoid the above defect in the focusing system by the movement of rear lens group, it is necessary to lessen the occurrence of the aberration particularly the spherical aberration in the rear lens group, but if the aberration is lessened in this way the spherical aberration of the whole lens system is remarkably undercorrection.

The telephoto objective of the invention is characterized in comprising a convergent front lens group and a rear lens group which includes a lens member axially movable to effect focusing in front of, or behind a lens member which remains stationary during focusing. This particular arrangement gives rise to the possibility of cancelling out the residual aberrations introduced by the convergent front lens group by suitable design of the stationary lens member of the rear lens group and gives high standard of stabilization of the various aberrations and particularly spherical aberration throughout the focusing range provided that the movable member is designed to give a good standard of stabilization of the aberrations throughout the focusing range.

Further, a good compromise has been achieved between the requirements of providing a large range of focusing adjustments with relatively small axial translations of the movable member of the rear lens group and of providing a distribution of powers between the stationary and movable parts of the objective which effects achievement of a high standard of aberration correction.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a diagrammatic view of an example of a telephoto objective according to an embodiment of the invention in two focusing positions.

FIG. 2 is a similar view of another example of the embodiment of the invention.

FIGS. 3*a*–3*c*is a graphic representation of aberration achieved in the example of FIG. 1 when focused for an infinite object distance.

FIGS. 4*a*–4*c*is a similar representation when focused for an object distance of 1,000 millimeters.

FIGS. 5*a*–5*c*is a graphic representation of aberration achieved in the example of FIG. 2 when focused for an infinite object distance.

FIGS. 6*a*–6*c* is a similar representation when focused for an object distance of 1,000 millimeters.

FIG. 7 is an axial sectional view of a barrel type mechanical mounting with a focusing mechanism adapted for use with the objective of the invention.

FIG. 8 is a similar view with a modification of the focusing mechanism.

FIG. 9 is a fragmentary sectional view of a focus-preselecting device in the focusing mechanism of FIGS. 7 or 8.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIGS. **1** and **2**, there are shown two specific examples of a preferred embodiment of the invention as comprising a front lens group A which has a positive, power and remains stationary during focusing, and a rear lens group which has a negative power and is divided into two parts B and C, the rear part C being made axially movable to effect focusing to suit differing object distances, while the front part B remains stationary during focusing. The stationary part B consists of a negative meniscus singlet lens member in the instance of FIG. **1**, or of a negative meniscus doublet lens member in the instance of FIG. **2**, with the first refracting surface counting from the front convex to the front, and with the rearmost surface having a radius of curvature which is smallest among all of the surfaces of member B. The movable rear part C is constructed from a negative meniscus doublet lens member with the first surface convex to the front, and with the rearmost surface having a radius of curvature which is smallest among all the surfaces of member C. The absolute focal length of member B is larger than that of member C. A diaphragm D which is stationary is located behind movable member C at a distance to permit the entire range of focusing movement thereof.

As the objective of FIGS. **1** or **2** is focused from the position C marked in solid line for an object at infinity to the position C' marked in broken line for a close object, movable member C progressively approaches the focal plane FP through the space of a distance Δx as defined by the following formula

$$\Delta x = \frac{-2}{B\left(1+\sqrt{1-\frac{4A}{B^2}}\right)}$$

wherein

$$A = \frac{1}{F}\ \frac{1}{Fc}\left(\frac{S}{Ff}+1\right)$$

$$B = \frac{1}{Ff}\left(\frac{S_1}{Ff}+1\right)-\frac{1}{F}\left(\frac{S_1-O_1}{F}+1\right)$$

where

S_1 is the object distance as measuring from the vertex of the first refracting surface of the objective;

F is the focal length of the complete objective when focused for an infinitely distance object;

Ff is the focal length of the combined group A and member B;

Fc is the focal length of the movable member C; O_1 is the distance from the vertex of the first refractings surface to the primary principal point of the complete object; and

Δx when measured in a direction to the focal plane takes a plus sign.

In order to facilitate the solution of aberrational problems, it is preferred to specify the characteristics of the members B and C by the following relationships:

$$0.4F < |FC| < 0.9F;\ Fc < 0 \quad (1)$$
$$0.15F < Rc < 0.25F \quad (2)$$
$$0.05 < F(Fcv \cdot Vcv) + f/(Fcc \cdot Vcc) < 0.05 \quad (3)$$
$$0.05F < Rb < 0.15F \quad (4)$$

wherein

Rc is the radius of curvature of the rearmost surface of the member C;

Rb is the radius of curvature of the rearmost surface of the member B;

Fcv is the focal length of the positive lens element of the member C;

Vcv is the Abbe's number value for the material of the positive lens element of the member C

Fcc is the focal length of the negative lens element of the member C;

Vcc is the Abbe's number value for the material of the negative lens element of the member C.

Condition (1) assists toward achievement of a good compromise between the requirements of providing a large range of focusing adjustment with relatively small axial movement of the movable member C and of providing excellent stabilization of the aberrations throughout the focusing range. When the power of member C is otherwise increased, it is made rapidly more difficult to achieve the desired high standard of aberration correction although the axial translation of member C may be decreased to obtain an equivalent focusing effect. Conversely, the use of a lens member having a power smaller than that corresponding to the upper limit of condition (1) as the focusing member requires a focusing mechanism of increased size due to the increased axial translations of the focusing member.

Condition (2) assists in minimizing the residual aberrations and particularly spherical aberration introduced by the focusing member C to provide a good standard of stabilization of the aberrations throughout the focusing range.

Condition (3) assists in the stabilization with focusing of chromatic aberrations.

The use of a lens member having the parameters within the ranges specified above as the focusing member C results in somewhat under-corrections of the spherical aberration, coma and astigmatism of the complete objective. In order to preserve a good state of correction of the image aberrations, the stationary lens member B of the rear lens group must be designed according to condition (4) to provide correspondingly over-corrected values of the above-identified aberrations.

The specific examples of a telephoto objective of the invention as illustrated in FIGS. **1** and **2** may be constructed in accordance with the numerical data given in Tables **1** and **3** below respectively, in which R_1, R_2... designate the radii of curvature of the individual surfaces of the objective counting from the front, the positive sign indicating that the surface is convex to the front and the negative sign that it is concave thereto, d_1, d_2... designate the axial separations between successive refracting surfaces of the objective, N_1, N_2... designate the refractive indices for the spectral d line of sodium of the materials from which the various lens elements of the objective are made, and V_1, V_2... designate the Abbe numbers of the materials.

It will be appreciated from the foregoing description that, with a telephoto objective consisting of a convergent front lens group and a divergent rear lens group, the present invention provides a two part rear lens group, only one part of which is axially movable for focussing purposes, thereby giving rise to the possibility of achieving a high standard of aberration stabilization throughout the range of focussing movement. Therefore, by comparison with a conventional telephoto objective which is made bodily movable for focussing, or which has a front lens group movable for focussing, the objective of the invention is improved with respect to the focussing manupulation owing to the decreased weight and bulk of the complete objective, which will in turn reduce the probability of producing an oscilation of the image at the focal plane when it is used in association with a hand-held camera. On the other hand, by comparison with a conventional telephoto objective having a rear lens group which made bodily movable for focussing, the objective of the invention is remarkably improved with respect to the imaging performance owing to the stationary part of the rear lens group which is designed to provide improved stabilization of the various aberrations throughout the focussing range. It is to be noted that the present invention is not limited to use in the construction of three-component telephoto objective described and is useful to facilitate the design of the focussing member for any telephoto lens including additional lens components of almost zero powers located in front of, or behind the front part B, or behind the rear part C of the rear lens group, and that further assistance in achieving a higher standard of correction of the image aberrations can be obtained if an additional component which remains stationary during focussing is employed for arrangement between the front and rear lens groups.

Referring now to FIG. 7, there is shown a lens mount with a cam-operated focussing mechanism adapted for use with the telephoto objective of the character described, where L_1 and L_2 designate the front and rear lens groups of the objective respectively, and L_{21} and L_{22} designate the stationary front and movable rear parts of the rear lens group L_2 respectively. This lens mount is connected to a single lens reflex camera, not shown, by an adapter 2 whose rear end constitutes a bayonet coupling engaging the camera housing. Rigidly connected to adapter 2 is a barrel 1 at one end thereof, the opposite end portion of which has a guide barrel 3 fixedly secured thereto and provided with a longitudinally elongated guiding slot 3*a*. Mounted within guide barrel 3 is a slidable sleeve 4 carrying the movable lens member L_{22}. The sleeve 4 can be moved longitudinally but can not be rotated with reference to barrel 3, as it is prevented from rotating by a pin 6 outwardly radially extending from the slidable sleeve 4 and provided with a roller rotatable thereabout in the guiding slot 3*a*. The roller 7 projects beyond the guiding slot 3*a* and engages with a herical camming groove 5*a* formed in the inner surface of a focus adjusting sleeve 5 which is rotatably mounted on guide barrel 3. The parts, 3*a*, 5, 5*a*, 6 and 7

constitutes the above mentioned camo perated focusing mechanism. Rigidly coupled to guide barrel **3** is a tubular extension **8** carrying the front lens group L_1 and the front part L_{21} of the rear lens group L_2 mounted therein in fixed relation to each other and to the extension **8.** The lens mount has a diaphgram device **10** mounted therein at a location behind the movable lens member L_{22}. The diaphragm device **10** is provided with a control lever **9,** and a presetting lever **11** cooperating with a diaphgram adjusting ring **12** rotatably mounted on barrel **1.** The control lever **9** serves to adjust the diaphragm device **10** to a preselected setting in response to an actuation of a camera release member. The presetting lever **11** serves to adjust the position of a diaphragm blade-operating cam member **13** in accordance with the preselected diaphragm value by the ring **12,** and also to transmit the diaphragm information to a diaphragm control mechanism not shown in the camera housing in response to a rotation of ring **12.** A filter being mounted in a filter holder **14** which is detachably mounted behind the diaphragm device **10** in the barrel **1.** The lens mount is further provided with a support member **15** having a nut formed therein for engagement with a bolt of a tripod not shown.

The operation of the focussing mechanism of FIG. **7** in connection with the diaphragm device **10** which constitutes a part of the exposure control apparatus of the camera. In order to make an exposure in the diaphragm preselection automatic exposure range, the operator turns the ring **12** to select a desired diaphragm value, thereby the position of the cam member **13** is adjusted through the presetting lever **11.** At the same time, the diaphragm information is introduced to the exposure control apparatus in the camera through the presetting lever **11.** On the other hand, when the camera is switched to the shutter preselection automatic exposure range, the position of the cam member **13** is adjusted in accordance with a computed diaphragm value through the presetting lever **11.**

In focussing the objective, the operator turns the rotary sleeve **5,** thereby the roller **7** is driven for movement along the guiding slot **3***a* through the roller **7** and camming groove **5***a* connection, causing axial translation of the slidable sleeve **4** with the lens member L_2 therein. What object the objective has been focussed for is recognizable either by the angular position of sleever **5,** or by looking through the viewfinder in which an image of the corresponding object is formed in sharpest focus. Next, the operator may depress the shutter release button not shown, thereby the diaphragm device **10** is first operated to the preselected setting through the control lever **9,** and thereafter the shutter mechanism is actuated to initiate an exposure.

The filter holder **14** is removably attached to the lens barrel so that various filters may be interchanged. When the filter is not used, it is desirable to use a transparent plate to adjust the optical path length.

FIG. **8** shows a modification of the focussing mechanism of FIG. **7** with employment of a longitudinally slidable focus-adjusting sleeve **51** in place of the rotary sleeve **5** of FIG. **7.** The sleeve **51** is fixedly connected to a slidable sleeve **52** carrying the movable lens member L_{22} through a pin **54** extending through a longitudinally elongated guiding slot **53***b* provided in the guide barrel **53** corresponding to the guide barrel **3** of FIG. **7.** In order to define the range of possible focussing movements of the lens member L_{22}, there is provided a longitudinal groove **53***a* formed in the outer surface of guide barrel **53** for engagement with a pin **55** internally radially extending from the focus adjusting sleeve **51.** In focussing the objective, the operator moves the external sleeve **51** to effect axial translation of the lens member L_{22}, as the internal sleeve **52** is guided through the pin **54** and guiding slot **53***b* connection.

FIG. **9** shows a focussing position preselecting device particularly adapted for association with the focussing mechanism of FIG. **7.** The device comprises a pair of radially grooved recesses **101***a* formed at the ends of a focus adjusting sleeve **101** corresponding to the sleeve **5** of FIG. **7** in longitudinal alignment with each other, a pair of click stop balls **103** which are biased by respective springs **104** in the opposite directions to each other for normal engagement with the respective recesses **101***a,* and a pair of focus presetting rings **102** rotatably mounted on the guide barrel corresponding to the part **3** of FIG. **7.** The rings **102** each has a hole longitudinally bored therein for the mounting of ball **103** and spring **104,** and are provided with respective fasteners having knobs **105.** In operating the device, the rings **102** are turned as a unit to place the reaction points thereof in registry with a graduation representing a desired object distance for which the objective is to be focussed, and then are secured in position fixed to the guide barrel by means of the operated knobs **105.** With this arrangement, when the focus adjusting sleeve **101** is turned to a position where the recesses **101***a* engage with balls **103,** the desired focussing effect is automatically obtained.

It will be appreciated form FIGS. **7, 8** and **9** that the present invention provides a focussing mechanism of simple construction which may be incorporated in the lens mount for the telephoto objective of the character described at a location close to the center of the physical length of the complete objective including the lens mount and, in some cases, of the center of gravity of the objective and camera assembly. Such a central location of the focussing mechanism permits easy management procedures for high speed smooth focus adjustments of the objective, while holding the assembly by hand, and accordingly faciliates to prevent the production of an oscillation of the image at the film plane which would be otherwise introduced by the small accidental motions of the assembly owing to the difficult manupulation thereof and the necessity of large driving torque in operation of focussing mechanism. Furthermore, the constructions of the telephoto objective of the character described and the focussing mechanism therefor are advantageous for the provision of focussing down to a shorter object distance.

What is claimed is:

1. A telephoto objective of high speed adjustable focus comprising a front lens group which has a positive refracting power and remains stationary during focussing, and a rear lens group which is divided into two parts, of which one part is axially movable to effect focussing to suit differing object distances, wherein said movable part of said rear lens being located behind the other part which is stationary during focussing and wherein the characteristics of the various lens elements of said front and rear lens groups and their spatial relationships to each other are substantially of the proportions indicated by the numerical data in the following table, in which R designates the radii of curvature of the refracting surfaces identified by the corresponding subscript numerals and numbered from the front to the rear of the objective, the positive sign indicating that the surface is convex to the front and the negative sign that

it is concave thereto, D designates the axial separations between successive refracting surfaces of the objective being numbered from the front to the rear; N designates the refractive indices for the spectral D line of sodium of the materials of the elements being numbered from the front to the rear; and ν designates the Abbe numbers of the materials:

3. A telephoto objective of high speed adjustable focus comprising:

a front lens group which has a positive refracting power and remains stationary during focussing; and

a rear lens group having a negative refracting power and composed of a stationary sub-group and at least one movable sub-group, said movable sub-group having a negative refracting power, a frontmost surface of which has a convex face toward the object, said movable sub-group being moved on the optical axis toward an image so as to cause the telephoto object to focus an object at a near distance from its focussing on an object at a far distance.

4. A telephoto objective according to claim 3, in which said stationary sub-group is arranged nearer the object than said movable sub-group.

5. A telephoto objective according to claim 3, in which said stationary sub-group has a negative refractory power and its frontmost surface is convex toward the object.

6. A telephoto objective according to claim 5, in which said stationary sub-group is a negative meniscus lens.

7. A telephoto objective according to claim 5, in which said stationary sub-group comprises a positive meniscus lens and a negative meniscus lens arranged in the written order.

8. A telephoto objective according to claim 3, wherein the absolute focal length of said stationary sub-group is larger than that of said movable sub-group.

9. A telephoto objective according to claim 8, in which said stationary sub-group comprises a positive meniscus lens and a negative meniscus lens arranged in the written order.

10. A telephoto objective according to claim 3, in which said front lens group comprises a positive lens, a negative lens and a positive lens.

11. A telephoto objective according to claim 10, in which said positive lenses is a biconvex lens, and said negative lens, is a negative meniscus lens having its concave face toward the object.

12. A telephoto objective of high speed adjustable focus comprising:

a primary lens group which comprises at least three lenses, has a positive refracting power and is stationary at a constant distance from the focal plane;

a middle lens group which is on the image side axially apart from said primary lens group and has a negative refracting power and front lens-surface of which group faces toward the object; and

a rearmost lens group which is first behind said middle lens group and has a negative refracting power, and comprises at least one positive lens and at least one negative lens, said rearmost lens group moving axially to the image side when refocussing is done from an object far from the object to an object near the object.

13. A telephoto objective according to claim 12, in which said primary lens group comprises a biconvex lens, a negative lens having the concave face toward the object and a positive lens arranged in the written order from the object side.

14. A telephoto objective according to claim 12, in which said middle lens group comprises a negative meniscus lens.

15. A telephoto objective according to claim 12, in which said rearmost lens group comprises a positive meniscus lens and a negative lens arranged in the written order from the object side.

16. A telephoto objective of high speed adjustable focus comprising a front lens group which has a positive refracting power and remains stationary during focussing, and a rear lens group which is positioned on the image side axially apart from said front lens group and has a negative refracting power, said rear lens group being divided into two parts of which one part is axially movable to effect focussing to suit differing object distance, and the other part has a negative refracting power and stationary during focussing.

17. A telephoto objective according to claim 16, wherein said movable part of said rear lens group is

located behind the other part which is stationary during focussing.

18. A telephoto objective according to claim 16, wherein said movable part of said rear lens group is located behind the other part which is stationary during focussing and composed of a plurality of lenses.

19. A telephoto objective according to claim 18, wherein said movable lens part of said rear lens group has a rearmost surface concave to the rear, and said rearmost surface has a radius of curvature which is smallest among all the surfaces of said movable part.

20. A telephoto objective according to claim 16, wherein said stationary part of said rear lens group has a frontmost surface convex to the front.

21. A telephoto objective according to claim 20, wherein said stationary part has a rearmost surface concave to the rear, and said rearmost surface has a radius of curvature which is smallest among all the surfaces of the stationary part.

22. A telephoto objective according to claim 16, wherein the movable part of said rear lens group has a negative refracting power, and the absolute focal length of the stationary part of said rear lens group is larger than that of said movable part, wherein said movable part is moved on the optical axis toward the image so as to cause the objective to focus an object at near distance from its focusing on an object at infinite distance.

[57] **ABSTRACT**

A telephoto objective lens comprising a normally stationary front lens group having a positive power and a rear lens group having a negative power axially movable for focusing, the front lens group including at least two positive members and at least one negative member, and the rear lens group including at least one positive member and at least one negative member. The rear lens group has a negative meniscus configuration as a whole with the first refracting surface counting from the front being convex to the front and with the rearmost surface being concave to the rear. As the objective lens is focused from the position for an object at infinity to the position for a close object, only the rear lens group is moved toward the image plane.

HIGH-SPEED ADJUSTABLE FOCUS TELEPHOTO OBJECTIVE LENS

BACKGROUND OF THE INVENTION

This invention relates to optical objectives, and more particularly, to a telephoto objective having a stationary front lens group of positive power and a rear lens group of negative power movable for focusing.

Although most optical objectives are bodily movable for focusing purposes, the focusing can be otherwise achieved by axial movement of either the front or the rear lens group of the optical objective.

In telephoto objectives, if made bodily movable for focusing, the amount of axial movement of the objective throughout the entire focusing range tends to increase, and this, in turn, calls for increases in the weight and bulk of the objective and the driving torque of its focusing mechanism such as those including helicoid structure as well as in the production cost thereof, thereby it being made more difficult to keep the weight and bulk of the complete objective including its mechanical mounting and focusing mechanism within easily manageable proportions.

In the case of a telephoto objective of the type in which the provision for focusing is made at a rear lens group thereof, it is possible to minimize the amount of focusing movement and further to reduce the size and cost of the focusing mechanism therefor, because of the relatively small weight and bulk of the rear lens group, which in turn results in a reduction of the driving torque which would be otherwise necessary for the focusing thereof. This provides an advantage of facilitating high-speed focus adjustment of the objective. Another advantage of this type telephoto objective is that the front lens group which is of a relatively large weight and bulk may be supported in fixedly secured relation with a camera body to minimize the probability of producing a jiggle or oscillation of the image at the focal plane by small accidental motions of the objective and camera assembly which is otherwise encountered, particularly when the objective is telephoto in nature. This type of telephoto objective is, however, susceptible to large variation of aberrations and particularly spherical aberration during focusing, and consequently high grade imagery cannot be preserved throughout. This is particularly true when the objective is constructed as comprising a front lens group which has a positive power and a rear lens group which has a negative power for the purpose of minimizing the overall length of the objective. In the objective of such construction, the front lens group produces a negative spherical aberration, while the rear lens group produces a positive spherical aberration, whereby the best balance between them is usually effected at a focusing position for an object at infinity. As the objective is focused from the infinity distant position to a close distance position, however, the height of incidence of an axial ray upon the rear lens group is decreased causing the rear lens group to contribute a decreased positive spherical aberration to the whole lens system. As a result, the image spherical aberration is remarkably undercorrected.

SUMMARY OF THE INVENTION

The present invention has for the general object to provide a telephoto objective lens having a rear lens group movable for focusing purposes and which is well corrected for high grade imaging performance throughout the entire focusing range.

To achieve this, the rear lens group is corrected for aberrations to a large extent, with a construction such that the rear lens group has a negative power, and the strongest convergent surface among the surfaces in this group is convex to the front, and the strongest divergent surface which is located on the image side of the strongest convergent surface is concave to the rear. By the term "strong" as herein used, it is meant that the radius of curvature of the surface is small. For the purpose of better understanding this, reference to FIG. 1 may be had wherein a surface designated by R_7 corresponds to the convergent surface, and a surface designated by R_9 corresponds to the divergent surface. With this rear lens group, it is impossible to provide a decreased variation of positive spherical aberration during focusing, as the difference between the maximum and minimum spherical aberrations occurring at different heights of incidence of an axial ray on the rear lens group depending upon the extent to which the rear lens group is corrected for spherical aberration.

On the other hand, the front lens group is corrected for spherical aberration by itself with resulting further decreased image spherical aberration of the complete telephoto objective. For this purpose, it is preferred to construct the front lens group from at least two positive lenses and at least one negative lens. For facilitating chromatic aberration correction, it is preferred to construct the rear lens group from at least one positive lens and at least one negative lens.

The above and other features of the present invention will be described in greater detail with reference to the accompanying drawings in which:

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is an axial sectional view of a telephoto objective according to one embodiment of the present invention.

FIG. 2 is an axial sectional view of another embodiment of the invention shown as mounted in a lens barrel with a focusing mechanism for a single lens reflex camera.

FIG. 3 is an axial sectional view of still another embodiment of the invention.

FIGS. 4, 5 and 6 are aberration curves of the objective of FIG. 1 occurring in a focusing position for an object at infinity.

FIG. 7, FIG. 8 and FIG. 9 are aberration curves of the objective of FIG. 1 occurring in a focusing position for a close object at a distance of 8 meters.

FIGS. 10, 11 and 12 are aberration curves of the objective of FIG. 2 occurring in a focusing position for an object at infinity.

FIGS. 13, 14 and 15 are aberration curves of the objective of FIG. 2 occurring in a focusing position for an object distance of 8 meters.

FIGS. 16, 17 and 18 are aberration curves of the objective of FIG. 3 occurring in a focusing position for an object at infinity.

FIGS. 19, 20 amd 21 are aberration curves of the objective of FIG. 3 occurring in a focusing position for an object at a distance of 12 meters.

FIG. 22 is an axial sectional view of a telephoto objective of a type different from the above showing the effectiveness of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIGS. 1, 2 and 3, there are shown three embodiments of the present invention each providing a telephoto objective adapted for use with a photographic camera and which comprises a normally stationary front lens group of positive power designated by A and a rear lens group of negative power designated by B moveable for focusing purposes. The front lens group A consists of two positive lens elements and one negative lens element. The rear lens group B consists of two lens elements which are either cemented together at their adjoining surfaces as shown in FIGS. 1 and 2, or air-spaced from each other as shown in FIG. 3, and is substantially configured to a negative meniscus lens as a whole, with the first refracting surface counting from the front being convex to the front, and with the rearmost refracting surface being concave to the rear, whereby the radii of curvature of the first and rearmost surfaces are smaller than that of the cemented surface, or those of the confronting surfaces thereof.

In focusing the telephoto objective from an object at infinity to a close object at a distance of 8 or 12 meters, the rear lens group B is moved behind a diaphragm D from a position marked in solid lines to a position marked by dashed lines by means, for example, including a slidable focusing ring R associated with a lens barrel L which is assembled with a camera body at a fitting ring M as shown in FIG. 2. The amount of focusing movement ΔX of the rear lens group B may be expressed by the following formulae

$$\Delta X = \frac{-2}{K\left(1 + \sqrt{1 - \frac{4J}{K^2}}\right)}$$

$$K \equiv \frac{1}{F} \cdot \frac{1}{Fb}\left(\frac{S_1}{Fa} + 1\right)$$

$$J \equiv \frac{1}{Fa}\left(\frac{S_1}{Fa} + 1\right) - \frac{1}{F}\left(\frac{S_1 - O_1}{F} + 1\right)$$

wherein S_1 is the object distance as measured from the vertex of the first refracting surface of the objective; F is the focal length of the complete objective occurring when focused at infinity; Fa is the focal length of the front lens group; Fb is the focal length of the rear lens group; and O_1 is the interval between the primary principal point of the complete objective focused at infinity and the vertex of the first refracting surface of the objective, the value of ΔX taking a plus sign when measuring the movement amount in the direction from the front to the rear.

In order to facilitate the solution of aberrational problems, it is preferred that the rear lens group and its lens components satisfy the following relationships:

$$0.4F < |Fb| < 0.9F,\ Fb < 0 \qquad \text{(a)}$$

$$3.5 < \frac{Rc + Rv}{Rc - Rv} < 8 \qquad \text{(b)}$$

$$-0.05 < \frac{F}{Fp \cdot Vp} + \frac{F}{Fn \cdot Vn} < 0.05 \qquad \text{(c)}$$

wherein F is the focal length of the complete objective when focused at infinity; Fb is the focal length of the rear lens group; Rv is the radius of curvature of a strong convex surface of the rear lens group; Rc is the radius of curvature of a strong concave surface of the rear lens group; Fp and Vp are the overall focal length and mean Abbe number of positive lens or lenses comprising the rear lens group respectively; and Fn and Vn are the overall focal length and mean Abbe number of negative lens or lenses comprising the rear lens group, respectively.

Condition (a) assists towards achievement of a good compromise between the requirements of providing a large range of focusing adjustments with relatively small axial translation of the rear lens group B and of providing the possibility of achieving a high standard of stabilization of the aberrations throughout the entire focusing range. Although the amount of axial translation of the rear lens group can further be decreased by decreasing the absolute focal length $|Fb|$ of the rear lens group from the lower limit 0.4F, it is made more difficult to compensate the variation with focusing of aberrations. Conversely, the use of a lens group having an absolute focal length longer than the upper limit 0.9F as the rear lens group requires a focusing mechanism of increased size due to the increased axial translation of the rear lens group.

In compensating for variation with focusing of aberrations, it is required that various residual aberrations and particularly spherical aberration ascribable to the rear lens group must be decreased. For this reason, the rear lens group must be designed to have a concave meniscus configuration directed rearwardly toward the image plane, as satisfying condition (*b*). When the upper limit of condition (*b*) is violated, residual spherical aberration ascribable to the rear lens group is objectionably increased with resulting increased variation of aberration during focusing. When the lower limit is violated, a difficult problem arises in balancing residual aberrations of the complete objective throughout the entire focusing range.

For stabilization with focusing of chromatic aberrations, it is preferred to correct the rear lens group for achromatizm to a modest degree as defined by condition (*c*).

Three examples of embodiments of the invention represented in FIGS. 1, 2 and 3 may be constructed in accordance with the numerical data given in Tables 1, 3 and 5 below respectively, in which R_1, R_2 . . . designate the radii of curvature of the individual surfaces counting from the front, the negative sign indicating that the surface is concave to the front; d_1, d_2 . . . designate the axial lens thicknesses of the individual elements, or air separations between the components of the objective; N_1, N_2 . . . . and V_1, V_2 . . . respectively designate the refractive indices for the sodium d-line of the spectrum and the Abbe numbers of the materials of which the various elements of the objective are made, and in addition the variation of an axial air separation between the front and rear lens group during focusing. The aberration coefficients of the objectives of FIGS. 1, 3 and 5 are given in Tables 2, 4 and 6 respectively, in which I: Spherical aberration; II: Coma; III: Astigmatism; P: Petzval sum; and V: Distortion as related to object at infinity.

The present invention is particularly concerned with the rear lens group provided to facilitate focusing with improved stabilization of the image aberrations. In this respect, the rear lens group B is capable of variation and can be split into two parts, for example, two negative meniscus members B_1 and B_2, as shown in FIG. 22, which are moved for focusing purposes in differential relation to each other and with reference to the front lens group, thereby giving an advantage of improving the state of correction of the image aberrations. This aberration corrected method is usually called "floating".

The basic construction of telephoto objective lens described is applicable with substantially equivalent result to another type of telephoto objective having a meniscus lens member of almost zero power with its convex surface rearwardly directed to the image plane, such meniscus lens being positioned just in front of or behind the moveable rear lens group without substantially affecting the aberrations.

What is claimed is:

1. A high-speed focus adjustable telephoto objective lens, comprising:

a fixed lens group which has a positive refracting power and has at least one negative lens, said fixed lens group further being fixed at a position separated from the image surface by a prescribed length,

a movable lens group, which has a negative refracting power and has at least one positive element lens and at least one negative element lens, wherein the front surfaces contacting air of these element lenses have their convex planes facing toward an object and the rear faces thereof contacting air have their concave planes facing toward an image, said movable lens group being located at an object side on an axis being separated from said fixed lens group, and the diameters of the element lenses within the movable lens group being smaller than the diameters of the lenses within the fixed lens group,

whereby said movable lens group is shifted toward an object as said telephoto lens is refocused from an object at far distance to an object at close distance.

2. A high-speed focus adjustable telephoto objective lens, comprising:

a front lens group which has a positive refracting power and consists of a plurality of lenses, said front lens group further being fixed at a position having a prescribed distance from the image surface of said objective lens, and

a rear lens group which has a negative refracting power and has at least one positive lens and at least one negative lens, wherein the frontmost lens surface within this group has its convex plane facing an object side and has a radius of curvature being smaller than that of said frontmost lens surface,

whereby as said objective lens is focused from an object at infinity to an object at a close distance, said rear lens group is moved rearwardly toward the image surface along an optical axis of said objective, and the amount of shifting ΔX of said rear lens is as follows:

$$\Delta X = \frac{-2}{K\left(1 + \sqrt{1 - \frac{4J}{K^2}}\right)}$$

$$K \equiv \frac{1}{F} \cdot \frac{1}{Fb}\left(\frac{S_1}{Fa} + 1\right)$$

$$J \equiv \frac{1}{Fa}\left(\frac{S_1}{Fa} + 1\right) - \frac{1}{F}\left(\frac{S_1 - O_1}{F} + 1\right)$$

wherein S_1 is the object distance as measured from the vertex of the first refracting surface of the objective; F is the focal length of the complete objective occurring when focused at infinity; Fa is the focal length of the front lens group; Fb is the focal length of the rear lens group; and O_1 is the interval between the primary principal point of the complete objective focused at infinity and the vertex of the first refracting surface of the objective, the value of ΔX taking a plus sign when measuring the movement amount in the direction from the front to the rear.

3. A high-speed focus adjustable telephoto objective lens according to claim 2, wherein said front lens group has a bi-convex lens, a negative meniscus lens of forward concavity and a positive lens of forward convexity arranged in this order from the front, and said rear lens group has a positive lens of forward convexity and a negative lens of rearward concavity arranged in this order from the front.

4. A high-speed focus adjustable telephoto objective lens according to claim 3, wherein said positive and negative lenses in said rear lens group are cemented together at their adjoining surfaces.

5. A high-speed focus adjustable telephoto objective lens according to claim 2, wherein said front lens group has two bi-convex lenses and a negative lens of forward concavity arranged in this order from the front, and said rear lens group has a positive lens of forward convexity and a negative lens of rearward concavity arranged in this order from the front.

6. A high-speed focus adjustable telephoto objective lens according to claim 5, wherein said positive and negative lenses in said rear lens group are cemented together at their adjoining surfaces.

7. A telephoto objective lens according to claim 2, in which said negative element lens of said movable lens group is located at a position closer to an image than the positive element lens of said movable lens group.

8. A telephoto objective lens according to claim 2, in which the positive element lens of said movable lens group and the negative element lens of the same are cemented together.

9. A high-speed focus adjustable telephoto objective lens with the various elements thereof having the characteristics and their spatial relationships to each other which are substantially of the proportions indicated by the numerical data in the following table:

Total focal length f = 400					F-number : 4.5		
R_1 =	269.35	d_1 =	15.0	N_1 =	1.43387	V_1 =	95.2
R_2 =	−167.16	d_2 =	0.57

[57] **ABSTRACT**

A retrofocus type wide angle objective lens comprising a negative lens group N and a positive lens group P having a diaphragm therein arranged in this order from the object side, said negative lens group N being constructed from a divergent front lens group F and a rear lens group R. When the lens is focused to a close object, only the rear lens group R located in the divergent light bundle from said front lens group F is moved in a different manner from that in which the other lens groups are moved in unison to effect good correction of aberrations in close photography.

RETRO-FOCUS TYPE WIDE ANGLE OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a retrofocus type wide angle objective lens in which aberrations are prevented from deteriorating even in short distance photography.

2. Description of the Prior Art

In general, the aberrational state of an optical lens varies with object distance. Ordinary photographic lenses are corrected for aberrations at infinity so that the closer the object position is with the photographing lens, the larger the aberrations become with the result that the picture quality on the film deteriorates.

This phenomenon is especially remarkable in optical systems of longitudinal asymmetry with respect to the diaphragm thereof and it has been a very serious problem in retrofocus type lenses as the field angle is large.

In general, the retrofocus type lens when focused to a cloe object produces spherical aberration, coma, astigmatism and curvature of field to a remarkable extent. Therefore, various techniques of correcting aberrations at short distances have been proposed.

However, most of these proposals are subjected to a limitation such that air spaces in which axial rays are parallel or substantially parallel with the optical axis be varied. This limitation is laid down for the purpose of producing to bad influence on the spherical aberration and back focus.

Although this method is effective for correction of astigmatism and curvature of field, generally speaking, it is difficult to effect good correction of coma. This is because the space defined as having parallel rays is not always coincidence with a space suitable for use in correction of coma, and because the degree of freedom is not sufficient so that it is difficult to obtain the space with parallel rays usuable for aberration correction. Even in this method, it is usual that the performance of the lens for close photography is not always satisfactory as compared with the performance for infinite photography.

SUMMARY OF THE INVENTION

The present invention has for the general object to improve the above mentioned difficult points and to provide a method of compensating deterioration of the image quality of an object at a short distance in a retrofocus type wide angle objective lens.

According to the present invention, the various aberrations and particularly coma of a retrofocus type lens are corrected from deterioration thereof in short distance photography by moving a lens group consisting of a negative lens and a positive lens in the lens system in a divergent light bundle which inevitably exists in the retrofocus type lens, thereby the image quality of an object at a short distance is improved to as a high standard as that of an object at infinity.

In a retrofocus wide angle objective lens of the present invention, therefore, there is provided a lens group having one or more negative lens or lenses and a positive lens arranged in this order from the object side in a divergent light bundle on the object side with respect to a diaphragm thereof to be moved when focusing in response to variation of object distance. In more detail, a retrofocus wide angle objective lens of its aberrations being prevented from deteriorating when making short distance photography is constructed from a lens group N having a negative refractive power and a lens group P, with a diaphragm provided therein, having a positive refractive power. Further, the above mentioned lens group N consists of a front lens group having a negative refractive power and a rear lens group, and the above mentioned rear lens group consists of, from the object side, at least one concave lens and one convex lens, the rear lens group being placed in a divergent light bundle from the front lens group. When the entire lens system is moved outwards in short distance photography, the amount of movement of the above mentioned front lens group and lens group P being moved in unison with each other is different from the amount of movement of the above mentioned rear lens group. Letting f_R be the focal length of the above mentioned rear lens, f the focal length of the entire lens system, and ω the semi-angle of field, we have $|f_R| > 0.1\omega f$. By satisfaction of this formula, it is made possible to preserve aberrations almost equivalent to those occurring when photographing an infinitely distant object.

The rear lens group constructed in accordance with the present invention comprises, from the object side, one or more negative lens or lenses and one positive lens, whereby it is preferred that the shape of the negative lens is meniscus, and the positive lens is a convex lens having a strong surface faced toward the object side. The term "strong" means that the radius of curvature is smaller.

Further, the front lens group is a divergent lens group constructed from a concave lens or lenses alone, or a divergent lens group containing at most one convex lens as located at the frontmost position.

And located just before the object side of the rear lens group is always the convex lens of the front lens group.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a lens block diagram showing a first embodiment of the present invention.

FIG. **2A**, FIG. **2B** and FIG. **2C** are various aberration curves of the optical system of FIG. **1** occurring when the object distance is infinite.

FIG. **3A**, FIG. **3B** and FIG. **3C** are various aberration curves of the optical system of FIG. **1** occurring at a magnification of −0.134 when the rear lens group R is moved in unison with the front lens group F and lens group P.

FIG. **4A**, FIG. **4B** and FIG. **4C** are various aberration curves of the optical system of FIG. **1** occurring at a magnification of −0.134 when the rear lens group R is moved with a different amount of movement from that movement of the front lens group F and lens group P.

FIG. **5** is a lens block diagram showing a second embodiment of the present invention.

FIG. **6A**, FIG. **6B** and FIG. **6C** are various aberration curves of the optical system of FIG. **5** when the object distanct is infinite.

FIG. **7A**, FIG. **7B** and FIG. **7C** are various aberration curves of the optical system of FIG. **5** at a magnification of −0.134 when the rear lens group R is moved in unison with the front lens group F and lens group P.

FIG. **8A**, FIG. **8B** and FIG. **8C** are various aberration curves of the optical system of FIG. **5** at a magnification of −0.134 when the rear lens group R is moved with a different amount of movement thereof from that of movement of the front lens group F and lens group P.

FIG. 9 is a lens block diagram showing a third embodiment of the present invention.

FIG. 10A, FIG. 10B and FIG. 10C are various aberration curves of the optical system of FIG. 9 when the object distance is infinite.

FIG. 11A, FIG. 11B and FIG. 11C are various aberration curves of the optical system of FIG. 9 at a magnification of −0.134 when the rear lens group R is moved in unison with the front lens group F and lens group P.

FIG. 12A, FIG. 12B and FIG. 12C are various aberration curves of the optical system of FIG. 9 at a magnification of −0.134 when the rear lens group R is moved with a different amount of movement thereof from that of movement of the front lens group F and lens group P.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENT

FIG. 1 is a lens block diaphragm showing the first embodiment of the present invention. In FIG. 1, lenses 1, 2 and 3 constitute a negative lens group N, and lenses 4, 5, 6 and 7 constitute a positive lens group P, the lens group N being divided into a front lens group (1) F having a negative refractive power and a rear lens group (2, 3) R. The lens group P and front lens group 1, 4, 5, 6 and 7 are secured in fixed relation with each other. On the other hand, the negative meniscus lens 2 and the positive lens 3 constituting the rear lens group R and positioned in a divergent light bundle emanating from the front lens group F are secured as a unit independently of the other lens groups. A is a diaphragm.

When the lens system is focused to an object at a short distance, it is moved as a whole toward the object, but the amount of movement, d, of the lenses (2, 3) is smaller than the amount of movement D of the lenses (1, 4, 5, 6, 7). As a result, the axial separation $d2$ between the lens 1 and the lens 2 is increased with decrease in the object distance, and the axial separation $d6$ between the lens 3 and lens 4 is decreased.

In the following, the reason why the aberration deterioration can be prevented by moving the rear lens group R, with the negative and positive lenses thereof arranged in this order, in the divergent light bundle considerably far away from the diaphragm A will be explained. In order to explain the correction principle, it is assumed that a parallel plane surface plate is inserted into the divergent light bundle in the lens system, and that the lens system is corrected for aberrations together with the parallel plane surface plate inserted therein. In such a lens system, a slight axial movement of the parallel plane surface plate does not cause variation of aberrations. In the case where this parallel plane surface plate is divided into a convex lens and a concave lens, while the combined lens resembling in shape the parallel plane surface plate and an appropriate air space is given between said convex and concave lenses, however, the axial movement of such a plate causes variation of aberrations, because higher order aberrations are apt to occur at a surface having a curvature. In the retrofocus type objective lens, therefore correction of spherical aberration, coma, astigmatism and curvature of field which are the more liable to collapse as the object distance becomes the smaller is made possible by designing the lens system so as to satisfy certain conditions for this portion.

The above-mentioned condition formula $|f_R| > 0.1\omega f$: when $|f_R|$ exceeds this range, aberration correction at short distances can not be effected. In other words, when the absolute value of the focal length of the rear lens group exceeds $0.1\omega f$, certain aberrations which are caused to deteriorate by focusing to a short distance can be well corrected on the one hand, but the other aberrations are produced out of balance to more than correction values on the other hand, so that as a whole it is impossible to preserve the aberration state occurring when the object is at infinity.

For example, when spherical aberration is corrected, the curvature of field and astigmatism are produced. Conversely, when the curvature of field and astigmatism are intended to be corrected, the spherical aberration is largely produced, thus it being made difficult to correct all the aberrations completely.

However, it is convenient from the standpoint of aberration correction at short distances that the value of $|f_R|$ is generally large, because the movement of the lens group is made in the divergent light bundle. However, there are many cases where it is better to positively use the movable lens portion in performing aberration correction for an object at infinity based on the lens configuration of the entire system and the power distribution. In that time, by satisfying the above mentioned condition formula, the character at short distances are also corrected.

As another meaning of the condition formula, when this condition formula is violated, the back focus and F-number vary at short distances. In other words, by satisfying this formula it is made possible to reduce variation of the back focus and F-number and to correct aberrations at short distances.

The reason why ω is included as a variable in the condition formula is that the larger the angle of field, the severer the correction of image surface is. In order that aberrations at short distances are corrected while maintaining balance of the overall aberrations, it is necessary to increase the lower limit of $|f_R|$.

In such a manner as the above, the performance at short distances can be corrected to as high as the performance an infinity. As a explanation of the effectiveness of this method, mention may be made of the degree of freedom such that there are two variable air spaces in the lens system. Further, based on the fact that the movable portion of the lens system is comprised of a negative lens and a positive lens, it can be pointed out that the coma aberrations are cancelled by the mutual lenses to result in almost no production of coma aberration even at short distances.

This reason will be explained theoretically. Letting II be the aberration coefficient of coma at infinit object position, III the aberration coefficient of astigmatism, and IV the aberration coefficient of sagittal curvature of field according to Matsui's notation, and letting δ the parameter of movement of the object, the coefficient IIo of coma in parameter δ for the case where the focusing is performed by moving the entire lens system in unison can be expressed as follows:

$$\mathrm{II}o = (1/K^2)\,[\mathrm{II} - \delta(2\mathrm{III} + \mathrm{IV} + \bar{\alpha}') + (\text{the terms of the higher powers of } \delta)]$$

wherein K is the parameter of object movement; and $\bar{\alpha}'$ is the quantity representing the inclination angle of a pupil-paraxial ray exiting from the rearmost surface.

For $\delta << 1$, neglecting the terms of the higher powers of IIo and replacing IV by II + P (wherein P is the petzval sum), we have

$$IIo = (1/K^2)\,[II - \delta(3III + P + \bar{\alpha}')]$$

On the other hand, $3III + P + \bar{\alpha}' \neq 0$ generally holds. It is, therefore, to be understood that the value of II varies with object distance.

For example, in the first embodiment shown in FIG. 1, the magnitude of II at the state of object infinity is 0.05, but it is decreased to −0.01 at a magnification of −0.134. For this reason, the balance of aberrations breakes with production of outward coma.

By moving the rear lens group, however, the coefficient of coma is shifted to (+) side, taking 0.01. Therefore, inward coma is produced. Taking into account the amounts of 5th order aberrations, we see that the coma aberration is reduced to zero as a whole.

Further, the rear lens group is constructed by combining a negative lens with a positive lens so that the absolute value of the overall focal length of this portion is longer than the focal length of the entire system, thus the refractive power being weak. Therefore, the deterioration of image quality by the eccentricity (parallel and inclination) of this movable portion is small.

Also the strength against the eccentricity can be said from the fact that the rear lens group is arranged on the object side of the diaphragm and in the divergent light bundle apart from the diaphragm.

In other words, beyond the positive lens group which is usually located on the object side of the diaphragm in the retrofocus type lens is located further on the object side the rear lens group, so that the distance from the center of the diaphragm to the lens is long. Therefore, this distance can be made close to the curvature of lens and therefore the influence due to the eccentricity becomes very dull, so that the image quality can be secured even from the eccentricity.

Further, even when the lens system is incorporated in a lens barrel which is made complicate by the mounting of a diaphragm mechanism linkable with the camera body, there is an advantage that the mechanism design of the lens barrel is easy and the overall size is minimized, because the rear lens group is positioned in the front part of the lens barrel as compared with the diaphragm rear or neighborhood which makes the lens barrel complicate. Also, the rear lens group has a negative lens and positive lens arranged in order so that there is a merit that the inclination of a light bundle entering the negative lens and the inclination of a light bundle exiting from the positive lens can be brought close to each other.

Next, the values of various dimensions of the first embodiment according to FIG. 1, of the second embodiment according to FIG. 1, of the second embodiment according to FIG. 5 and of the third embodiment according to FIG. 9 are given below.

First embodiment (FIG. 1) f = 1, F_{NO} = 2.8, ω = 37°

r_{14} =	−0.6405	d_{14} = 0.00702		
r_{15} =	25.9050	d_{15} = 0.09123	N_8 = 1.69350	V_8 = 53.3
r_{16} =	−1.0729			

*is a variable space

The length from the first surface to the rearmost surface = 1.9706

Back focus = 1.2807

$|f_R|$ = 150.49

At a magnification of −0.134:

d_4 = 0.36881

d_8 = 0.09368

In the third embodiment, lens **3** and lens **4** are movable independently of the other lenses.

What is claimed is:

1. A retro-focus wide-angle objective lens corrected for short distance photography, comprising:

a first lens group N at the object end and having a negative refractive power,

a second lens group P closer to the image end and having a positive refractive power, said first lens group N including a front lens group having a negative refractive power and a rear lens group, said front lens group producing a divergent light bundle,

said rear lens group being located in the divergent light bundle from the front lens group, said rear lens group having a negative lens toward the object and a first positive lens,

said second lens group P including a front positive lens facing said first positive lens of said rear lens group and a diaphragm disposed toward the image end of said front positive lens,

said first and second lens groups N and P being movable toward the object for short distance photography, said front lens group and said second lens group P being movable in unison with each other at a rate different from the rate of said rear lens group.

2. A lens as in claim **1**, wherein said front lens group of said first lens group N includes a negative lens adjacent said rear lens group.

3. A lens as in claim **2**, wherein said rear lens group includes a negative meniscus lens concave to the image, said rear lens group having a biconvex lens with one surface more convex than a second surface, said one surface being directed toward the object end.

4. A lens as in claim **2**, wherein said front lens group consists of a single negative meniscus lens concave to the image.

5. A lens as in claim **2**, wherein said front lens group consists of two negative meniscus lenses concave to the image.

6. A retrofocus wide-angle objective lens corrected for short distance photography, comprising

a pair of adjoining negative lenses with a first variable air space therebetween,

a pair of adjoining positive lenses with a second variable air space therebetween, said negative lenses being disposed toward an object end and said positive lenses toward an image end of the objective lens,

said lens toward the image end of said second variable air space forming at least a portion of a positive lens group having a positive refractive power, said lens toward the object end of said first variable air space forming at least a portion of a front lens group having a negative refractive power and said lenses between the variable air spaces forming a rear lens group,

a diaphragm in said positive lens group disposed toward the image end of said positive lens facing the second variable air space,

all of said lenses being movable toward the object for short distance photography, the rate of movement of said front lens group and said positive lens group being equal and in unison and being different from the rate of movement of said rear lens group.

7. A lens as in claim **6**, wherein said first variable air space is larger and said second variable air space is smaller during photography of an object at an infinite distance as compared with the air spaces during close-up photography.

8. A retrofocus wide-angle objective lens corrected for short distance photography, comprising:

a first lens group and a second lens group and a third lens group in order from an object end to an image end,

said first lens group having a divergent power, said second lens group including a negative group having at least one negative meniscus lens concave to the image, and one positive lens closer to the image end than the negative group,

said third lens group having convergent power and having a positive lens toward the object end,

a diaphragm incorporated into said third lens group closer to the image end than said front positive lens,

means for moving the first and third lens groups and maintaining a constant space therebetween, means for moving the second lens group at a rate different from that of said first lens group during short distance photography.

9. A lens as in claim **8**, wherein said first lens group has a negative lens adjacent to said second lens group.

10. A lens as in claim **9**, wherein said one positive lens of said second lens group is a double convex lens having two convex surfaces, one convex surface being more convex than the other of the convex surfaces and facing the object end.

11. A lens as in claim **8**, wherein said first lens group consists of a single negative meniscus lens concave to the image.

12. A lens as in claim **8**, wherein said first lens group consists of two negative meniscus lenses concave to the image.

[57] **ABSTRACT**

An extremely high speed wide angle objective lens system, wherein a reducing Newtonian finder telescope is arranged in front of an objective lens group which produces a real image on an image plane. Rules or conditions are stated, and several specific examples are given. In many of the examples, the back focus distance is relatively large, thus making the lens system suitable for use with a mirror reflex camera where room is needed for swinging the reflex mirror.

HIGH SPEED WIDE ANGLE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

This invention relates to objectives such as used on cameras or other optical equipment, for forming a real image on photographic film or other suitable receiving surface. The object of the invention is to produce what may be regarded as a new species of extremely high speed wide angle objective, with relatively long back focus so that there is ample space for swinging a reflex mirror if it is desired to use the objective with a single lens reflex camera. A high quality image is produced, with a usable diameter of the entrance pupil which is greater than 0.73 times the equivalent focal length of the entire lens system.

Reference is made to German Pat. Nos. 1,187,393, published on 18, Feb. 1965, and 1,250,153, published on 14 Sept. 1967, both granted for inventions of Erhard Glatzel, one of the joint inventors of the present U.S. application. The present invention may be regarded as an improvement on the lenses disclosed in these German patents.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a lens diagram illustrating the general features of one embodiment of the present invention; and FIGS. 2–15 are similar lens diagrams illustrating other embodiments.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The objective lens system of the present invention (sometimes referred to herein, for brevity, merely as a "lens" or an "objective") may be described in general as a composite structure having a rear section or group or member similar in general to an ordinary conventional objective, these parts being collectively identified in the accompanying lens diagrams by the letter O. In front of this rear group or objective portion of the complete system, there is placed a plurality of components constituting, in effect, a Newtonian finder objective, designated as a whole in the lens diagrams by the letters NS. This Newtonian section NS, in turn, may be regarded as having two groups or members, a front group NN of diverging or negative optical power, and behind it a converging or positive ocular group NO.

The light from a distant object is front of the lens enters first the diverging group NN and passes through it, then entering and passing through the converging ocular group NO, and then enters the main objective group O in a bundle of rays approximately parallel to the optical axis, although possibly slightly diverging or slightly converging when the rays reach the first surface of the objective group O. In designing a lens of this special type with which the present invention deals, it is found that, especially when a lens of very high speed and wide angular field of view is desired, certain rules or conditions or limits of relationship of the parts to each other should be observed in order to obtain a high quality image free of troublesome aberrations. These conditions or limits, compliance with which is found to be highly desirable, may be briefly stated as follows:

1. The focal length of the diverging group NN at the front of the Newtonian finder telescope section is not less than 0.106 times and not more than 0.690 times the focal length of the converging ocular group NO of the Newtonian telescope section NS. This feature or condition gives assurance that, on account of the reducing effect of this relationship, the beam or rays entering the system from the distant object can, on account of the diverging action of this Newtonian or reverse Galilean telescope system, enter the main objective O with from 1.53 to 2.73 times the bundle heights and thus with from 2.3 to 7.45 times the bundle cross sectional areas entering from the object side. On the other hand, due to the limitation in downward direction of the reduction scale, there is no need to have excessively strong collecting refractive powers in the main objective group or member O which produces the real image, and which would lead to an increase in the aberrations of higher order both in the central field and in the lateral image field. This possible disadvantage can be successively eliminated when the relationship of the group NN to the group NO is within the limits just mentioned.

2. This diverging group NN has at least three components, one of which, at or near the front of this group, is a negative component having a rear surface bounded by air and concave toward the rear of the system, another of which is a positive component located behind the negative component just mentioned, and a third one of which is another negative component located behind the positive component and having a rear surface concave toward the rear and constituting the rearmost surface of this diverging group NN.

3. The converging ocular group NO should be spaced rearwardly from the diverging group NN sufficiently to provide between them an air lens of diverging action having a paraxial surface refractive power sum (ϕ_t) which has a negative numerical value not less than 0.948 times and not more than 1.808 times the equivalent refractive power (Φ) of the entire lens system.

4. In contrast to the conventional Newtonian telescopic finder system, which usually has only a single element ocular portion, the ocular group NO according to the present invention has a plurality of components spaced axially from each other to provide an air lens of collecting action followed by a positive components, such air lens acting to provide, for a middle bundle of rays, a strongly divergent ray path bent by the positive component to a ray path differing only slightly from a paraxial course, that is bent to a course which may be slightly divergent or slightly convergent, if not exactly parallel to the optical axis. Thus the lens designer operating in accordance with the teaching of the present invention is not forced to design the Newtonian system NS to produce a strictly telecentric course of the rays from the rear surface of the Newtonian system to the entrance of the objective group O, but it is entirely possible to design the part NS so that the rays enter the part O with a slight convergence or divergence, when this may be desirable for the sake of fine correction of the entire system. This freedom of choice to produce slight convergence or divergence at this point would result in only an insignificant dioptric effect on the fundamental properties of the main objective O and/or the back focus of the entire objective system.

5. The main objective group or portion O should have a paraxial intrinsic focal length (f_O) which is not less than 1.53 times and not more than 2.73 times the equivalent focal length (F) of the entire lens system. The importance of this design rule or condition will be understood when it is borne in mind that if the stated upper limit is exceeded, the difficulties in obtaining a

high relative aperture increased progressively in an undesirable manner, while if the lower limit is violated, this would read to an increase in the aberrations of higher order. These undesirable consequences are successfully eliminated by following the design rules or conditions above set forth, thereby giving the optical designer great freedom in the arrangement of many lens details, as may be readily noted by observing the details of the specific examples given below, and noting, in comparing one example with another, how many of these details can be varied.

The new lens system of the present invention can be provided in a particularly advantageous manner with one or two aspherically shaped lens surfaces, in order to carry out specific correction processes by means of the aspherical surfaces. Thus the possibility is established of maintaining a large number of the individual lens elements free of specifically these partial effects of the correction process, as for instance for utilization of the reduction of aberrations of a higher order. It will be noted from some of the examples that the aspherical surfaces can be introduced with great advantage not only in the main objective assembly or group (O) which produces the real image, but also, in a manner both effective and surprising, in the Newtonian system assembly (NS).

It may be mentioned here that when considering the various limits or ranges of variable factors as mentioned above, it is customary to allow a tolerance of less or minus 5%.

The various examples of the following tables illustrate that many of the components can be formed either as single individual lens elements, or as doublets or other split components formed of a plurality of individual lens elements. Frequently, but not necessarily, the neighboring radii of curvature are made the same both in size and in sign, so that they may be cemented if desired. It may be pointed out in this connection that the lens diagrams which illustrate various embodiments of the invention are to be regarded as "exploded" view, with adjacent lens surfaces slightly separated from each other for the sake of clarity of illustration, even though in the data tables it may be indicated that there is zero spacing, denoting a cemented surface.

In the data tables, all linear measurements such as radii, thicknesses, and spacings are not given as absolute dimensions, but rather are stated as proportions of the equivalent focal length (F) of the entire objective lens system, which is considered as unity. That is, F = 1.00000. The individual lens elements are indicated by the letter L with a subscript corresponding to the number of the individual lens element as numbered consecutively from front to rear, except that in some instances two or more related lens elements are given the same numerical subscript followed by a letter of the alphabet to distinguish one from another.

The notations or symbols used in the data tables and also in the lens diagrams are in accordance with the notations and symbols often used in many lens patents, and will be well understood by those skilled in the art. For instance, the radii of curvature of the front surface and the rear surface of each element are indicated by R and R', respectively, with a subscript indicating the number of that particular element. Positive values of R or R' indicates surfaces convex toward the front of the lens, and negative values indicates surfaces concave toward the front, in accordance with customary usage. The end of the lens toward the distant object or longer conjugate is referred to for convenience as the front, and the end toward the image (that is, toward the camera, if the lens system is used on a photographic camera) is referred to for convenience as the rear of the lens. The light is assumed, in accordance with conventional lens patent practice, to enter from the front, and to pass through the lens from left to right.

The axial thicknesses of individual lens elements are indicated in the tables by the letter d with a subscript identifying the particular element. Axial spacings between elements are indicated by the letter s likewise with a subscript, but in the case of these spacings, the subscript refers to the identifying number of the lens in front of and the lens behind the space is question. Zero spacing indicates elements cemented to each other. All spacings greater than zero refer to air spacings. The lens elements or groups of elements which may be regarded or submembers are indicated by Roman numerals.

The index of refraction is indicated by n with a subscript identifying the lens element, in some of the tables. In other tables, the indices of refraction are given in a column headed n_d for the sake of compactness when the data also include the Abbe number or dispersive index, stated in an adjacent column headed v_d. When an objective is designed for use in only a very narrow spectral range, the refractive index refers specifically to this narrow range. If the lens system is to be used over a wide spectral range, as for example in color photography, then instead of monochromatic image error correction, achromatism should be brought out over the wider spectral range required. For this purpose, in known manner, the glasses used in the elements are to be chosen so that the color dispersion of the glasses used serves to eliminate the chromatic deviations or errors due to the wavelengths which enter into consideration.

During the course of development of this invention it was found, by way of confirmation, that upon the development of the so-called preforms or initial forms of the objectives, and then during the course of the following technical rough development to produce a rough form in known manner with the first correction normally customary in the Seidel range (third order), the use of one of the standard refractive indices can take place in a routine manner. A convenient index to use for this purpose is the index of refraction for the yellow d-line of the helium spectrum, with a wavelength of 5876 Angstrom units. Data for this wavelength are customarily shown in many commercial catalogues of manufacturers of optical glasses.

In the heading of each data table there is indicated the figure number of the particular lens diagram which is intended to illustrate the specific example in the table. In this connection it should be borne in mind that the lens diagrams are not intended to be drawn strictly to scale, but are intended merely to furnish a quick visual indication of the general characteristics of the particular specific example. Thus a single lens diagrams is sufficient to illustrate two or more specific examples which are of the same general configuration but which may differ somewhat from each other in thicknesses, spacings, curvatures, or other factors.

The specific example tables also indicate, in each case, the relative aperture for which the particular example is intended, expressed as a conventional f number, and the angular field of view, expressed in degrees, and the back focus from the axial vertex of the

last lens element to the focal plane (for an object at infinity) expressed in proportion to the equivalent focal length (F) of the entire objective lens system. The heading of each table also indicates the diameter of the entrance pupil, expressed in proportion to the equivalent focal length (F) of the entire system, and the refractive power of the entire Newtonian finder telescope system NS expressed in proportion to the refractive power (ϕ) of the entire object lens system as a whole.

The first five examples relate to embodiments of the invention which are developed with only spherical surfaces. Then, in examples 6–15, data are given for ten additional embodiments of extremely high image-forming ability, which are provided with aspherical surfaces. As already indicated, the lens system of the present invention is particularly suitable and advantageous for introduction of aspherical surfaces to provide a very high quality of image.

In these examples, the possible breaking down of lens components by splitting into a plurality of individual elements is shown both by the data in the tables, and pictorially in the lens diagrams, both for the negative group NN and for the ocular group NO of the Newtonian finder telescope NS. Possible splitting of components within the main objective part O which forms the real image, is also indicated both pictorially and by the data in the tables.

A few comments on some of the specific examples will be given, before turning to the actual data tables themselves. In example 1 (illustrated by the diagram in FIG. 1). there is given a compilation of data for a preform of a lens system according to the invention, intended for a relative aperture of f/1.35 and a total field angle of 52°, in which the Newtonian finder telescope (NS) is constructed in the simplest fashion from a three part Newtonian negative or diverging group (NN) and a two part Newtonian ocular (NO), the entire objective being provided with a monochromatic precorrection in the Seidel range of third order.

Example 2 (FIG. 2) shows an embodiment in which the Newtonian occular (NO) has a total of three individual elements, in which a doublet of diverging action which is concave toward the front is split into two individual elements of opposite sign of power. This is followed by a biconvex lens element. In order to illustrate the wide possibilities of development opened up by the new principle of design, this biconvex lens element is shown as an equal sided or equiconvex lens, constituting the last element of the Newtonian finder telescope (NS) at the rear end thereof. This embodiment of the invention is contemplated for an angular field of view of 53° and a relative aperture of $f/1.33$ and a corresponding entrance pupil diameter of 0.752 F. It is monochromatically precorrected in the region of the third order. The back focus, for an object at infinity, is somewhat greater than 1.40 F, thus allowing room for installing this lens system in mirror reflex cameras currently on the market.

In contrast to this, the structure in example 3 (illustrated in FIG. 3) has the collecting component of the Newtonian ocular (NO) split into two individual lens elements with refractive power of the same sign, so that the lens designer working in accordance therewith is shown, based on these data, this specific development within the scope of the present invention. This practical example is intended for a total field angle of 60° and an entrance pupil diameter of 0.769° F, corresponding to a relative aperture of f/1.30. It is monochromatically precorrected in the third order Seidel range, since there is here concerned an extremely high speed lens system for the recording of substantially monochromatic signals which lie within a very narrow spectral range.

The same is also true of all those examples which give only the refractive indices of the glasses without mention of the Abbe numbers or dispersive indices. On the other hand, examples 4 and 5 are embodiments designed for forming an image of multi-color objects within the visible spectrum, and accordingly the types of glasses used are characterized by giving both the refractive indices and the Abbe numbers, which assure achromatization over the required broad spectral range of visible light.

The same method is also taken as a basis for the following examples, which are equipped with aspherical surfaces for further correction of aberrations and enhancement of image quality. In examples 6 and 13, only one aspherical surface has been introduced into the system. In examples 7–12 as well as examples 14 and 15, two aspherical surfaces are provided in each example.

In order to prove the broad scope of use which is opened up so successfully for practical use by the new principle of design and its concrete rules of technical action, it is shown by way of demonstration in the following data tables that such aspherical surfaces can be arranged either in the Newtonian finder telescope portion or section (NS) of the system, or in the main objective portion or section (O) which produces the real image, or in both of such sections. Likewise, aspherical surfaces can be used either in the entrance part (EO) of the main objective (O), or in the rear portion of this main objective (O), or in both.

The aspherical development of a deformed surface is determined by the known camber expression:

$$P = c_1.H^3 + c_2.H^4 + c_3.H^8 + c_4.H^8 + c_5.H^{10},$$

wherein H is the height of the perpendicular to the axis at its specific place of surface penetration. The values of the coefficients c for each individual example including an aspherical surface are given at the end of the appropriate data table. It is also shown by the data that two or more neighboring surfaces can be combined to form pairs of cemented surfaces in the main objective part (O).

It should be emphasized that the previously mentioned characteristic enlargement (V_{NS}) as known applies strictly to the region of Gaussian dioptrics only when the paraxial rays from the Newtonian finder telescope (NS) and therefore also from the Newtonian ocular (NO) emerge "telecentrally," and thus have an infinitely long image distance at this place. In practice, as in certain telescopes or Galilean glasses, the course of such rays will frequently not be precisely telecentric, but will emerge from the telescope system with a back focus which is numerically very long. It is known to the optical designer to use the reciprocal of such an accidentally occurring very long back focus with reversed sign of the power for the arithmetical compensation for the determination of the strict paraxial enlargement (V_{NS}) in the same way as is customary in the case of a practical telescope system, to bring about the precise telecentric ray path on the side of the eye of the observer, simply by accurate focusing adjustment of the ocular. The corresponding above treatment of the ar-

ithmetical determination of the strict value of the paraxial enlargement of the finder telescope part is also indicated for the new objectives of the present invention, whenever no ocular adjustment is provided between the diverging objective (NN) and the collecting ocular (NO) and the internal spacing distance between them (s_i) is thus constant.

In the case of objective lens systems for installation, for example, in motion picture cameras, these fast objectives of the present invention may be given relatively extremely long structural length, for additional reduction of aberrations of higher order. Furthermore it may be desirable to provide these objectives with a very long back focus, for example in order to facilitate the mechanical arrangement of fixed or movable deflection elements between the last lens element and the image plane. Examples 16–20 indicate that, in accordance with the present invention, it is possible to produce such systems with entrance pupil diameters which can be increased to more than 0.95 times the equivalent focal length (F) of the entire objective.

It should be mentioned that in the specific examples which include aspherical surfaces, the value given in the data table for the radius of the aspherical surface refers to the vertex radius of the surface in question, at the axial vertex point at the place of passage of the optical axis.

In order to show the breadth of use of the new principle of design in accordance with the present invention, numerical values for certain partial features of the various examples are given in the following tables I and II. The numerical values given in these tables are the rounded-off results of a multi-place computation by digital electronics. In each case the values are stated with respect to the total equivalent focal length (F) considered as unity, of the entire objective lens system as a whole, or with respect to the total refractive power (Φ) of the entire system. Of course the refractive power is the reciprocal of the focal length, as well understood in the art.

From the numerical values of the individual focal length (f_{NN}) of the Newtonian negative component (NN) on the one hand, and the air lens refractive power (ϕ_l) of the air lens between this group and the following ocular group (NO) on the other hand, it can easily be noted by comparing these two numerical values, with due consideration to their common negative sign, that in fact a very strong divergent ray path prevails within the Newtonian ocular (NO) for the central bundles of rays, which accordingly also continues into the lateral area of the image.

In the last vertical column of table II, there is an indication of which claim or claims, among the first five claims, is intended to relate to the particular example in question. This provides a good view of some of the relationships of different examples to each other, and of the intended scope of the claims which are expressed in general language, as distinguished from claims containing specific tabular data.

What is claimed is:

1. An extremely high speed wide angle objective lens system for forming an image of a distant object in front of said system on an image plane in rear of said system, said lens system comprising in succession from front to rear

1. a diverging group (NN) composed of a plurality of components,

2. a converging ocular group (NO), and

3. a main objective group (O) serving to form a real image on said image plane in rear of said main objective group,

said diverging group (NN) and said converging ocular group (NO) together forming a Newtonian finder telescope (NS) in the nature of a reverse Galilean telescope, said groups being so formed and dimensioned and so related to each other that

4. the focal length of said diverging group (NN) is not less than 0.106 and not more than 0.690 times the focal length of said converging ocular group (NO), and

5. said diverging group (NN) has at least three components,

i. of which is a negative component having a rear surface which is bounded by air and which is concave toward the rear,

ii. another of which is a positive component located behind said negative component, and

iii. another of which is a negative component located behind said positive component and having a rear surface which is concave toward the rear and which constitutes the rearmost surface of said diverging group (NN),

iv. there being an air lens of diverging action between said first mentioned negative component and said positive component, and an air lens of converging action between said positive component and said other negative component,

6. said converging ocular group (NO) is spaced rearwardly from said diverging group (NN) to provide between them an air lens of diverging action having a paraxial surface refractive power sum (ϕ_l) which in negative numerical value is not less than 0.948 and not more than 1.808 times the equivalent refractive power (Φ) of the entire lens system,

7. said converging ocular group (NO) has a plurality of components spaced axially from each other to provide an air lens of collecting action followed by a positive component, such air lens acting to provide, for a middle bundle of rays, a strongly divergent ray path bent by said positive component to a ray path differing only slightly from a paraxial course,

8. said main objective group (O) has a plurality of components receiving rays from said converging ocular group (NO) and transmitting them to produce a real image on said image plane, and

9. said main objective group (O) has a paraxial focal length which is not less than 1.53 and not more than 2.73 times the equivalent focal length of the entire lens system.

2. A lens system as defined in claim 1, wherein said main objective group (O) has an entrance component (EO) at the forward end of said group (O), said entrance component having two adjacent lens elements having an inner neighboring pair of surfaces (IN) which have a collecting surface power sum (ϕ_{IN}) not less than 0.167 nor more than 0.357 times the equivalent refractive power (Φ) of the entire lens system.

3. A lens system as defined in claim 1, wherein the forward one of said three components of said first diverging group (NN) comprises at least two negative lens elements separated by an air space shaped to provide an air lens of diverging action, through which light rays entering the front of the lens system must pass before entering the next succeeding one of said three components of said diverging group (NN).

4. A lens system as defined in claim 1, wherein said converging ocular group (NO) includes a component split into two adjacent individual lens elements.

spacings being expressed in proportion to the equivalent focal length of the entire system, which is considered as unity:

[57] **ABSTRACT**

An optical apparatus is provided with an objective and an autocollimation lens having a position and orientation bearing a known relationship to the position and orientation of the objective. A grating has alternating transmissive and non-transmissive portions. The grating is so positioned relative to the autocollimation path of the autocollimation lens that the latter projects an image of the grating onto the subject, and the image of the grating on the subject is projected back onto the grating. A photoelectric detector derives from the light projected back onto the grating an electrical signal indicative of the degree of focus of the objective. The setting of the objective is controlled in dependence upon the electrical signal.

METHOD AND ARRANGEMENT FOR AUTOMATICALLY FOCUSSING AN OBJECTIVE ONTO A SUBJECT, USING AUTOCOLLIMATION

BACKGROUND OF THE INVENTION

The invention relates to a method and arrangement for automatically focussing an objective onto a subject or test object. More particularly, the invention relates to automatic focussing expedients involving autocollimation and the use of gratings for generating an electrical signal which can be used to control the operation of means for automatically adjusting the setting of the objective.

It has been many times proposed (for example in Federal Republic of Germany published patent application DT-OS **1,908,687**) to use gratings or rasters located in the autocollimation beam path of a camera objective or autocollimation objective. Specifically, these known expedients have involved the projection of the image of one grating onto the subject or test object. Then the image, on the subject, of the first grating is projected, using autocollimation, onto the second grating. The extent to which the image of the first grating registers with the second grating is detected photoelectrically, by detecting the intensity of the light projected onto the second grating, and an electrical signal is generated for controlling electromechanical means for effecting proper or optimal focussing of the objective.

The known proposals for effecting automatic focussing in this way have not, to our knowledge, met with any practical success. The reason for this, at least in part, is that the use of two discrete gratings or rasters is relatively complicated and expensive, because they must be properly adjusted relative to each other and kept properly adjusted with very great precision.

SUMMARY OF THE INVENTION

It is a general object of the invention to provide a method and arrangement for effecting automatic focussing of an objective in which use can be made of only a single grating or raster in the autocollimation path of the objective or separate autocollimation lens.

According to the most general concept of the present invention, this object is achieved by projecting the image of the light-transmitting portions of the grating onto the subject or test object, and then projecting such image on the subject back along the autocollimation path onto the selfsame grating.

In this way, it becomes possible to dispense altogether with the second grating, obviating the necessity for the complicated and difficult fine adjustment of the relative positions of the two gratings.

The invention also embraces a number of particular concepts concerning the disposition of components of an optical system to effect the above-mentioned action in a variety of ways. However, these will best be understood from the description, below, of preferred embodiments.

The novel features which are considered as characteristic for the invention are set forth in particular in the appended claims. The invention itself, however, both as to its construction and its method of operation, together with additional objects and advantages thereof, will be best understood from the following description of specific embodiments when read in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** depicts a first embodiment of the invention in which the grating employed in a transmission-absorption grating;

FIG. **2** depicts a second embodiment of the invention in which the grating employed is a transmission-reflection in which the grating employed is a transmission-reflection grating;

FIG. **3** depicts a third embodiment of the invention in which the grating employed is comprises of alternating first and second portions, with the first portions being transmissive and the second portions being inclined reflecting surface portions;

FIG. **3***a* is an enlarged-scale view of a portion of the grating of FIG. **3**; and

FIG. **4** depicts a fourth embodiment of the invention in which the grating employed is a transmission-reflection grating arranged at an angle relative to the autocollimation path.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In the embodiment of FIG. **1**, a source **1** of modulated light transmits light through a condenser **2** through an inclined semitransmissive mirror **7** towards an absorptiontransmission grating **4**. The grating **4** is comprises of light-transmissive portions which alternate with nontransmissive portions. The light passing leftwards through the transmissive portions of grating **4** is projected by an autocollimation objective **3** onto the subject or test object **5**, to form on the subject **5** an image of the transmissive portions of the grating **4**. The light from the image on the subject **5** is reflected back towards the autocollimation objective **3**, which in turn projects the light image on the subject **5** back onto the grating **4**. The back-reflected light passing through the transmissive portions of grating **4** impinges upon the front surface of semitransmissive mirror **7** and is deflected out of the autocollimation path towards a photoelectric detector **6** operative for generating a signal whose value is indicative of the intensity of received light.

The electrical signal generated by the photoelectric detector **6** serves as a control signal applied to means **10** for adjusting the settings of the autocollimation objective **3** and of an associated camera objective **12**. The autocollimation objective **3** can be shifted in the directions indicated by the double-headed arrow **M**, and the adjusting means **10** also effects corresponding shifting adjustment of the camera objective **12**.

The construction of the adjusting means **10** does not as such form part of the present invention. However, by way of example, the adjusting means **10** can be comprised of a positioning motor activatable by the user of the camera to move the autocollimation objective **3** and accordingly the camera objective **12** through their entire range of distance settings. During the performance of this range of movement, the value of the photoelectric signal applied to adjusting means **10** will change. The adjusting means **10** can include a resettable circuit for detecting and registering an extreme value of the light-indicating signal. Thereafter, the adjusting means **10** causes the autocollimation objective **3** and the camera objective **12** to be moved once more through their entire range of distance settings. However, during the movement, as soon as the value of the light-indicating signal reaches the extreme value regis-

tered during the preceding cycle of movement, the adjusting motor stops, so that the autocollimation objective 3 and camera objective 12 will assume and maintain the position corresponding to the extreme value of the light-indicating signal. These positions are assumed to correspond to proper, or at least optimal, focus. It will be understood that the manner of operation of the adjusting means 10 just explained could be principle be different.

In the embodiment of FIG. 1 the splitting of the light beam does not occur until after the light, during its return trip, passes through the transmissive portions of the grating 4 a second time. In this embodiment, the extreme value to which the adjusting means 10 responds will be the maximum light intensity value as indicated by the maximum photocurrent.

It will be understood that the adjusting means 10 can adjust the distance settings of autocollimation objective 3 and of camera objective 12 in two separate but simultaneous actions, or else adjust the setting of only one of the objectives, with the other objective being connected, via a suitably designed linkage, to assume predetermined settings pre-correlated with the settings of the first objective.

In the embodiment of FIG. 2, the grating 4*a* is a transmission-reflection grating. It is comprised of alternating transmissive and non-transmissive portions. The non-transmissive portions, at the side of the grating facing towards the subject or test object 5, are mirrored so as to be reflecting.

In the embodiment of FIG. 2, the modulated light from source 1 is projected by condenser 2 through the transmissive portions of grating 4*a*, and through a semitransmissive mirror 7*a* towards an autocollimation objective 3 which projects an image of the transmissive portions of the grating 4*a* onto the surface of the subject or test object 5. At the same time, the autocollimation objective 3 projects an image of the light image on subject 5 back through semitransmissive mirro 7*a* onto the grating 4*a*. It will be noted that in the embodiments of both FIGS. 1 and 2 the grating is located in the back focal plane of the autocollimation objective 3. The light projected back onto the grating 4*a* is reflected off the reflecting grating portions towards the back side of semitransmissive mirror 7*a*, and from there is reflected towards the photoelectric detector 6. The signal generated by photoelectric detector 6 is utilized to control the adjusting means 10 in the manner described with respect to FIG. 1. In the embodiment of FIG. 2, however, the objectives 3 and 12 are automatically stopped in positions corresponding to minimum light intensity and minimum value of the photocurrent.

In the embodiment of FIG. 3, the grating 4*b* employed is comprised of alternating first and second portions. The first portions are simple transmissive portions. The second portions have inclined mirrored surfaces each making an angle with respect to the general plane of the grating 4*b*. The grating 4*b* of FIG. 3 is depicted, on a larger scale and in somewhat greater detail, in FIG. 3*a*. The use of a grating 4*b* having the illustrated inclined reflecting surfaces makes unnecessary the use of the separate semitransmissive mirrors 7 and 7*a* of FIGS. 1 and 2.

IN the embodiment of FIG. 3, modulated light from source 1 is projected by condenser 2 through the transmissive portions of grating 4*b* towards the autocollimation objective 3. The autocollimation objective 3 projects an image of the transmissive portion of the grating 4*b* onto the surface of subject or test object 5. At the same, the autocollimation objective 3 projects an image of light image on subject 5 back towards the surface of grating 4*b*. The part of the back-reflected light incident upon the reflecting inclined surface portions of grating 4*b* are deflected out of the autocollimation path towards the photoelectric detector 6. In other respects, the automatic focussing is performed as explained with reference to FIGS. 1 and 2.

In the embodiment of FIG. 4, use is made of a transmission-reflection grating 4*c* comprised of alternating transmissive and non-transmissive portions, with the non-transmissive portions being reflecting at the side of the grating4*c* facing towards the subject or test object 5. In FIG. 4, the light source 1 is not lined up with the optical axis of the autocollimation objective 3. Instead, the light source 1 cooperates with a pivotally mounted mirror 8 which deflects light from source 1 towards a cylindrical lens 9 to effect a linewise or strip-formed illumination of the grating 4*c*. The angle of inclination of grating 4*c* relative to the optical axis of autocollimation objective 3 is no selected that, during each period of movement of the pivotal mirror 8, the system goes through its whole range of distance settings. However, if the autocollimation objective 3 has a short focal lenght, which is usually the case, there may not be space enough in the lens arrangement to allow the deflection of a sufficient amount of light out of the autocollimation path and towards the photodetector 6. With this in mind, use is preferably made of the type of grating depicted in FIGS. 3 and 3*a*, to increase the angle of deflection of the back-reflected light, and use is furthermore preferably made of a field lens 13 whch serves, in a per se conventional manner, to increase the intensity of the light.

The arrangement of FIG. 4 operates somewhat differently from the arrangements of FIGS. 1–3. In FIGS. 1–3, the autocollimation objective 3 and the camera objective 12 were both moves through their whole range of distance settings and then stopped at the setting corresponding to an extreme value of the photocurrent generated by photodetector 6. In FIG. 4, however, the autocollimation objective 3 is not moved during the automatic focussing operation. Instead, the setting of the camera objective 12 is correlated with the angular position of the pivoting mirror 8. During a first or test run-through, the adjusting means 10 moves the camera objective 12 through its entire range of distance settings while simultaneously moving the pivotaing mirror 8 through its entire range of pivotal movement. For example, the camera objective 12 and the pivoting mirror 8 can be connected by a suitably designed linkage. A circuit in the adjusting means 10 registers an extreme value of the photocurrent generated during this period of movement. The cycle of movement is then repeated, and the pivoting mirror 8 and camera objective 12 are stopped when they reach a position corresponding to the extreme photocurrent value registered during the preceding cycle of movement. In this embodiment, the extreme value in question will be a photocurrent minimum.

In the foregoing embodiments, use has been made of an autocollimation objective 3 discrete from the camera objective 12. However, it is also within the scope of the invention to utilize the camera objective itself to project the image of the light-transmissive grating portions back onto the grating.

It will be understood that each of the elements described above, or two or more together, may also find a useful application in other types of constructions and arrangements, differing from the types described above.

While the invention has been illustrated and described as embodied in an automatic focussing arrangement making use of separate camera and autocollimation objectives, it is not intended to be limited to the details shown, since various modifications and structural changes may be made without departing in any way from the spirit of the present invention.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can be applying current knowledge readily adapt if for various applications without omitting features that, from the standpoint of prior art, fairly constitute essential characteristics of the generic or specific aspects of this invention.

What is clamed as new and desired to be protected by Letters Patent is set forth in the appended claims.

1. A method for automatically focussing onto a subject the objective of an optical apparatus provided with autocollimation lens means having a position bearing a predetermined relationship to the position of the objective, comprising the steps of so positioning a grating relative to the autocollimation path of the autocollimation lens means as to cause the latter to project an image of the grating onto the subject and to cause the image of the grating on the subject to be projected back onto the grating and into steady register with the grating structure to an extent dependent upon the degree of focus of the objective; using photoelectric means to derive from the light projected back onto the grating an electrical signal indicative of the extent to which the image of the grating projected back onto the grating is in steady register with the grating structure and accordingly indicative of the degree of focus of the objective; and controlling the operation of means for adjusting the setting of the objective by applying the electrical signal to such means.

2. The method defined in claim **1**, wherein the step of positioning the grating comprises using a absorption-transmission grating having alternating transparent and non-transparent portions and positioning the grating in the region of the focal plane of the autocollimation lens means at that side of the autocollimation lens means which faces away from the subject and intermediate the autocollimation lens means and semitransmissive mirror arranged intermediate the autocollimation lens means and a light source in such a manner that light from the light source is transmitted through the semitransmissive mirror and through the absorption-transmission grating, projected by the autocollimation lens means onto the subject, reflected back from the subject and projected back onto and through the grating onto the semitransmissive mirror, and reflected off the semitransmissive mirror to the photoelectric means.

3. The method defined in claim **1**, wherein the step of positioning the grating comprises using a transmission-reflection grating having alternating transmissive and reflecting portions and positioning the grating in the region of the focal plane of the autocollimation lens means at that side of the autocollimation lens means which faces away from the subject and intermediate a light source and a semitransmissive mirror arranged between the grating and the autocollimation lens means in such a manner that light from the light source is transmissive grating portions and through the semitransparent mirror towards the autocollimation lens means and projected by the latter onto the subject, reflected back from the subject projected back through the semitransmissive mirror onto the reflecting grating portions, reflected from the reflecting grating portions onto the semitransmissive mirror, and reflected from the semitransmissive mirror onto the photoelectric means.

4. The method defined in claim **1**, wherein the step of positioning the grating comprises using a grating having alternating first and second portions, the first portions being transmissive portions and the second portions being inclined reflecting portions lying in respective planes each oriented at an angle to the general plane of the grating, and positioning the grating in the region of the focal plane of the autocollimation lens means intermediate the latter and a light source with the inclined reflecting portions facing towards the subject and in such a manner that light from the light source is transmitted through the transmissive portions of the grating towards the autocollimation lens means, projected by the latter onto the subject, reflected back from the subject towards the autocollimation lens means, projected by the latter onto the grating, and reflected off the inclined reflecting portions of the grating onto the photoelectric means.

5. The method defined in claim **1**, wherein the step of positioning the grating comprises using a transmission-reflection grating having alternating transmissive and reflecting portions, positioning the grating in the region of the focal plane of the autocollimation lens means but inclined relative to the optical axis of the autocollimation lens means, projecting light through the grating using a light source and a pivotable mirror which receives light from the light source and reflects the received light towards the grating so that the light from the source passes through the grating, is projected by the autocollimation lens means onto the subject, is reflected back from the subject and projected by the autocollimation lens means onto the grating, and reflected off the reflecting grating portions at an angle to the optical axis of the autocollimation lens means and towards the photoelectric means, wherein the step of using photoelectric means to derive an electrical signal comprises pivoting the pivotable mirror until the electrical signal assumes a value indicative of a certain degree of focus.

6. A method for automatically focusing the objective of an optical apparatus onto a subject using autocollimation, comprising the steps of so positioning a grating relative to the autocollimation path of the objective as to cause the latter to project an image of the grating onto the subject and to cause the image of the grating on the subject to be projected back onto the grating and into steady register with the grating structure to an extent dependent upon the degree of focus of the objective; using photoelectric means to derive from the light projected back onto the grating an electrical signal indicative of the extent to which the image of the grating projected back onto the grating is in steady register with the grating structure and accordingly indicative of the degree of focus of the objective; and controlling the operation of means for adjusting the setting of the objective by applying the electrical signal to such means.

7. The method defined in claim **6**, wherein the step of positioning the grating comprises using an absorption-

transmission grating having alternating transparent and nontransparent portions and positioning the grating in the region of the focal plane of the objective at that side of the objective which faces away from the subject and intermediate the objective and a semitransmissive mirror arranged intermediate the objective and a light source in such a manner that light from the light source is transmitted through the semitransmissive mirror and through the adsorption-transmission grating, projected by the objective onto the subject, reflected back from the subject and projected back onto and through the grating ont the semitransmissive mirror, and reflected off the semitransmissive to the photoelectric means.

8. The method defined in claim **6,** wherein the step of positioning the grating comprises using a transmission-reflection grating having alternating transmissive and reflecting portions and positioning the grating in the region of the focal plane of the objective at that side of the objective which faces away from the subject and intermediate a light source and a semitransmissive mirror arranged between the grating and the objective in such a manner that light from the light source is transmitted through the transmissive grating portions and through the semitransparent mirror towards the objective and projected by the latter onto the subject, reflected back from the subject projected back through the semitransmissive mirror onto the reflecting grating portions, reflected from the the reflecting grating portions onto the semitransmissive mirror, and reflected from the semitransmissive mirror onto the photoelectric means.

9. The method defined in claim **6,** wherein the step of positioning the grating comprises using a grating having alternating first and second portions, the first portions being transmissive portions and the second portions being inclined reflecting portions lying in respective planes each oriented at an angle to the general plane of the grating in the region of the focal plane of the objective intermediate the latter and a light source with the inclined reflecting portions facing towards the subject and in such a manner that light from the light source is transmitted through the transmissive portions of the grating towards the objective, projected by the latter onto the subject, reflected back from the subject towards the objective, projected by the latter onto the grating, and reflected off the inclined reflecting portions of the grating towards the photoelectric means.

10. In an optical apparatus having an objective, an arrangement for automatically focussing the objective onto a subject, comprising, in combination, autocollimation lens means having a position and orientation bearing a predetermined relationship to the position and orientation of the objective; a light source located to that side of the autocollimation lens means which faces away from the subject; a grating having alternating transmissive and non-transmissive portions, the grating being located intermediate the light source and the autocollimation lens means and so positioned that an illuminated image of the grating is projected by the autocollimation lens means onto the subject, reflected back from the subject towards the autocollimation lens means and projected back onto the grating and into steady register with the grating structure to an extent dependent upon the degree of focus of the objective; photoelectric means operative for deriving from the light projected back onto the grating an electrical signal indicative of the extent to which the image of the grating projected back onto the grating is in steady register with the grating structure and accordingly indicative of the degree of focus of the objective; and adjusting means operative for adjusting the setting of the objective in dependence upon the electrical signal.

11. The apparatus defined in claim **10,** where in the grating is a transmission-absorption grating having alternating transmissive and absorptive portions, and further including a semitransmissive mirror located intermediate the grating and the light source and having a position and orientation such that light from the image of the grating on the subject reflected back onto the grating passes through the transmissive portions of the grating to the semitransmissive mirror and is reflected off the latter to the photoelectric means.

12. The apparatus defined in claim **10,** wherein the grating is a tranmission-reflection grating having alternating transmissive and reflecting portions, and further including a semitransmissive mirror located intermediate the grating and the autocollimation lens means and having a position and orientation such that light from the image of the grating on the subject reflected back towards the autocollimation lens means is projected by the latter through the semitransmissive mirror onto the grating towards the semitransmissive mirror, and reflected off the latter towards the photoelectric means.

13. The apparatus defined in claim **10,** wherein the grating is a grating having alternating first and second portions, the first portions being transmissive portions and the second portions being inclined reflecting portions lying in respective planes each oriented at an angle to the general plane of the grating, the grating being so positioned and oriented relative to the autocollimation path of the autocollimation lens means and relative to the photoelectric means that light from the image of the grating on the subject reflected back onto the grating is reflected off the inclined reflecting portions of the grating towards the photoelectric means.

14. The apparatus defined in claim **10,** wherein the grating is a transmissive-reflection grating having alternating transmissive and reflecting portions, the grating being located in the region of the focal plane of the autocollimation lens means but inclined relative to the optical axis of the autocollimation lens means, the position and orientation of the grating being such that light from the image of the grating on the subject reflected back onto the grating is reflected off the reflecting portions of the grating towards the photoelectric means, and further including a pivotally mounted mirror between the grating and the light source, and said adjusting means for adjusting the setting of the objective in dependence upon the electrical signal comprising means for adjusting the setting of the objective in dependence upon both the electrical signal and the angular position of the pivotally mounted mirror.

15. In an optical apparatus having an objective, an arragement for automatically focussing the objective onto a subject using the effect of autocollimation comprising, in combination, a light source located to that side of the objective which faces away from the subject; a grating having alternating transmissive and non-transmissive portions, the grating being located intermediate the light source and the objective and so positioned that an illuminated image of the grating is projected by the objective onto the subject, reflected back from the subject towards the objective and projected back onto the grating and into steady register with the grating structure to an extent dependent upon the degree of focus of the objective; photoelectric means operative

for deriving from the light projected back onto the grating an electrical signal indicative of the extent to which the image of the grating projected back onto the grating is in steady register with the grating structure and accordingly indicative of the degree of focus of the objective; and adjusting means operative for adjusting the setting of the objective in dependence upon the electrical signal.

16. The apparatus defined in claim **15**, wherein the grating is a transmission-absorption grating having alternating transmissive and absorptive portions, and further including a semitransmissive mirror located intermediate the grating and the light source and having a position and orientation such that light from the image of the grating on the subject reflected back onto the grating passes through the transmissive portions of the grating to the semitransmissive mirror and is reflected off the latter to the photoelectric means.

17. The apparatus defined in claim **15**, wherein the grating is a transmission-reflection grating having alternating transmissive and reflecting portions, and further

including a semitransmissive mirror located intermediate the grating and the objective and having a position and orientation such that light from the image of the grating on the subject reflected back towards the objective is projected by the latter through the semitransmissive mirror onto the grating, reflected off the reflecting portions of the grating towards the semitransmissive mirror and reflected off the latter towards the photoelectric means.

18. The apparatus defined in claim **15**, wherein the grating is a grating having alternating first and second portions, the first portions being transmissive portions and the second portions being inclined reflecting portions lying in respective planes each oriented at an angle to the general plane of the grating, the grating being so positioned and oriented relative to the autocollimation path of the objective and relative to the photoelectric means that light from the image of the grating on the subject reflected back onto the grating is reflected off the inclined reflecting portions of the grating towards the photoelectric means.

[57] **ABSTRACT**

An adjusting device for a television camera consists of a resilient tubular member which is arranged between the window of the pick-up tube and the objective and which is compressed when an adjusting member acts on the neck of the tube. The deformation of the tubular member enables accurate distance adjustment without it being necessary to rotate the objective or the housing.

DEVICE FOR ADJUSTING THE DISTANCE BETWEEN THE OBJECTIVE AND THE PICK-UP TUBE IN A TELEVISION CAMERA

The invention relates to a television camera comprising an objective, a pick-up tube and a device for adjusting a distance between the objective and the pick-up tube, the said device comprising a displacement mechanism, including a return mechanism, for the longitudinal displacement of the pick-up tube.

It is known to adjust the position of the objective with respect to the target of the pick-up tube in television cameras by screwing an objective holder until an optimum focussed image is obtained. The devices used consists of a threaded holder wherein the objective is mounted. The threaded holder usually comprises a blocking member, for example, in the form of an adjusting screw.

An adjustment problem occurs if the objective comprises a reflex view-finder which does not permit the rotation of the objective. In that case mechanical "prepositioning" must be performed, and the adjustment must be completed by a very restricted rotation of the objective. This final adjustment preferably does not amount to more than one-eighth revolution of the objective and is smaller as the distance between the viewfinder and the housing of the camera is smaller.

The invention has for its object to facilitate this adjustment by utilising a rigidly arranged objective and an axially displaceable pick-up tube.

A device for adjusting the distance between the objective and the pick-up tube in a television camera of the kind set forth according to the invention is characterized in that the displacement mechanism comprises a fixed ring which at least partly enclosed the pick-up tube, an abutment piece and an adjusting member, the abutment piece being arranged between the said adjusting member and the pick-up tube, the return mechanism comprising a resilient member which is arranged between the rigidly arranged objective and the movably arranged pick-up tube.

The return mechanism is mounted in a tubular element, the ends of which cooperate with circular edges formed on the objective holder and on the window of the pick-up tube. The movable mechanism comprises retaining means which, in a preferred embodiment, include a ring which grips the edge of the objective and/or of the tube.

The length of the return mechanism in the rest position is slightly larger than the final adjusting distance between the objective and the window of the pick-up tube.

The abutment piece is a component which can be secured, for example, to the pumping stem of the pick-up tube.

The tubular resilient element is made of plastic material.

The invention will be described in detail hereinafter with reference to the drawing.

FIG. 1 is a partial sectional view of a television camera comprising the device in accordance with the invention.

FIGS. 2 and 3 show embodiments of resilient members for an adjusting mechanism in accordance with the invention.

A television camera as shown in FIG. **1**, comprises a housing **1** which accommodates electronic circuits for operating a pick-up tube **2** and for the output of image signals. The housing **1** has connected to it an objective **3** and a reflex view finder **4**. The objective comprises a diaphragm **5**. The housing furthermore comprises a grip **6** which also serves for the passage of connection cables. The adjusting mechanism for the longitudinal displacement of the pick-up tube comprises a ring **7** wherein at least part of the pick-up tube is slid. This ring is fixed with respect to the camera housing by a supporting member **8** which is secured to the chassis of the housing, for example, by transverse connections **9**. A displacement member **10**, in this case consisting of a screw which cooperates with a nut or a thread in the chassis, enables displacement of the pick-up tube in the longitudinal direction via an abutment piece **11**. For accurate adjustment, it is necessary that the pick-up tube can remain in permanent contact with the displacement member; to this end, a return mechanism **12** is arranged between the pick-up tube **2** and the objective **3** or an element which forms part of the objective and which occupies a fixed position with respect thereto in the longitudinal direction such as, for example, the diaphragm **5**. In this preferred embodiment the return mechanism comprises a cylindrical resilient member.

In a further preferred embodiment, the cylindrical component has a thin or corrugated wall which enables deformation in the longitudinal direction. On its end this member can comprise portions having a larger thickness, so that the support by the round edges of the objective and the tube is enhanced. FIG. **2** is a sectional view of a preferred embodiment of such a cylindrical member, consisting of two portions, one of which is conical and fits, for example, on an objective having a diameter which is smaller than that of the window of the tube and which is contacted by a substantially cylindrical second portion **14**. The tubular member is provided on its outer surface with a ring **15** whereto a supporting member can be coupled which is secured either to the tube or to the objective. Due to the use of such a tubular member, decentring during assembly, when no pressure is yet exerted, is avoided.

FIG. **3** shows a further embodiment of a retaining means. A ring **16**, arranged on an end of a resilient cylinder, has an inner diameter which is adapted to the pick-up tube **2** or to that of a ring of the objective holder. A broken line indicates that the resilient cylinder can also have a conical shape. The cylinder can also be of a double construction, a conical or non-conical cylinder then being situated one on each side of the ring.

The resilient member is preferably of a plastic material by moulding.

The abutment piece **11** (FIG. **1**) is formed by a component of plastic material which is connected to the pumping stem of the pick-up tube or which is secured on the jacket of the pick-up tube.

The adjusting device is mounted, for example, as follows: a tubular member is secured against the objective, is arranged on the end of the pick-up tube or is accommodated in the supporting member, after which the pick-up tube is slid into the ring of the supporting member of the pick-up tube and is so pressed that the resilient member presses against the window as well as against the objective; subsequently, the abutment piece is positioned and is clamped lightly against the tube by the screw. The length of the resilient member is chosen such that adjustment is possible over a distance which is smaller than this length. The distance between the

window and the target of the pick-up tube is rather exactly defined, which enables determination of the maximum length of the resilient member.

Adjustment is effected by tightening the screw, thus compressing the resilient member; when the adjusting point has been passed, the resilient member will tend to retain the original height when the screw is turned in the opposite direction, thus pushing back the pick-up tube, the pick-up tube, the abutment piece and the displacement member then constantly being maintained on contact with each other. Blocking is effected in known manner, for example, by the clamping of a ring or by blocking by means of a screw. The resilient member offers the additional advantage that it constitutes a dust-tight chamber between objective and window of the pick-up tube.

What is claimed is

1. A television camera comprising an objective, a pick-up tube and a device for adjusting a distance between the objective and the pick-up tube, the said device comprising a displacement mechanism, including a return mechanism, for the longitudinal displacement of the pick-up tube, characterized in that the displacement mechanism comprises a fixed ring which at least partly encloses the pick-up tube, an abutment piece, and an adjusting member, the abutment piece being arranged between the said adjusting member and the pick-up tube, the return mechanism comprising a resilient member which is arranged between the rigidly arranged objective and the movably arranged pick-up tube.

2. A television camera as claimed in claim **1,** characterized in that the resilient member which forms part of the return mechanism consists of a deformable tubular component.

3. A television camera as claimed in claim **2,** characterized in that the tubular component comprises portions on its ends which can be coupled to circular edges of the objective and of the window of the pick-up tube.

4. A television camera as claimed in claim **3,** characterized in that the portions situated on the ends of the tubular component are formed by edges of the tubular component.

5. A television camera as claimed in characterized in that the tubular component is made of plastic material.

6. A television camera tube as claimed in claim **1** characterized in that return mechanism comprises retaining means.

7. A television camera as claimed in claim **6,** characterized in that the retaining means are formed by a ring.

8. A television camera as claimed in claim **6,** characterized in that the said retaining means are formed by at least one of the ends which grips the edge of the objective and/or the tube.

9. A television camera as claimed in claim **1,** characterized in that the length of the return mechanism in the rest position is slightly larger than the final adjusting distance between the objective and the window of the tube.

10. A television camera as claimed in claim **1,** characterized in that the abutment piece is a component which can be mounted on the sleeve of the tube.

WIDE ANGLE OBJECTIVE HAVING A NON-SPHERICAL SURFACE

BACKGROUND OF THE INVENTION

This invention relates to a wide angle objective for a single lens reflex camera.

Objectives for single lens reflex cameras are required to have a back focal length sufficiently long to permit for the quick return operation of the mirror mechanism. In single lens reflex cameras of 35mm format type, it is necessary that this distance be at least 36mm. Wide angle objectives for such single lens reflex cameras are constructed in the form of retrofocus lens in which concave lenses are arranged in the object-side of the lens system for the purpose of meeting the aforementioned requirement. These concave lenses contribute an increase in the back focal length to the lens system, but they have adverse effects on the correction of aberrations, because of the asymmetry of lens configuration of the resulting lens system with respect to the center thereof. Particularly barrel distortion and negative coma which are produced by the object-side concave lenses are more difficult to be corrected in high degree over the entire field. As the field angle of the objective increases, or as the overall focal length is decreased, it is necessary to increase the retro ratio, or the ratio of the back focal length to the overall focal length. As a result, the asymmetry of the lens configuration is intensified which complicates the correction of the aforementioned aberrations. Particularly with wide angle objectives which operate with a retro ratio of more than two, it is impossible to preserve a high standard imagery with respect to the aforementioned aberrations so long as all of the refracting surfaces in the lens system are spherical.

SUMMARY OF THE INVENTION

The present invention has for the primary object to provide a wide angle objective which operates with a retro ratio of more than two and of which the first surface counting from the front is configured in a non-spherical form such that the curvature is increased with distance from the optical axis by the use of which the barrel distortion and negative coma produced by the object-side negative meniscus lenses are corrected.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a diagrammatic view of an objective optical system according to Example **1** of the present invention.

FIGS. **2A, 2B, 2C** and **2D** are curves illustrating various aberrations of the optical system of FIG. **1.**

FIG. **3** is a diagrammatic view of an objective optical system according to Example **2** of the present invention.

FIGS. **4A, 4B, 4C** and **4D** are curves illustrating various aberrations of the optical system of FIG. **2.**

FIG. **5** is a diagrammatic view of an objective optical system according to Example 3 of the present invention.

FIGS. **6A, 6B, 6C** and **6D** are curves illustrating various aberrations of the optical system of FIG. **5.**

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Aberration correction of an optical lens system is facilitated by the provision of a non-spherical surface. For the most effective correction of the aforementioned distortion and coma aberrations by the non-spherical surface, it is preferred to arrange the non-spherical surface in a position where an extra-axial oblique pencil of light rays passes across it at a longest distance from the optical axis. This is because oblique aberrations are susceptible to the surface of higher incident height and because the axial aberrations are influenced by the surface to a smaller extent. For this reason, in the retrofocus objective in which an oblique pencil of light cuts across the first surface at a point extremely farther from the optical axis than the other surfaces. Therefore, if the most effective correction of aberrations is to be effected, the non-spherical surface is used in the place of the first surface.

On the other hand, as shown in FIGS. **1, 3** and **5,** the objective optical system in accordance with the present invention is constructed as comprising eight optically aligned lens members. A first member counting from the front comprises one or two negative meniscus lenses of forward convexities. A second member comprises a negative meniscus lens component of forward convexity which is in the form of either a singlet, or a doublet composed of a positive lens and a negative lens cemented together at their adjoining surfaces, or, if desired, it may be composed of a positive meniscus lens and a negative meniscus lens spaced apart from each other at a minute air space. A third member comprises a positive lens component with the front surface having a smaller radius of convex curvature which is in the form of either a singlet or doublet of a bi-convex lens and a negative lens cemented together. A fourth member is a negative meniscus lens of forward convexity. A fifth member comprises a bi-convex lens component which is in the form of either a singlet or a doublet composed of a positive meniscus lens and a bi-convex lens cemented together. A sixth member comprises a negative lens component of forward concavity which is in the form of either a singlet or a doublet composed of a bi-convex lens and a convex lens cemented together. A seventh member is a positive meniscus doublet of forward concavity composed of a bi-concave lens and a bi-convex lens cemented together. An eighth member is a bi-convex lens. A diaphragm is located between the fifth and sixth members.

Further, the retrofocus objective of the construction described above has the first surface which is configured in a non-spherical form represented by the general formula

$$X = \frac{Y^2}{R_1 - R_1\sqrt{1 - \left(\frac{r}{R_1}\right)^2}} + BY^4 + CY^6 + DY^8 + EY^{10} + \ldots .$$

wherein

X : The abscissa taken along the direction of incoming light on the optical axis.

Y : the ordinate perpendicular to the abscissa

R_1: the radius of curvature of the first non-spherical surface at the vertex, being characterized in that

$$\frac{0.0005}{f^3} < B < \frac{0.1}{f^3}$$

wherein f is the overall focal length of the system.

This non-spherical surface is in such a form that the curvature is increased with distance from the optical axis. Particularly by defining the non-spherical coefficient of the fourth order term as $0.0005/f^3 < B < 0.1/f^3$, the aforementioned aberrations which are introduced by the object-side concave lenses into the lens system can be well compensated for. When the lower limit is violated, the correction of the aforesaid aberrations is more difficult to accomplish. When the upper limit is violated, the correction of astigmatism and higher order aberrations are more difficult to accomplish.

The relationship set out above facilitates the correction of various aberrations of the retrofocus wide angle objective. As far as the best lens design is concerned, the high degree of correction is obtainable by the use of certain relationships set out in detail below. The relationships are particularly concerned with the negative meniscus lens of the fourth member arranged in rear of the plurality of negative meniscus lenses and a positive lens, the bi-convex lens of the fifth member arranged just in front of the diaphragm and the positive cemented meniscus lens of the seventh member arranged beyond the sixth member rearwardly from the diaphragm.

$$0.7 < |R_s| < 2.0\ R_s < 0 \quad (1)$$

wherein R_s is the radius of curvature of the rear surface of the fifth member, or of the surface just in front of the diaphragm.

$$\overline{Na} < \overline{Nb} \quad (2)$$

wherein $\overline{Na}$ is the average value of the refractive indices of all the positive lens elements in the objective, and $\overline{Nb}$ is the average value of the refractive indices of all the negative lens elements in the objective.

$$1.65 < N_{IV} < 2.0 \quad (3)$$

wherein N_{IV} is the refractive index of the fourth member, or in general, of the negative lens arranged in front of the positive lens just in front of the diaphragm.

$$0.2 < (N_{VIIb} - N_{VIIa}) < 0.5 \quad (4)$$

wherein N_{VIIIa} is the refractive index of the positive lens in the seventh member, or in general, the cemented lens component in the rear of the negative lens component just in rear of the diaphragm, and N_{VIIb} is the refractive index of the negative lens in the same lens component.

These relationships have the following meanings. Relationship (1): In order to effect a good state of correction of coma aberrations it is necessary that the surface just in front of the diaphragm is of relatively strong convex curvature to produce a positive coma which is balanced with the negative coma introduced into the system by the object-side concave lenses. When the upper limit is violated, a good state of correction of coma is made difficult. When the lower limit is violated, spherical aberrations and astigmatism deteriorate. For a severer condition, the upper limit may be defined as 1.7.

Relationship (2) facilitates the compensation for over-correction of curvature of field which becomes serious in the retrofocus wide angle objective. By selecting all the concave lenses having an average refractive index higher than the average refractive index of all the convex lenses, the Petzval sum is prevented from being over-corrected and the curvature of field is reduced.

Relationship (3) cooperates with relationship (2) to reduce the positive spherical aberrations as well as field curvature of the fourth member by selecting a particularly high refractive index glass for employment in the fourth member of particularly strong curvature.

Relationship (4): as the refractive index of the negative lens in the seventh member is comparatively higher than that of the positive lens thereof, a diverging action is imparted to the cemented surface at the adjoining lens surfaces of the doublet composed of these negative and positive lenses so as to influence in a desirable manner the correction of extra-axial aberrations. This correction operates effectively with the marginal portions of the image so that a good state of correction of field curvature, coma and distortion is preserved over the entire field. For severer conditions, the lower limit may be defined as 0.25.

Three examples of a specific wide angle objective optical system may be constructed in accordance with the numerical data given in Tables 1 through 12 below with respect to the characteristics of the various elements of the lens system and their spatial relationships to each other, non-spherical surface factors and aberration coefficients. As is evident from the aberration curves in FIG. 2, a lens system constructed according to the specified numerical data in Table 1 is well corrected for various aberrations. The various symbols in the tables have the following meaning.

R: the radii of curvature of the respective lens elements

D: the axial thicknesses of the respective lens elements and axial air spaces between the successive lens elements

Nd: the refractive indices for the d line of the sodium spectrum of the respective material glasses

T: an interchangeable filter

S: a diaphragm.

* the radius of curvature of the non-spherical surface at the vertex on the optical axis.

Example 1:

What is claimed is:

1. A wide angle objective optical system comprising a lens system wherein the first surface of the system is configured in a non-spherical form and is represented by the formula

$$X = \frac{Y^2}{R_1 - R_1\sqrt{1-\left(\frac{Y}{R_1}\right)^2}} + BY^4 + CY^6 + DY^8 + EY^{10}$$

wherein

X : the abscissa taken along the optical axis in the direction of incoming light,

Y : the ordinate perpendicular to the abscissa,

R_1 : the radius of curvature of the non-spherical surface at the vertex of the optical axis and wherein the optical elements have the following data:

$f = 14.300$

$FN_o = 2.8$

$2\omega = 114.2°$

[57] **ABSTRACT**

An objective of the expanded Tessar type, having five elements constituting four components (two of the elements being cemented to each other to form one component), all of the components being air spaced from each other. The front two components (in the direction from the object or long conjugate side toward the image or short conjugate side) are both positive. Numerical limits or ranges are given, for certain designated features of the lens system. If a lens of this type is so designed that the designated features fall within the specified ranges, improved results are attained.

OBJECTIVE LENS SYSTEM WITH FIVE ELEMENTS

BACKGROUND OF THE INVENTION

This invention relates to an objective lens system of what may be called the expanded Tessar type, which type is disclosed, for example, in U.S. Pat. No. 2,105,799. The lens has a front member, designated in the drawing and in the examples as Vgl (standing for the German word Vorderglied) and a rear member designated as Hgl (standing for the German word Hinterglied). The front member is made up of three individually air spaced lens elements, and the rear member is a doublet consisting of two lens elements of opposite sign of power, cemented to each other to constitute a single component. A diaphragm space is provided between the front member and the rear member. The neighboring cemented surfaces of this doublet constituting the rear member constitute a collecting cement surface. In the front member, the front element is an unequal-sided collecting element, followed at a small finite air spacing by a positive meniscus which is convex toward the front and concave toward the rear, this meniscus being followed, in turn, by an unequal-sided negative lens which has its most strongly curved surface in the form of a surface concave toward the rear. A dispersing air lens is formed between the rear surface of the second element and the front surface of the negative lens constituting the third element.

SUMMARY OF THE INVENTION

In a five element objective of the expanded Tessar type, a valuable increase in the picture taking quality of the lens is achieved if, in order to keep the proportion of primary abberrations small, the first pair of collecting lenses into which the rays of light enter from the remote object are both made of glass having a refractive index (for the d-line of the helium spectrum, wavelength 5876 Angstrom units) is greater than 1.6454. The use of such glass for the first two elements fundamentally provides assurance that, from the very start, the refractive index proportional values of these glasses in the aberration coefficients of third order are in the desirable range of less than 2.55 for the coefficient $n/(n-1)$, and less than 6.50 for the coefficient $n^2/(n-1)^2$. These coefficients are respectively referred to hereafter as x' and x''. The importance of keeping these values of x' and x'' less than 2.55 and 6.50, respectively, can be seen from the well known work by I. C. Gardner, "Application of the algebraic abberration equations to optical design," published as U.S. Bureau of Standards Scientific Paper No. 550, 1927, particularly equation 24 on page 95, and appendix 4, page 201, value column 4.

Values within these limits are known in the art from German patent 1,190,216, but have not been generally recognized in the art as being important, as will be seen from Table I below, which shows these values of the refractive indices for the first two elements of a lens of this same general type, according to typical prior patents, and the resulting coefficient values x' and x'', and shows in comparison thereto the corresponding values for the examples of the present invention.

According to the present invention, a lens system of this general type above described should have certain other features or physical characteristics not found in the prior art, which give greatly improved results, when these additional features are within the values or limits stated, the lens otherwise being of the kind described above. These additional features or conditions which are highly desirable, according to the present invention, are the following, which may be regarded as rules of design for the front pair of collecting lenses.

Feature (a). The front radii R_1 and R_2, respectively of the front positive lens elements L_1 and L_2, respectively, which are both of convex curvature toward the front, are so dimensioned with such curvature with respect to each other that the reciprocal of Gardner's curvature index is within the range or limits of + 0.109 and − 0.275. For further explanation of the Gardner curvature index, see the above cited work by Gardner. The reciprocal of the curvature index for these first two lens elements may be written as $\overline{\sigma}_{2,1}$, which is the quotient of the difference in radii $R_2 - R_1$ divided by the sum of these radii $R_2 + R_1$.

Feature (b_1). The relative distribution of the proportional portions of the Petzval picture curvature between the front lens element L_1 and the following positive meniscus element L_2 is so dimensioned that the difference in the Petzval curvature portions $\dot{B} - \dot{A}$ is within the limits or range of $+0.124\,\Phi$ and $-0.599\,\Phi$, wherein Φ represents the equivalent refractive power of entire lens system. The Petzval curvature portion B is the refractive power of the second lens element divided by the index of refraction of the glass used for this lens, that is, $\dot{B} = \phi_2 : n_2$. Similarly, the Petzval curvature portion $\dot{A} = \phi_1 : n_1$. That is, in each case the Petzval curvature portion of a lens element is the corresponding lens power divided by the corresponding index of refraction.

Feature (b_2). The quotient $(\overline{\psi}\,\dot{B}\dot{A})$ of the difference of the above Petzval curvature portions $(\dot{B} - \dot{A})$ of these two front collecting lenses divided by the sum $(\dot{B} + \dot{A})$ of these two Petzval curvature portions is within the limits or range of + 0.089 and − 0.625. In this connection, one may note the recognized theory that the lens power ϕ_x for a lens of either glass or air of any order x is equal to the sum of the two associated surface powers $\phi_x + \phi_x'$, in which connection each surface power means $\phi_x = (n_x' - n_x) : R_x$.

BRIEF DESCRIPTION OF THE DRAWING

The single FIGURE of the drawing is a schematic exploded diagram indicating the general configuration of the lens according to the present invention, and is not necessarily drawn to scale, as it is intended to be a schematic representation of all of the various specific embodiments here disclosed, even though the embodiments may differ from each other somewhat in specific dimensions of radii, thicknesses, and spacings.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

As stated above, in connection with feature *a*, an important feature of the invention is the design of the lens system in such a way that the Gardner curvature index is within the limits above stated. Within the stated limits, it may be either positive or negative. Those skilled in the art will immediately recognize, from what has been said above, that if the Gardner curvature index is to be positive, then the front surface R_1 of the first lens element L_1 must be of greater curvature (that is, of less radius) than the front surface R_2 of the positive meniscus lens element L_2. Similarly, if it is

desired to have a negative value for the Gardner curvature index, then the front surface R_1 must be of lesser or weaker curvature (i.e., greater radius) than the surface R_2 of the second lens element. If the radii of curvature of the front faces of the first two lense elements are exactly equal, then the Gardner curvature index will be zero.

By dimensioning the lens components to achieve a Gardner curvature index within the limits above specified for feature *a*, a particularly excellent balancing of the dioptric effect on the course of the zonal abberations in the finitely opened parts of the beam of light can be established for the first time for the central and middle region of image field. If the above stated upper limit of a positive value of the Gardner curvature index is exceeded, this would lead to enlargement of the longitudinal aberration deviation in the zonal inner region. If the Gardner curvature index range above stated is exceeded in the negative direction, this would lead to an increase of aberration in the region of the beam cross section close to the edge.

By utilizing also the above stated rule or feature b_1 with respect to the Petzval curvature, in conjunction with feature *a*, it is possible to achieve a particularly suitable stretching of the residual image curvature over the extended field of view by dimensioning the lens to comply with feature b_1 and at the same time to comply with feature *a*, there is obtained a dioptric action which is both surprising and very excellent, on the course of the image curvature over the entire useful field of view. Dimensioning the two positive lens components L_1 and L_2 at the front of the lens system (these components also being designated, in the diagram and elsewhere, as components $\underset{\cdot}{A}$ and $\underset{\cdot}{B}$) in such a way as to comply with the above stated rule b_1 relating to the Petzval image curvature, one achieves for the first time a previously unknown balancing out of the Petzval coefficients to increase the quality of the picture image in a practical manner of carrying out the technical embodiment. Within the range stated for this rule, if one achieves a Petzval coefficient of zero, then we have the coefficient $\underset{\cdot}{B}$ exactly equal to the coefficient $\underset{\cdot}{A}$, since the two have the same sign. Such a value of zero is achieved in example 1 given below, as will be observed from Table II.

The extremely great increase in picture quality achieved by dimensioning the lens system to comply simultaneously with the two rules or features *a* and b_1 in a lens system of the expanded Tessar type initially identified above, will be clearly evident to those skilled in the art, after reading the present disclosure, particularly with reference to the widened field of view. It is very important that in the pair of collecting lenses at the front of the objective, the front lens L_1 is at a substantially larger distance from the corresponding position of the entrance pupil EP than the positive meniscus L_2 which follows this front lens L_1. For this reason not only do the collecting front surfaces R_1 and R_2 of these two collecting lenses act toward producing extremely different beam path lengths up to the stop or diaphragm, but furthermore in this connection the lens coefficients of the Petzval image curvature (and therefore $\underset{\cdot}{A}$ on the one hand and $\underset{\cdot}{B}$ on the other hand) also have the particular importance of their position within the course of the beam in their influence on the shape of the two astigmatic image shells and the astigmatism has the angle-corresponding difference in each case between the sagittal and the tangential image point in the lateral course of these image shells. The above mentioned position of the entrance pupil refers to the image of the diaphragm produced by the lens elements in front of the diaphragm, considered in a direction forwardly (opposite to the direction of incoming light) from the location of the stop of diaphragm.

In order to make clear in particular this previously generally insufficiently known optical event even for the zonal astigmatic beam course, it may be stated here, under permissible simplification, that in the concrete case of example 3 given below, the front surface vertex of the surface R_1 is at a distance of + 0.5062 F from the image associated with it of the axial base point of the stop or diaphragm, while the axial vertex point of the front surface R_2 of the positive meniscus is at a distance from the corresponding image of the location of the stop of only + 0.2531 F. (F represents the equivalent focal length of the entire lens system.) Therefore this comparison difference for the front lens L_1 with respect to that of the positive meniscus L_2, is practically exactly twice as great as in the case of the latter, since the quotient of these two comparative values of the associated pupil positions is 1.99991, and thus the beam path lengths, referred to the location of the pupil, of the oblique beams is practically in the ratio of 2:1, for these two characteristic collecting surfaces.

The feature or rule of construction b_1 teaches in detail that in its positive range of positions, the dimensioning of the positive meniscus in accordance with the power of refraction and collection of the glass, is to be chosen such that its lens coefficient of the Petzval image curvature $\underset{\cdot}{B}$ is less than + 0.124Φ greater than the partial coefficient $\underset{\cdot}{A}$ of the front lens L_1. Thus an advantageous relaxation, so important for the obtaining of the advance or improvement, is assured in practice. On the other hand, in the negative range of positions of this feature or rule b_1 the Petzval lens coefficient $\underset{\cdot}{A}$ is greater than the coefficient $\underset{\cdot}{B}$ of the positive meniscus, and in accordance with the inventive concept, is to be dimensioned in such a manner that its negative numerical value is within the limits or range from zero to − 0.599Φ as compared with the numerical value $\underset{\cdot}{B}$ meniscus the lens coefficient of the menicus L_2, in order to make certain that the beams coming from the object and passing through the pair of collecting lenses are not already imparted by the first element L_1 an intolerably high image curvature partial coefficient, which would lead to a rise in zonal aberration of the lateral image shells and thus counteract the intended increase in performance.

Furthermore in accordance with the invention, in order to insure that, without any possibility of doubt, the distribution of the lens partial coefficients of the Petzval image curvature on the two front lens elements L_1 and L_2 will be advantageous, it is desirable that the lens components be so dimensioned that they fulfill also a third rule or condition stated above as feature b_2. This third feature is related to the second feature b_1 but is somewhat different therefrom. It relates, as already mentioned above when it was initially stated, to the reciprocal of the image curvature distribution number as the quotient of the difference $\underset{\cdot}{B}-\underset{\cdot}{A}$ divided by the sum $\underset{\cdot}{B}+\underset{\cdot}{A}$. As already stated above, if this distribution number is positive, it should be within the limits or range of + 0.089 and zero, and if negative it should be within the limits or range of − 0.625 and zero.

These three rules or features *a* and b_1 and b_2 in their entirety (that is, considering all three rules simultaneously) unequivocally set forth the principle of con-

struction of an objective according to the present invention. It should be recognized, of course, that the numerical limits above stated are subject to the usual tolerance of plus or minus 5%, as customary in the optical design field when stating numerical values or ranges. Also it should be recognized that we are here talking about improvements in a lens system of the extended or expanded Tessar type identified or defined near the beginning of this specification. The herein stated rules or features for improving performance of lens systems of the expanded Tessar type do not necessarily apply to lenses of other types.

From the analysis of the above stated features or rules of construction and a careful consideration of the other information given in this disclosure, it will be apparent to a person skilled in this art, that in agreement with recognized teaching, there is not only a definite redundance provided by following the subsidiary condition b_2 for the second main feature b_1 but at the same time there is also established a framework of dimensioning which at the same time permits the maintaining of the astigmatism small in the edge portions of the extended lateral field of view. The extreme optical importance for the total picture performance is in this connection now obvious (as a result of the present disclosure) to the person skilled in the art when he bears in mind, in accordance with the recognized but frequently disregarded teaching, that the Petzval theorem is of importance for the image curvature if and only if the the beam combination is punctiform even laterally of the axis. This teaching is stated in the standard reference work "Theorie und Geschichte des Photographischen Objektivs" (Theory and History of Photographic Objectives) by M. von Rohr, published by Julius Springer, Berlin, 1899, page 359, lines 31–34. The expression "punctiform" means that there is concerned a focusing with astigmatism-free combining of the image in the lateral parts of the field of view.

The present new principle of construction with its requirement that all three of the rules or features above stated be simultaneously satisfied, in the very specific type of expanded Tessar lens initially identified, has been fully confirmed in the course of extensive investigations. This principle importantly and surprisingly establishes an advance in the art, and the investigations also show at the same time that before these rules of construction were recognized, it was impossible to realize in practice a great improvement in the picture performance. Before the making of the present invention and the recognition of the importance of simultaneously fulfilling the above stated rules or features, it was at most conceivable to obtain very small and unsubstantial improvements for a certain course of aberration, only by tolerating an extremely detrimental or injurious increase in the aberrations of higher order for the predominant majority of other aberrations in or outside of the central parts of the image. The analysis of the present invention and of the consequences of its dioptric effect make it possible clearly to see that the aberration-free beam courses coming from the object within the pair of collecting lenses arranged at the front of the overall system is to be subjected only to very specifically measured portions of aberrations during its passage through this pair of collecting lenses L_1 and L_2, since the lens components following these lenses in the direction toward the shorter conjugate or image, otherwise cannot lead to a proper compensation of image aberrations. Hence as a practically necessary consequence, there are disturbing residual aberrations which oppose the desired improvement in the image, and also, if extreme types of glass are used, unavoidable aberrations of higher order which greatly impair the combining of the image, if one does not design the lens in accordance with the inventive principles here disclosed.

There have been previous proposals for increasing the picture performance of the five lens objective of the expanded Tessar type with which the present invention deals. One of these proposals, that disclosed in U.S. Pat. No. 2,105,799 and the corresponding British patent 476,349, has become known to a wide group of experts, particularly by the publication in the supplement by K. Michel to the "Handbuch der wissenschaftlichen und angewandten Photographie" (Handbook of scientific and applied photography) published by Springer, Vienna, 1943, page 28, FIG. 22. The description given therein of the variation of the aberration in the central part of the image (FIG. 22*a*) shows the extremely large zonal defects of spherical aberration (solid line curve) and deviation from the sine condition (dashed line curve) which clearly confirm the above statements. Such defects may have been entirely acceptable for the state of the art at that time, but are no longer acceptable at the present time, when a higher quality of performance is demanded. FIG. 22*b* of the above cited publication shows the astigmatic image-point deviations for the position of the sagittal image points (solid line curve) as well as for the tangential image points (dashed line curve).

From this information given in the publication just cited, it can be seen that even with an inclination of the main beam of 20° the astigmatism reaches the critical limit of 1.0% of the equivalent focal length, increasing in the case of an inclination of the beam of 25.5° to 2.09%, and thus exceeding the permissible amount which modern photographic technique specifies for the existence of an image combining which is considered to be good according to today's standards.

With a knowledge of the present disclosure of the new principle of construction and its optical importance, a comparative analysis readily shows the man skilled in the art that not only are the detailed statements in connection with the present patent application fully confirmed, but that, in addition, this older form of construction of five-lens expansions of the Tessar type must necessarily have such an aberration-affected beam combination of finitely opened and finitely inclined beam bundles that the comparative numerical values in the case of this older objective lie far outside the characteristic framework and the combination of features in accordance with the present invention. The present invention enables this specific type of five-lens partially cemented objective to be designed by using the rules or features herein stated, in a manner which is very simple for such an important increase in picture performance.

In the following data tables, **14** specific examples of lens systems according to the present invention are given. In all of these examples, all linear measurements such as radii, thicknesses, and spacings are stated as proportions of the equivalent focal length (F) of the entire objective or lens system, which is considered as unity. That is, $F = 1.0000$. The individual lens elements are indicated, both in the example tables and in the schematic drawing, by the letter L with a subscript corresponding to the number of the individual lens

element as numbered consecutively from front to rear, that is, from 1 to 5. The lens components are indicated by capital letters A through D, the first three lens elements being regarded as individual components, while lens elements **4** and **5**, being cemented to each other, are regarded as a single component D. For convenience of illustration, the elements L_4 and L_5 are shown in the diagram as being slightly separated from each other, but actually they are cemented to each other as shown by the designation of zero spacing at this point, in all of the tables of specific examples.

The radii of curvature of the front surface and the rear surface of each element are indicated by R and R', respectively, with a subscript indicating the number of that particular element. Positive values of R or R' indicates surfaces convex toward the front of the lens, and negative values indicate surfaces concave toward the front, in accordance with customary usage. The end of the lens toward the distant object or longer conjugate is referred to for convenience as the front, and the end toward the image (that is, toward the camera, if the lens is used on a photographic camera) is referred to for convenience as the rear of the lens. The light is assumed, in accordance with conventional lens patent practice, to enter from the front, and to pass through the lens from left to right as indicated by the arrow in the lens diagram.

Axial thicknesses of individual elements are indicated in the tables by the letter *d* with a subscript referring to the identifying number of the particular lens element. Spacings between the elements are indicated by the letter *s* with a subscript corresponding to the identifying number of the lens element in front of the space and lens element behind the space. For example, s_{12} indicates the space between element **1** and element **2**, and s_{23} indicates the space between element **2** and element **3**, and so on. Zero spacing indicates elements cemented to each other. All spacings greater than zero refer to air spacings. In all examples, the space s_{34} between element **3** and element **4** is considered the central space (CS) in which the stop or diaphragm is to be located.

The index of refraction of the glass used for each element is shown either by the symbol *n* with a subscript referring to the individual lens element, or by data in a column headed n_d, the latter being used for the sake of compactness when the data also includes the Abbe number or dispersive index, in a column headed ν_d. When an objective is designed for use in only a very narrow spectral range, the refractive index refers specifically to this narrow range. If the lens is to be used over a wide spectral range, as for example in taking color photographs, then instead of monochromatic image-error correction, an achromatism should be brought about over the wider spectral range required. For this purpose, in known manner, the glasses are to be chosen so that the color dispersion of the glasses used, defined by their corresponding ν value or Abbe number, serves to eliminate the chromatic deviations or errors due to the wavelengths which enter into consideration.

During the course of making this invention it was found, by way of confirmation, that upon the development of the so-called initial forms or preforms of the objective, and then in the course of the subsequent technical rough shaping (rough form) in known manner with the first correction normally customary in the Seidel range (third order) the use of one of the standard indices of refraction can take place in a purely routine manner. A convenient index to use for this purpose is the index of refraction for the yellow d-line of the helium spectrum, with a wavelength of 5876 Angstrom units. Data for this wavelength is customarily shown in many commercial catalogues of manufacturers of optical glasses.

In addition to the values of the linear dimensions and the characteristics of the glass, the example tables also indicate, at the top of each table, the intended relative aperture, the total field angle designated as numeral $2w_o$ provided for, as well as the resultant back focus s_{oo}'.

The first four examples relate to preforms in accordance with the invention which are provided in the region of the third order with monochromatic precorrection, the indices of refraction used in these examples being based on the above mentioned wavelength of 5876 Angstrom units.

The fact that the invention provides a truly novel principle of construction is made clear not only by the scope of use both with respect to relative aperture and with respect to angular extent of the image field, but also by the fact the front element in its three-lens overall combination can be developed either with a negative paraxial power of its own (examples 6, 8, 9, and 10) or with a positive power (examples 1, 2, 4, 5, 7, 11, 12, 13, and 14) or with a completely free power or refraction and therefore with an intrinsic power of 0 (example 3) provided that the new rules of construction in accordance with the invention are satisfied.

Example 1

The specific examples given above show the wide scope for practical use of the new principles of construction herein disclosed, with respect to a range of relative apertures from *f*/3.5 (example 5) to *f*/1.2 (example 13) with various useful angular fields which,

depending on the purpose of use, may cover an angle from about 18° (example 14) to about 54° (example 8).

The great importance of the new features or rules of construction herein disclosed, in obtaining improved imageforming performance in five-lens objectives of the expanded Tessar type herein discussed, is shown particularly impressively by a comparison of the data of the preforms indicated with the construction data for the precisely corrected objectives. Reference may be had in this connection to such a data comparison between example 2 on the one hand and example 7 on the other hand. Furthermore, from a comparison of the data of example 3 with the data of example 10, and from a comparison of the data of example 4 with the data of example 11, it can be clearly noted what slight variations within the scope of the new principles of design need only be still effected to arrive from a simplified form of construction to an extremely precisely corrected embodiment, by following the inventive concepts in accordance with the design rules or features here disclosed.

It may also be pointed out that examples 12 and 13 are particularly useful for photographing signals by means of photoelectronic picture tubes. For this purpose, both examples 12 and 13 are corrected with due consideration of the action of a selected filter plate (SF) as well as an emulsion support plate (TP), the latter having its rear surface coinciding with the image then directly adjacent the photoelectronic recording layer. In example 12, the filter plate (SF) is developed with flat parallel surfaces arranged at a distance of 0.107637 F axially from the last lens vertex R'_5. This plate has an axial thickness d_{SF} of 0.080728 F. The emulsion plate (TP) has a thickness d_{TP} of 0.064582 F, following at a distance of 0.15905 F behind the filter plate. Both plates are made of the same type of glass, having an index of refraction of 1.51680, and an Abbe dispersion index of 64.12.

In example 13, both plates are of the same type of glass used in example 12, but the spacing and thicknesses are somewhat different. The distance of the first plate behind the vertex of the last lens surface is 0.108226 F, the thickness of this plate is 0.081170 F, the distance from the rear surface of this plate to the front surface of the emulsion support plate is 0.083876 F, and the thickness of the emulsion support plate is 0.064936 F.

The following tables I and II give data useful in comparing various features of the lenses according to examples 1–14 with each other and in comparing them with typical constructions of the prior art. Table I gives numerical values, for comparison purposes, of the indices of refraction of the glass of the first two lens elements, indicated in the respective columns headed n_1 and n_2, and the values of the coefficients calculated therefrom, explained near the beginning of this specification and identified there as x' and x'', in the columns with those respective headings. These respective numerical values are given for all of the 14 specific examples embodying the present invention, at the bottom portion of Table I, and are also given, in the top portion of Table I, for certain selected typical lenses of the prior art. The first line, under the prior art section, gives the calculated values for British patent 476,349. The second and third lines give the calculated values for examples 1 and 2, respectively, of German gebrauchsmuster 1,882,723, while the fourth and last line of the prior art section of this table, gives the calculated values for the lens disclosed in German patent 1,190,216.

In Table II, the numerical values are given, for the same prior art patents and for the 14 specific examples of the present invention, with respect to the three special features of the present invention, in the respective columns headed (*a*) and (b_1) and (b_2), corresponding to the designation of these special features of the present invention in the above discussion.

In stating limits or ranges for the various features of the invention, in the claims or elsewhere, it should be borne in mind that ranges are subject to a tolerance of plus or minus 5%, as customary in the optical field.

What is claimed is:

1. An objective of five lens elements, divided into a front member of three elements all air spaced from each other, and a rear member of two lens elements cemented to each other to form a single component, the two elements of said rear member being of opposite sign of power and the neighboring surfaces thereof forming a collecting cement surface;

the front lens element of said front member being a collecting lens having unequal front and rear surfaces;

the second lens element being a positive meniscus concave toward the rear and slightly air spaced rearwardly from said front element;

the third lens element being separated from the second element by a dispersing air space, said third element being a negative lens having unequal front and rear surfaces and having its rear surface concave toward the rear and having its rear surface more strongly curved than its front surface;

said front element and said second element both being formed of glass having an index of refraction for the yellow d-line of the helium spectrum which is within the range limits of 1.6454 and 1.80279;

said objective being characterized by the presence of all of the following features:

a. the respective radii of the front surfaces of said front element and said second element are so related to each other that the reciprocal of the Gardner curvature index for those two surfaces is within the range limits of + 0.094 and − 0.244;

b_1. said front element and said second element are so dimensioned relative to each other that the difference of the Petzval curvature portion of the second element minus the Petzval curvature portion of the front element is within the range limits of + 0.092 Φ and − 0.541 Φ; and

b_2. the quotient of said difference of the Petzval curvature portion of the second element minus that of the front element divided by the sum of said Petzval curvature portions of the front and second elements is within the range limits of + 0.076 and − 0.566;

said reciprocal of said Gardner curvature index being determined as the quotient of the radius of the front surface of said second element minus the radius of the front surface of said front element, divided by the sum of the two radii; and

said Petzval curvature portion of each of said front and second elements being determined as the quotient of the power of the respective lens element divided by the index of refraction of the glass of which the respective element is made.

2. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

F = 1.00000 f/2.9 $2\omega o = 50°$ $s\infty' = +0.6341$ F

		$R_1 = +0.39000$		
A	L_1		$d_1 = 0.09000$	$n_1 = 1.6810$
		$R_1' = +0.91453$		
			$s_{12} = 0.00140$	
		$R_2 = +0.35150$		
B	L_2		$d_2 = 0.07000$	$n_2 = 1.7200$ Vgl.
		$R_2' = +0.70339$		
			$s_{23} = 0.02844$	
		$R_3 = +2.35386$		
C	L_3		$d_3 = 0.02055$	$n_3 = 1.7850$
		$R_3' = +0.25217$		
			$CS = s_{34} = 0.10163$	
		$R_4 = +2.50017$		
	L_4		$d_4 = 0.028999$	$n_4 = 1.6380$
D		$R_4' = +0.32000$		
			$s_{45} = 0$	Hgl.
		$R_5 = +0.32000$		
	L_5		$d_5 = 0.115965$	$n_5 = 1.7440$
		$R_5' = -1.13500$		

all linear dimensions being expressed in proportion to the equivalent focal length of the entire lens system considered as unity, the symbols having the meanings explained in the foregoing specification.

3. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/2.7 $2\omega o = 53°$ $s_\infty' = +0.6341$ F		
A	L_1	$R_1 = +0.3910$ $R_1' = +0.8200$	$d_1 = 0.08620$	$n_1 = 1.717$
			$s_{12} = 0.00250$	
B	L_2	$R_2 = +0.3450$ $R_2' = +0.7450$	$d_2 = 0.07060$	$n_2 = 1.717$ Vgl.
			$s_{23} = 0.02750$	
C	L_3	$R_3 = +2.5000$ $R_3' = +0.2485$	$d_3 = 0.02050$	$n_3 = 1.785$
			$CS = s_{34} = 0.100020$	
D	L_4	$R_4 = +2.5000$ $R_4' = +0.3200$	$d_4 = 0.02900$	$n_4 = 1.638$
			$s_{45} = 0$	Hgl.
	L_5	$R_5 = +0.3200$ $R_5' = -1.1350$	$d_5 = 0.116025$	$n_5 = 1.744$

all linear dimensions being expressed in proportion to the equivalent focal length of the entire lens system considered as unity, the symbols having the meanings explained in the forgoing specification.

5. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/1.6 $2\omega o = 33°$ $s_\infty' = 0.3890$ F		
A	L_1	$R_1 = +0.576$ $R_1' = +3.580$	$d_1 = 0.1915$	$n_1 = 1.734$
			$s_{12} = 0.0027$	
B	L_2	$R_2 = +0.454$ $R_2' = +0.684$	$d_2 = 0.1207$	$n_2 = 1.788$ Vgl.
			$s_{23} = 0.0600$	
C	L_3	$R_3 = +8.180$ $R_3' = +0.295$	$d_3 = 0.0375$	$n_3 = 1.847$
			$CS = s_{34} = 0.1702$	
D	L_4	$R_4 = +1.900$ $R_4' = +0.516$	$d_4 = 0.0375$	$n_4 = 1.500$
			$s_{45} = 0$	Hgl.
	L_5	$R_5 = +0.516$ $R_5' = -1.033$	$d_5 = 0.206996$	$n_5 = 1.784$

4. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/2.3 $2\omega o = 43°$ $a_\infty' = +0.6383$ F		
A	L_1	$R_1 = +0.4440$ $R_1' = +1.9000$	$d_1 = 0.08700$	$n_1 = 1.6780$
			$s_{12} = 0.00180$	
B	L_2	$R_2 = +0.4530$ $R_2' = +0.5700$	$d_2 = 0.06850$	$n_2 = 1.7440$ Vgl.
			$s_{23} = 0.05250$	
C	L_3	$R_3 = -7.2440$ $R_3' = +0.3076$	$d_3 = 0.06677$	$n_3 = 1.7280$
			$CS = s_{34} = 0.12000$	
D	L_4	$R_4 = +1.7160$ $R_4' = +0.3900$	$d_4 = 0.02440$	$n_4 = 1.5810$
			$s_{45} = 0$	Hgl.
	L_5	$R_5 = +0.3900$ $R_5' = -0.9530$	$d_5 = 0.08090$	$n_5 = 1.7440$

all linear dimensions being expressed in proportion to the equivalent focal length of the entire lens system considered as unity, the symbols having the meanings explained in the foregoing specification.

6. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/3.5 2ωo = 52° $s_{\infty}' = +0.6751$ F		n_d/ν_d	
A	L_1	$R_1 = +0.34480$			
		$R_1' = +0.68793$	$d_1 = 0.070785$	1.67790/55.20	
			$s_{12} = 0.002441$		
B	L_2	$R_2 = +0.31175$			
		$R_2' = +0.65413$	$d_2 = 0.062974$	1.67790/55.20	Vgl.
			$s_{23} = 0.028070$		
C	L_3	$R_3 = +2.38868$			
		$R_3' = +0.22715$	$d_3 = 0.014645$	1.72151/29.25	
			CS = $s_{34} = 0.096414$		
D	L_4	$R_4 = +1.69108$			
		$R_4' = +0.24946$	$d_4 = 0.017574$	1.68900/49.46	
			$s_{45} = 0$		Hgl.
	L_5	$R_5 = +0.24946$			
		$R_5' = -1.27733$	$d_5 = 0.059801$	1.74400/44.77	

all linear dimensions being expressed in proportion to the equivalent focal length of the entire lens system considered as unity, the symbols having the meanings explained in the foregoing specification.

7. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/2.9 2ωo = 53.5° $s_{\infty}' = +0.6341$ F		n_d/ν_d	
A	L_1	$R_1 = +0.39063$			
		$R_1' = +0.81969$	$d_1 = 0.086215$	1.71700/47.99	
			$s_{12} = 0.002395$		
B	L_2	$R_2 = +0.34563$			
		$R_2' = +0.74651$	$d_2 = 0.070649$	1.71700/47.99	Vgl.
			$s_{23} = 0.027541$		
C	L_3	$R_3 = +2.31031$			
		$R_3' = +0.24823$	$d_3 = 0.020356$	1.78472/25.76	
			CS = $s_{34} = 0.100585$		
D	L_4	$R_4 = +2.76560$			
		$R_4' = +0.31936$	$d_4 = 0.020356$	1.63854/55.38	
			$s_{45} = 0$		Hgl.
	L_5	$R_5 = +0.31936$			
		$R_5' = -1.13309$	$d_5 = 0.116151$	1.74400/44.77	

relationship to each other are substantially as indicated below:

all linear dimensions being expressed in proportion to the equivalent focal length of the entire lens system considered as unity, the symbols having the meanings explained in the foregoing specification.

8. An objective as defined in claim **1**, wherein the characteristics of the lens elements and their spatial relationship to each other are substantially as indicated below:

		F = 1.00000 f/2.9 2ωo = 51° $s_{\infty}' = +0.6988$ F		n_d/ν_d	
A	L_1	$R_1 = +0.35015$			
		$R_1' = +0.90521$	$d_1 = 0.069804$	1.71700/47.99	
			$s_{12} = 0.001225$		
B	L_2	$R_2 = +0.42220$			
		$R_2' = +0.59635$	$d_2 = 0.042862$	1.71700/47.99	Vgl.
			$s_{23} = 0.027187$		
C	L_3	$R_3 = +57.93723$			
		$R_3' = +0.26829$	$d_3 = 0.051434$	1.72830/28.68

[57] **ABSTRACT**

The main objective of the microscope is shifted from the stereoscopic viewing position to a position in which its optic axis coincides with the optic axis of one of the twin variable magnification optical systems used for stereoscopic viewing. This shifted position provides better resolution for photography and measurement and reduces the correction requirements on the main objective. The shift of the objective is coordinated with a shift of the object under observation or a countershift of the upper part of the microscope in order to maintain the same field of view of the object.

BINOCULAR MICROSCOPE WITH IMPROVED MONOCULAR PHOTOGRAPHIC AND MEASURING CAPABILITY USING MOVABLE OBJECTIVE

This invention relates to a stereomicroscope of the kind in which a main objective is used with a twin variable magnification binocular system.

Stereomicroscopes of this type are known. In these instruments the direction of view through the main objective to the object under observation in the object plane uses eccentric rays through the objective falling obliquely on the object. Only in this way does the observer have the possibility of obtaining a spatial impression of the observed object. In order to obtain monocular individual photographs of the objects observed, supplementary camera attachments are used.

Stereomicroscopes are frequently used for measurements, blood counts and similar determinations.

A disadvantage of these known stereomicros lies in the fact that the direction of viewing passes eccentrically through the main objective and falls obliquely on the object to be measured or photographed. For this reason, the photographs obtained are seriously deteriorated. Measuring errors arise in the measurement of distances as the result of parallax and of oblique projection. For this reason, stereomicroscopes have been used only for measuring tasks of low accuracy requirements.

In order to avoid this disadvantage, it has already been proposed that in the variable magnification system used with the objective, a triplet of identical variable magnification systems should be used instead of the usual twin systems, the third being the central system between the two used for binocular viewing that is rotationally symmetrical with the main objective. Since in modern stereo microscopes variable magnification is generally carried out in continuous fashion with so-called zoom objectives, great design and manufacture costs are involved in the provision of the optical and mechanical components of the variable magnification system. For these reasons the proposed solution of providing a triplicate magnification system has not worked out in practice.

It is an object of the present invention so to improve a stereomicroscope that for measuring and for photography, the principal ray from the object observed coming perpendicularly through the main objective will come within the scope of the variable magnification optical system.

SUBJECT MATTER OF THE PRESENT INVENTION

Briefly, means are provided to change the relative position of the main objective with regard to at least one of the twin variable magnification optical systems in a stero microscope, so that the optical axis of the main objective can be brought into alignment with the optical axis of one of the two twin variable magnigication systems. This is preferably done by moving the main objective relative to the casing of the twin variable magnification optical systems, and that may be done in coordination with a shift of the object under observation to prevent too great a change of the field of view between stereo viewing and photography.

The invention is further described by way of example with reference to the annexed drawing in which the single FIGURE is a diagram of the optical system of a stereomicroscope according to the present invention.

The main objective is designated **1** in the drawing. Above the main objective **1** are twin variable magnification optical systems consisting respectively of the lenses **2, 3** and **2',3'**. These twin optical systems geometrically subdivide the rays entering through the main objective and respectively lead the two ray bundles through erecting prisms **4** and **4'** to intermediate image planes **5** and **5'** respectively. As the result of the provision of the erecting prisms **4** and **4'**, monocular images that are unreversed laterally and vertically of the object under observation lying in the object plane **6** are produced. Eyepieces **7** and **7'** serve for viewing the projected monocular images in the intermediate image planes **5** and **5'** respectively. By means of a mechanical arrangement symbolically shown by the dashed line **10,** the position of the main objective **1** can be so changed that its optical axis A_1—A_1 coincides with one of the optical axes of the respective twin variable magnification systems, in the example shown the axis A_2—A_2 which is the optical axis of the system comprising the lenses **2** and **3.** When the main objective **1** is shifted to that position, which is shown with a dot-dash line in the FIGURE, the central or principal ray from the object plane **6** through the main objective is a ray that also goes perpendicularly through the center of the lenses **2** and **3,** which is to say that the optic axes of the lenses **1, 2** and **3** coincide.

The mechanical arrangement for changing the position of the main objective can be a mounting that can be slid in a guide by half the distance between the optical axes A_2—A_2 and A_3—A_3 of the respective twin optical systems **2, 3** and **2',3'**. It is also possible to mount the main objective **1** in a rotatable eccentric mounting **11** that can be rotated by 180° relative to the casing of the twin optical systems, in which case the spacing between the optical axis A_1—A_1 of the main objective and the axis of rotation of its mounting amounts to half the spacing between A_1—A_1, and one of the respective optical axes of the twin variable magnification optical systems.

It is not absolutely necessary to change the position of the main objective in the instrument. It is also conceivable that the position of the main objective should remain unchanged and that the position of one or both of the twin variable magnification optical systems could be changed.

A substantial advantage of the invention lies in the fact that when a photographic camera is mounted either on the tubus of the microscope or between the tubus and the variable magnification system, perfect monocular individual photographs can be made. A further advantage lies in the fact that no errors arise through parallax or oblique projection when measurements are made when the microscope of the present invention is in its measuring and photographing configuration.

For visual observation, the requirements for the main objective are not as exacting as for measurements and for photography. For this reason, there is a further advantage in the invention that lower requirements are set for the correction of the main objective if photography is always done with the principal rays passing perpendicularly through the center of the main objective. This results in considerable cheapening of the manufacture of the optical elements of the microscope.

When the position of the main objective is changed, a different field of view (different picture section) of an object in the object plane is projected on the intermediate image plane (the image plane **5** in the example illustrated). In order to correct for this change, the object is simply moved by the same length in the same direction as the main objective, as indicated by the dashed line **10** in the FIGURE, or else the upper portion of the stereomicroscope is shifted by the same distance but in the opposite direction.

The provision of a mechanical linkage to produce simultaneously a change of position of the main objective and a correction movement of the object or of the binocular microscope upper portion by coupling the two movements so that both functions can be accomplished by actuating a single operating lever in order to convert the microscope from the binocular viewing position to the photographing and measuring position can be so readily devised that it need not be further described here.

We claim:

1. A stereomicroscope comprising a main objective and twin variable magnification optical systems arranged for stereoscopic viewing through said main objective and further comprising means for producing relative displacement of said main objective and at least one of said twin optical means with respect to each other between a monocular viewing position in which the optical axis (A_1—A_1) of said main objective (**1**) is coincident with the optical axis (A_2—A_2) of one (**2, 3**) of said twin optical systems to minimize errors of parallox and oblique projection and a stereoscopic viewing position in which said optical axis (A_1—A_1) of said main objective (**1**) is equidistant between the optical axes (A_2—A_2, A_3—A_3) of said twin optical systems (**2,3; 2',3'**).

2. A stereomicroscope as defined in claim **1,** in which said means for producing relative displacement is constituted by means for moving said main objective relative to said twin optical systems.

3. A stereomicroscope as defined in claim **2,** in which said main objective is mounted on a sliding carriage and said sliding carriage is laterally movable in a guide fixed in the casing of the twin variable magnification optical means.

4. A stereomicroscope as defined in claim **2,** in which said main objective is eccentrically mounted in a rotatable mounting located in front of the variable magnification twin optical means.

5. A stereomicroscope as defined in claim **2,** in which means are also provided for movement of the object under observation in coordination with the operation of said means for moving said main objective.

[57] **ABSTRACT**

An apparatus for measuring and evaluating a subject's visual field presents a target image, consisting of a spot of light, at a series of selected locations within the subject's visual field. Means are provided to monitor his resulting eye movement and positions in response to each target presentation. A projection apparatus presents the target images at various locations and in a programmed sequence. The apparatus also includes means for making a photographic plot of those presented targets which the subject has seen or missed, as desired. Determination of whether subject has seen or missed a particular target is evaluated by logic systems which discriminate between eye movement and positions displaying characteristics indicative of whether the subject has seen or missed the target. The logic discriminates between blinks, hunting eye movements and other characteristic positions and movements which are indicative of the subject having seen the target. Means also are provided to enable selective coarse or fine mapping of selected regions of the subject's visual field.

OBJECTIVE PLOTTING OF VISUAL FIELDS BY EYE MOVEMENT MONITORING

BACKGROUND OF THE INVENTION

Measurement of one's visual field is important for a variety of reasons including the diagnosis of glaucoma as well as other human visual system diseases or impairments. In general, the prior techniques for determining one's visual field and any blind spots have been quite slow and tedious and require a definite subjective response from the person being tested in order to determine whether he has sighted the target at a particular location in his visual field. Additionally, the previously employed tests require administration by one having relatively high degree of skill such as an ophthalmic technician, optometrist or ophthalomologist. For example, in the most common type of visual field test, a hand held target such as a small disc at the end of a wand, is moved about the subject's visual field by the examiner while the subject fixates on a central point. During movement of the hand held target through the subject's field, the examiner asks the subject repeatedly whether he can see the movable target as it is passing from location to location. The examiner may plot, manually, the location of each point which is seen by the subject, or alternatively, he may plot those locations which the subject is unable to see, and which, therefore, define his blind spot.

In order to overcome the uncertainties and difficulties in the foregoing testing techniques some attempts have been made to automate partly the foregoing visual field test, such as employing an arrangement for automatically presenting a series of targets to the subject. Although these devices are somewhat faster than the completely manual test described above, they still are relatively slow and require that the subject respond consciously and intentionally when he sees the target. For example, the response may be verbal or may be indicated by the subjective manipulation of a lever or a button.

Also among the primary difficulties in obtaining fast and accurate plots of the subject's visual field is that the examiner must be assured that the subject's line of sight is directed toward a central fixation point or other known reference point before the target is presented to him. In some instances this may be quite difficult when problems of communication exist between the subject and the examiner as, for example, when testing the young, the aged, or persons whose native language is different than that of the examiner. Furthermore, any such difficulties render efficient and accurate testing still more complicated because it may confuse the results of the test.

A further difficulty in conducting visual field tests with prior techniques is that an indication by the subject that he has seen the target may be the result of hunting eye movements in which, he did not at first actually see the target but moved his eyes about slightly, in a searching motion, and then having seen the target, then moved his eyes directly to it. The present invention employs means for discriminating between such hunting movements and movements in which the presented target was initially seen by the subject.

It is among the primary objects of the invention to provide an apparatus for determining a subject's visual field which avoids the foregoing and other difficulties.

SUMMARY OF THE INVENTION

The invention takes advantage of the natural voluntary or involuntary eye movements which results when a target is presented suddenly to a subject within his visual field. Measurement of the eye movement or change in eye position in response to presentation of the target is employed to determine whether the subject has seen the target. The eye movements may be detected and monitored by a technique described in U.S. Pat. No. 3,473,868 in which the direction and magnitude of the eye movements are translated into electrical signals. Electronic logic means are provided for discriminating between signals which represent eye movements characteristic of the subject having actually seen the target from other types of eye movements such as blinks, hunting or searching movements or the like which produce electrical impulses unrelated to the subject's actual initial detection of the target image. The logic means includes a decision logic circuit which evaluates whether the subject actually visually detected the target by reference to the number and magnitude of the subject's eye movements within an extended time interval which includes the interval during which the target image is presented and a short period thereafter.

The invention employs a target image projector which develops a narrow collimated light beam and directs the beam sequentially toward selected locations on a screen which is within the subject's expected visual field. The position of the intermittent light beam and target image on the screen is determined by reflecting the beam, from its source, off one surface of a double faced mirror toward the screen. The attitude of the mirror is controllable to selectively direct the beam in the desired direction by stepping motors which are positioned in accordance with preprogrammed digital information. The location of the target image on the screen, as presented to the subject, may be recorded permanently and automatically on photographic film incorporated into the projector. In the preferred embodiment, the photographic film is of the Polaroid type which enables immediate inspection after the test has been completed. The photographic recording is made by employing a second light beam which is reflected off the opposite face of the controlled mirror toward the photographic film. The second, reflected beam is directed along the same axis as the first projection beam, but from the opposite direction and impinges on the film at a location which is dependent on the angle of incidence of the beam to the mirror which corresponds to the direction of the light beam which impinges on the target screen. Shutters are provided in association with each of the first and second light beams, the first shutter being employed to control the timing and duration of presentation of the target light and the second shutter means being employed to expose the photographic film to the second beam. In another mode of operation only those points which are not observed are photographically recorded to provide a plot of the subject's blind spot or spots. The second shutter is controlled automatically in response to the logic circuitry which evaluates whether the subject has seen or missed a particular target.

The stepping motor arrangement for changing the attitude of the mirror also enables the device to be programmed to present a sequence of targets on the screen in close proximity to each other rather than more widely spaced locations about the screen. This

enables more precise plotting and evaluation of an area of the subject's blind spot or spots after the more coarse presentation of the target spots has indicated the general location of the blind spot or spots. The device may be operated in a mode in which the more precise evaluation is effected automatically when a subject has missed a presented target.

It is among the primary objects of the invention to provide an improved technique for determining and plotting a subject's visual field.

Another object of the invention is to provide an improved technique in which the subject's response to a series of targets presented at various locations in his visual field is determined objectively without subjective response on his part.

A further object of the invention is to provide an arrangement for making a permanent record of the subject's visual field.

Still another object of the invention is to provide an improved technique for plotting and measuring a subject's visual field without requiring that the test be administered by highly skilled personnel.

Another object of the invention is to provide an improved technique by which eye movements characteristic of a subject's actual sighting of a target presented within his visual field may be discriminated from other types of eye movements automatically.

DESCRIPTION OF THE DRAWINGS

The foregoing and other objects and advantages of the invention will be understood more fully from the following further description thereof, with reference to the accompanying drawings wherein:

FIG. **1** is an illustration of the invention set up in readiness for use;

FIG. **2** is a sectional plan illustration of the mirror positioning mechanism as seen from line **2—2** of FIG. **1** and showing portions of the mechanism broken away;

FIG. **3** is a sectional elevation as seen along the line **3—3** of FIG. **2**;

FIG. **4** is a side elevation of the mirror positioning mechanism as seen along the line **4—4** of FIG. **2**;

FIG. **5** is a sectional view of the mirror positioning mechanism as seen along the line **5—5** of FIG. **4**;

FIG. **6** is a sectional elevation of the mirror positioning mechanism as seen along the line **6—6** of FIG. **5**;

FIG. **7** is an enlarged illustration of the low friction bearing by which the mirror is mounted;

FIG. **8A** and **8B** illustrate a schematic of the control logic electronics of the invention;

FIG. **9** is an illustration of the relative locations of the vernier target images with respect to each other and to the location of the primary target image on the presentation screen;

FIG. **9A** is an illustration of an alternative configuration of vernier target locations;

FIG. **10** is a schematic illustration of the electronic logic circuitry for controlling the positioning of the mirror mechanism;

FIG. **11** is a schematic illustration of the electronic logic system for controlling presentation of the vernier target images;

FIG. **12A** is a DC plot of a subject's response when an actually presented target has been missed;

FIG. **12B** is a DC plot of an ideal "target seen" response;

FIGS. **12C** and **12D** are DC plots of a three saccade response in which the subject initially detected the target but required a minor correctional saccade to focus directly on the target;

FIG. **12E** is a DC plot of a subject's response where the target was detected but where his eyes returned to the central fixation point before the target light was switched off;

FIGS. **12F** and **12G** are DC plots of the subject's eye movement where he did not see the target image and moved his eyes to hunt or search for the target;

FIG. **12H** is a DC plot representative of a blink;

FIG. **13** is a schematic diagram of the decision logic circuitry; and

FIG. **14** is a block diagram illustrating diagrammatically the relationship between the various functions of the logic circuits.

DESCRIPTION OF THE PREFERRED EMBODIMENT

FIGS. **1–3** shows generally the apparatus employed in the invention which includes a projector-camera housing **10** in which is mounted the mirror mechanism **12.** The housing **10** includes a front wall **14** and a rear wall **16,** having apertures **18, 20** respectively which can be opened or closed by a projection shutter **22** and film shutter **24.** The mirror mechanism **12** includes a double faced mirror **26** having a front face **28** and a rear face **30.** The mirror **26** is arranged so that it will reflect the light beam **32** from a projection light **34,** mounted to a sidewall **36** of the housing, **10** through the projection shutter **22** and onto the projection screen **38.** The opposite sidewall **40** of the housing **10** supports a second light source **42** which directs a beam of light **44** toward the rear face **30** of the mirror **26** along the same axis as that of the light beam from the projection light **34.** The beam from the second light source **42** is reflected from the mirror surface **30** in a direction which is opposite that of the reflected projection beam **32** from the front face **28** of the mirror **26.** The recording light beam **44** is directed toward a film plane, indicated diagrammatically at **46** and disposed at the rear of the housing **10** by any of a variety of well-known film holding devices **48.** The double faced mirror **26** thus directs the projection beam **32** to a selected location on the screen and simultaneously directs the recording beam **44** (when it is operated) to a corresponding location in the film plane **46,** as controlled by the attitude of the mirror **26.**

The mirror **26** is mounted for adjustable movement by the mirror mechanism **12.** The mirror mechanism is mounted to a support block **50** which is secured to the interior of the housing **10.** As shown more fully in FIGS. **2–7,** the mirror mechanism **12** includes a driven bevel gear segment **52.** The mirror **26** is secured to and across the diameter of gear **52** by a bracket **54** and lies in a plane perpendicular to that of the gear **52.** The mirror **26** and gear **52** are supported for rotation in unison about the central axis of the gear **52** by means of a yoke **56** having a low friction bearing **58** which supports the upper edge of the mirror, by bracket **62,** and a low friction bearing **60** which supports the opposite face of the gear **52,** by bracket **54,** to enable the mirror **26** and gear **52** to rotate in unison about a common axis defined by the bearings **58, 60.** The yoke **56** is mounted for rotation about a horizontal axis to rotate the mirror **26** and gear **52** bodily about that horizontal axis. To this end the yoke **56** is secured to the end of an outer cylinder **64** which is mounted for rotation to the block **50** by bearings **63.** The cylinder **64** has a gear **66** secured thereto which is rotated by a worm gear **68** which

is driven, in turn, by a stepping motor **80** mounted to the block **50.** The mirror **26** and gear **52** are rotatable with respect to the yoke **56** by means of an inner cylinder **72** which extends through and is rotatable within the outer cylinder **64.** One end of the inner cylinder **72** extends into and is supported at the yoke by bearing **73** and has a bevel gear **74** secured thereto which meshes with driven bevel gear **52.** The opposite end of the inner cylinder **72** extends outwardly beyond the end of the outer cylinder **64** and has a collar **75** secured thereto. The collar **75,** in turn, is rotatably mounted to the block **50** by bearing **77.** The inner cylinder **64** is driven by a gear **76** secured thereto which is driven by the worm gear as described above. The worm gear is secured to shaft **78** of stepping motor **70.** The stepping motors **70, 80** of the mirror mechanism **12** are operated by the position logic system which, in turn, is controlled by the digital information on the program card or the vernier positioning system to orient the mirror **26** to present the target image at any desired location within the subject's visual field and also direct the recording light beam (when operated) to a corresponding location in the film plane. The second light source **42** is mounted to a sidewall of the housing in alignment with the axis of rotation of the inner and outer cylinders **72, 64.** The inner cylinder **72** is hollow along its length to enable the light beam from the second light source to impinge on and be reflected by the mirror **26.**

For convenience in the further description herein, the mirror axis of rotation extending through the bearings **58, 60** will be referred to as the X axis and the axis of rotation of the mirror by means of the yoke **56** will be considered as the Y axis. Similarly, step motor **70** will be referred to as the X step motor and step motor **80** will be referred to as the Y step motor.

In order to monitor the position and eye movements of the subject during the test, the device may include a partially reflective plate **82** mounted above and forwardly of the housing **10** so as to be directly in front of the subject's view when his head is properly placed in the head rest and chin support **84.** Plate **82** is adapted to enable the subject to view the screen **38** and is disposed at an angle to his general line of sight to enable a light source **86,** preferably infrared, to reflect from the plate **82** and illuminate the subject's eyes. The image from the subject's eyes is, in turn, reflected from the plate **82** toward an imaging arrangement **88** which includes a ground glass screen **90** on which the reflected image of the subject's eye may be focused, employing the technique described in the aforementioned U.S. patent. As described in that patent a pair of vertically spaced photoelectric cells **92** and horizontally spaced photoelectric cells **94** are located on or adjacent the screen **90** and are aligned with selected regions of the image of the subject's eye on the screen **90.** Variations in the output signals from the photocells **92, 94** are dependent on the direction and magnitude of the subject's eye movements and their signals are processed in the logic circuitry as described more fully herein. Imaging arrangement **88** preferably is mounted for adjustment to the housing **10** to facilitate initial alignment of the photocells **92, 94** with the subject's eye image on the screen **90.** This may include a bracket **96** pivoted for horizontal movement to the housing **10** and a vertical elevation screw **98** carried by the bracket **96** and in engagement with the end of the barrel **100,** the other end of the barrel **100** being pivoted to the bracket at trunnions **102.**

GENERAL DESCRIPTION OF OPERATION

The invention employs a number of electronic logic systems which are interrelated as shown diagrammatically in FIG. **14.** The primary logic systems include a control logic circuit, a positioning logic circuit, a decision logic circuit and a vernier logic circuit. A typical cycle might begin by an output from the control logic circuit to step a card reader and read the card bearing digital information corresponding to an intended location of the target image. The digital information is fed into the position logic circuitry which controls the mirror positioning mechanism **12** and positions the mirror in the intended attitude. In the embodiment of the invention described, digital data is included in the card for the positions of each of the X and Y motors with the Y motor being positioned first and then the X motor. When the Y motor has been driven to its intended position, a "Y position ready" signal is fed into the control logic to cause the card reader to advance to the next column of X positioning information on the digital information card. This is fed into the position logic and the X motor is driven to its intended position. During the stepping of the motors **70, 80** the position of the X or Y step motor being driven is fed back to the position logic circuit for comparison with the intended position corresponding to the digital positioning input. The control logic includes means for delaying operation of the other elements of the invention during positioning of the mirror. After that delay has elapsed and the mirror has been positioned the control logic resumes operation to open the projector shutter and turn on the projector light to present the target image on the projection screen while simultaneously turning off the central, reference fixation target light. The target image will be located at a predetermined angular distance, within approximately 40°, from the central reference fixation target. The position and movement of the subject's eyes, during and slightly after presentation of the target image, is monitored by the photocells **92, 94** and their output is fed into the decision logic which evaluates whether the subject has seen or missed the presented target. The seen/missed decision from the decision logic is fed back into the control logic and, depending on whether the manual inputs to the control logic were set to record seen or missed targets, the control logic will operate the camera shutter and the camera light to make, or not to make, a photographic plot of that target image.

Means are also incorporated in the invention for checking the subject's cooperation in the test by enabling "dummy" targets (those in which there is no target presented) to be "presented" to the subject. In the event that the output from the photocells indicates eye movement indicating that the subject did "see" the dummy target, the control logic causes a "dummy seen" indicator light on the operator's control panel to turn on thus advising the operator of the subject's uncooperativeness.

It should be noted that the shutter mechanisms are opened and closed whether a real target or a dummy target is presented. This is desirable when the shutter mechanism selected makes audible operating sounds which might be heard by the subject. By operating the shutters for each mode the subject cannot tell audibly whether the target is real or a dummy.

The invention also includes means for evaluating the subject's visual field closely about the region in which

he missed an actually presented target. For this purpose the vernier logic circuit may be employed. The vernier logic circuit is set into operation when the control logic receives a signal from the decision logic indicating that the subject missed an actual target. When the vernier logic circuit is initiated, the control logic is disabled from operating the card reading mechanism and the positioning of the mirror, to present the vernier target images, is controlled entirely by the vernier logic circuit. When the vernier target images have been presented the vernier logic causes the position logic to return the mirror to the attitude which it was in before the vernier sequence and the positioning logic is then enabled to be responsive to the digital positioning information from the card reader. The control logic causes the card reader to be advanced to the next informational word corresponding to the next intended target location and the sequence is begun anew.

The electronic logic systems may be housed conveniently in a control module **110** which houses the card advancing and reading mechanism which includes an exposed slot **112** to receive the card. The module **110** may also house a strip chart recorder **464** to provide a supplemental record of subject's eye test. The module **110** also includes a control panel which includes a manual target positioning means **112,** a start switch **114,** a stop switch **116,** a "dummy seen" indicator light **118,** a record seen/missed selector switch **120,** a vernier in/out switch **122,** a manually controllable switch **124** for turning the reference fixation target on or off, a "disable double saccade" switch **126** and a number of intensity controls **128** for the target light, recording light and reference fixation light.

DESCRIPTION OF CONTROL LOGIC

FIGS. **8A** and **8B** show the circuitry controlling and coordinating the operation of the machine. The sequence of operation is begun by applying a pulse to line **150** through flip-flop **152** and through OR gate **154** to trigger monostable multivibrator **156.** When first starting the sequence of operation the starting pulse may be applied to line **150** through manual start switch **114.** Succeeding pulses are applied to line **150** through flip-flop **152** which is operated in a manner described herein. The high output pulse from multivibrator **156** is amplified and fed through line **160** to initiate operation of a card advancing and reading device **162** which may be of any of a variety of commercially available designs. It should be noted that while the present embodiment of the invention is described as employing digital programming information in the form of a machine readable card, other information, storage and reading techniques may be employed such as tape or the like as is well known in the art. The pulse from multivibrator **156** is also applied to multivibrator **164** through OR gate **166.** Multivibrator **164** has a delay constant (will remain at a high output) sufficient to delay presentation of the target image long enough to enable the card advancing and reading mechanism **162** to position the card so that its digital information may be read as well as to provide sufficient delay for the stepping motors of mirror mechanism **12** to position the mirror, as for example, a delay of approximately 1 second. The output from multivibrator **164** also is directed through line **168** to a gating circuit **170** (FIG. **8A**) which has an AND function. The output from gate circuit **170** is fed through NAND gate **172** and inverter **174** to apply a high input to monostable multivibrator **176.** The other inputs to the gating circuit **170** are from the positioning logic circuitry, described below, which is effective to apply a high input to gating circuit **170** when the mirror has been positioned in accordance with the digital information on the input card, as described herein. With the mirror properly positioned, monostable multivibrator **176** is triggered and its output is directed, through line **178** to actuate the driving mechanism for the projection shutter **22** to open the projection shutter. In the embodiment shown this may be achieved by applying the output from the multivibrator **176** to the input of an enabled NAND gate **180,** inverting the low output from gate **180** to a high state through inverter **182** and applying the high pulse to the shutter mechanism to open the shutter. Multivibrator **176** has a time delay sufficient to maintain the projection shutter open while the target light is being presented. For example, the delay may be of the order of 2.75 seconds.

It is desirable to delay the operation of the target light until the projection shutter **22** has been opened fully. To this end simultaneously with actuation of monostable multivibrator **176,** the pulsed output from inverter **174** is also applied to monostable multivibrator **184** which has a delay constant of the order of 55 milliseconds, depending on the time required to open the shutter fully. The high output pulse from multivibrator **184** is fed into monostable multivibrator **186** which, in turn, controls operation of the target light. The output from multivibrator **186** causes the target light **34** to turn on through line **188** to NAND gate **190** and inverter **192** to the switch mechanism (not shown) for the target light. Gate **190** is normally enabled because of the normally high state of line **236** as will be described. Multivibrator **186** has a delay constant sufficient to remain in a high output state and present the target image for a predetermined time interval long enough to afford the subject a sufficient opportunity to detect and respond to the target. By way of example, a delay constant of the order of 2.2 seconds would be typical. It is desirable to switch the central reference fixation target light **193** off when the target image is presented. This may be accomplished automatically by connecting line **188** through an inverter **189** to the central fixation light. When multivibrator **186** switches high to present the target light, the output from inverter **189** switches low to extinguish the central fixation light **193.** When multivibrator **186** returns to its stable state, turning off target light **134,** the output from inverter **189** will return to its high state to re-present the central reference fixation target. In an alternative mode of operation the central fixation light **193** may be maintained on at all times, including the time in which the target is presented, by line **191** which is connected to the panel switch **124.**

The subject's eye movements and positions are monitored during an extended time interval which includes the predetermined time interval of the presentation of the target image. As described, the output from the photocells **92, 94** is evaluated by the decision logic circuitry to determine whether the subject actually visually detected the target image. In order to provide ample opportunity for the decision to perform its function the output from multivibrator **186** is applied concurrently to monostable multivibrator **194** which has a delay constant sufficient for the subject's eye positions and movements to be monitored by the photocells **92, 94** and the resulting signals processed through the decision logic circuitry. The delay constant of multivibrator

194 preferably is somewhat longer than the time constant of multivibrator 186 to enable the decision logic to evaluate eye movements after the target image has been extinguished, for the full extended time interval. The delay may be, for example, of the order of 3 1 seconds. **This is desirable because the subject's eyes may move after the target light has been extinguished, as when returning his vision to the central fixation point as described herein.**

When the decision logic has evaluated whether a subject actually visually detected the presented target image, it then remains for the photographic recording system to make, or not make, a photographic plot of the target image location, as determined by the mode of operation which the examiner has selected. To this end as multivibrator 194 returns to its stable, low output state, the pulse triggers multivibrator 196, and the output of multivibrator 196 is directed through line 198 to the camera shutter mechanism to open the camera shutter 24. At the same time, the output from multivibrator 196 is directed through line 200 through inverter 202 to apply a low signal at NAND gate 180 which will insure that the projector shutter is closed. This precludes ambient light from reaching the film plane as might occur if the projection shutter 22 remained opened at the same time as the camera shutter. Simultaneously with the actuation of multivibrator 196, the output from multivibrator 194 is applied to monostable multivibrator 204 which is effective to delay further sequencing of the photographic recording functions until the camera shutter 24 is open fully. The delay will depend on the characteristics of the shutter mechanism and may for example, be of the order of 55 milliseconds. It may be noted that monostable multivibrator 196 has a time delay constant sufficient for the logic and control circuits to "decide" whether or not to make a photographic plot of the relative location of the target image as described below. By way of example, the delay may be of the order of 1.2 seconds. When the camera shutter 24 has been opened fully, the return to its stable, low output state of multivibrator 204 triggers multivibrator 206. Multivibrator 206 sets the control logic circuitry in readiness to cause a photographic record of the position of the target to be made, depending on whether the target light was actually presented, whether it was a "dummy" in which case no target would have been presented, whether the subject "saw" or "missed" the target or dummy and whether the intended mode of operation, as controlled by a suitable selector switch on the panel of the control box, is set to record "seen" or "missed" points.

As shown in FIGS. 8A and 8B the output from multivibrator 206 is directed through line 208 to one of the inputs *a* of each of the NAND gates 210, 212, 214, 216. Each of gates 210, 212, 214 and 216 also has an input *b* which is controlled by the decision output from the decision logic circuitry. As described more fully herein, the output from the decision logic circuitry is a signal which is indicative of whether the subject's eye positions and movements where characteristic of his having "seen" the target. As shown in FIG. 8B the output from the decision logic circuitry is applied to monostable multivibrator 218 and the output from multivibrator 218 is directly connected to input *b* of each of NAND gates 210 and 214. The output from multivibrator 218 is also connected, through inverter 220 to input *b* of each of NAND gates 212 and 216. Each of the gates 210, 212, 214, 216 also includes an input *c*, as through line 222, which controls gates 210, 212, 214, 216 in the event that a "dummy" target was presented. The state of line 222 may indicate a "dummy" either by a manual dummy presentation switch on the control panel or from appropriate digital information programmed into the card. Line 222 is connected directly to input *c* of each of the NAND gates 210, 212 and is applied, in an inverted form, through inverter 224 to input *c* of each of the NAND gates 214, 216.

Gates 210, 212 are effective to detect, respectively, whether a dummy signal was "seen" or whether it was "missed," as it should have been. Gates 214, 216 discriminate between actually presented targets which are "seen" or "missed." For example, assuming that an actually presented target was seen and that the manually controlled panel switch (which controls the output of flip-flop arrangement 230), to selectively record points seen or points missed, is in the "record seen" configuration. Where the target was actually presented, line 222 is at a low state which applies low inputs to terminals *c* of gates 210 and 212 and high inputs to terminals *c* of gates 214, 216. Inputs *a* of each of gates 210, 212, 214, 216 are high at this time, from the output of multivibrator 206 through line 208. A target which was actually seen will result in an output pulse from the decision logic to pulse multivibrator 218. This will result in a high input to terminal *b* of NAND gate 214 and a low input to terminal *b* of NAND gate 216. The resulting high output of gate 214 is passed through OR gate 226 and the high output from OR gate 226 is applied to NAND gate 228. The other input to NAND gate 228 is high because of its connection to the output of OR gate 229, which was high because of the high output from NAND gate 216. This results in a pulse at the output from NAND gate 228 which triggers the recording light source. Had the subject under test missed the presented target, input *a* to NAND gate 216 would have remained in its inverted high state thus maintaining its output low which, through OR gate 229, would maintain NAND gate 228 in its previous state. The result would be no output pulse from NAND gate 228 and the record light source would not be triggered.

If it is desired to record the missed targets, thus providing a photographic plot of only the missed points, the panel controlled record seen/missed selector 230 may be set manually to switch the state at line 232 from high to low which sets one of the input terminals of NAND gate 228 at a high state through inverter 234 and OR gate 229. The low state of line 232 is applied directly to one of the inputs to OR gate 226. When the presented target is missed, there will be no pulse from multivibrator 218 and its output will remain low, resulting in a high output from gate 216 which, through OR gate 226, will generate a low output pulse from NAND gate 228, thus triggering the recording light source and making a photographic plot of that missed point. If, however, the target is seen, the output pulse from multivibrator 218 will be applied to input *b* of NAND gate 214 which will switch gate 214 to a low output state with a corresponding low output state from OR gate 226. NAND gate 228 will not be triggered and no photographic recording will be made.

In those instances where it is desired to spot check the subject's response by providing a "dummy" target, the state of line 222 may be changed from low to high either by a manually operable switch on the face of the control panel or by preprogrammed digital instruction on the program card. In either event, when the state of

line 222 is switched to high, the high state is applied to inputs *c* of NAND gates 210, 212, respectively. Inputs *a* of gates 210, 212 are also at a high state. Gates 214, 216 are disabled from operating the recording light during this mode of operation by means of the low output of the inverter 224. The low output from inverter 224 also is applied, through line 236 to an input of NAND gate 190, thus disabling gate 190 (FIG. 8A) and precluding operation of the target light.

When a "dummy target" is presented and "missed" input *b* to gate 210 will be low, resulting in a high output from gate 210 which, is inverted through inverter 238. The output from inverter 238 is employed to control the operation of an indicator light 240 on the panel which, when lit, indicates that the subject moved his eyes when there was no target presented. Here, however, where the "dummy target" was missed, the output from inverter is low and the indicator 240 is not lit. The "dummy missed" indication also results in a high input at terminal *b* of gate 212, thus switching the output of gate 212 to a low state which, in turn, is applied at the input terminal *b* of NAND gate 242. This generates a high output state from gate 242 which is passed through OR gate 154 and is employed to actuate multivibrator 156, to step the card reading mechanism and begin a new cycle of operation.

Where the dummy target has been "seen" the high output from multivibrator 218 is applied to input terminal *b* of gate 210 resulting in a low output from that gate. This actuates the "dummy seen" indicator light on the panel which advises the operator that the subject is moved his eyes in a search for the target or is otherwise being uncooperative in the test. It also switches AND gate 242 through line 241 to pulse multivibrator 156 and advance the card reading mechanism.

After the foregoing arrangement has completed its cycle of evaluating whether the subject detected or missed a real or dummy target and a photographic plot of the seen or missed points has been made, the card reader is sequenced to its next position to read the next column of digital information from the preprogrammed card and begin a new cycle of operation.

When the target image is presented, the inputs to terminals *c* of gates 210, 212 will be low resulting in a high output from these gates into NAND gate 242. If the real target was seen the low output from gate 214 will be inverted at inverter 244 and the resulting high signal will be applied to an input of NAND gate 246. In most instances (except as described below in connection with operation of the vernier logic circuitry) the other input to gate 246 will also be at a high state, resulting in a low output from gate 246 which applied to terminal *c* of gate 242 thus causing a high output pulse to be applied to multivibrator 156 through OR gate 154 to advance the card reader and begin a new cycle is described above.

Where an actually presented target has been missed (assuming that the device is not being operated in its vernier mode) gate 242 is switched by switching its input *d* low. This results from the low output of NAND gate 254 when an actual target has been missed. Input *b* to gate 254 is set high when not operating in vernier (as will be described). Input *a* to gate 254 is controlled by the output from gate 260. NAND gate 260, in turn, has one input *a* set high when not operating in the vernier mode through the high state in line 413 which is inverted, at inverter 261 to a low output state which, in turn, is applied to input *b* of gate 263 maintaining the output of gate 263 high which is applied to input *a* of NAND gate 260. When an actual target has been missed, output of gate 216 switches low resulting in a high output pulse from NAND gate 260 which switches gate 254 low and in turn switches NAND gate 242.

As will be described more fully with regard to the vernier logic circuitry, when in the vernier mode, a series of targets are presented in a programmed sequence which is incorporated into the logic circuitry itself and is not embodied in the preprogrammed digital input information. For this reason, the card reading and stepping mechanism must be disabled while the vernier sequence is being performed. Whether the vernier cycle is to be employed in a given test is controlled manually by the operator at a switch at the control panel. Once the switch has been set by the operator, the vernier circuit will operate automatically in response to a subject having missed a real target and the card reading mechanism will be disabled. The card reading mechanism is disabled by maintaining a low output from gate 242. Inputs *a* and *b* of gate 242 are maintained at a high state when the target image is actually presented and missed. This results from the high output of gate 246 which, in turn, results from the low output of inverter 244 which, in turn, results from the high output of gate 214 when an actual target has been missed. Input *d* of gate 242 also is maintained at a high state when an actual target is missed and when operating in the vernier mode. To this end, the manual vernier switch operates a flip-flop 248 which, when the vernier is "in", is at a high output state. The high state from flip-flop 248 is applied to line 250 and is inverted through inverter 252 and the resulting low state is applied to input *b* of NAND gate 254. The resulting high output from gate 254 is applied at input *d* of gate 242 thus disabling that gate. After the device begins operation of the vernier mode, inputs *c* and *d* to gate 242 are maintained at a high state, thus maintaining the card stepping and reading mechanism 162 disabled throughout the vernier operation, which results from line 413 being switched to a low state. This maintains the output from gate 246 into input *c* of gate 242 high. The output from gate 254, which is applied to input *d* of gate 242 also is maintained high as a result of the low output from inverter 252 which occurs when operating in the "vernier in" mode.

With the card advancing and reading mechanism disabled the presentation of the vernier target images is initiated by an output pulse from monostable multivibrator 256 as will be described more fully herein. The input to multivibrator 256 is dependent on whether the device is being operated in a "vernier in" mode and also whether a real target has been missed. When operating in the "vernier in" mode, the high state in line 250 is fed into input *b* of NAND gate 258 to enable that gate. When an actually presented target is missed, the output from gate 216 switches low which, in turn, switches the output from NAND gate 260 high thus switching gate 258 to its low output state. This is inverted at inverter 262 and the resulting pulse is employed to trigger multivibrator 256 and pulse line 266 to begin the functioning of the vernier control logic as will be described.

Should it be desired to stop the machine at any time this may be done by operating panel stop switch 116 which controls a flip-flop 171 to the disable gate 172 and preclude further sequencing of the control logic.

DESCRIPTION OF POSITIONING LOGIC

The circuitry for controlling the position of the mirror **26** includes means for both manually and automatically feeding digital information into the machine regarding the desired attitude of the mirror and/or whether a particular target is to be a real or dummy target. The mirror positioning logic receives inputs, selectively, from the vernier control circuitry as well as from the programmed digital information card or tape. As mentioned above, when operating in the vernier mode the sequential positioning of the mirror is a function of the circuitry incorporated into the vernier circuit itself. However, when the position of the mirror is to be controlled by the digital information on the program card or tape, a separate input to the positioning logic is employed. For this purpose, and as shown in FIG. **10,** the card reader indicated generally at **300** includes a plurality of output gates **301** which are set to a state corresponding to the information read by the card reader and which corresponds to the target coordinates. This data is transferred to a seven bit register **304** which stores the digital information regarding the particular coordinates of the intended target location. The register **304** feeds a comparator **306.** The comparator **306** also receives feedback input corresponding to the actual position of the X and Y stepping motors **70, 80** at any given time. To this end, step motors include follower potentiometers **308, 310** which step with the motors **70, 80** and are employed to feed back, in analog form, a signal corresponding to the position of their respective step motors **70, 80.** The analog information is fed through an analog-to-digital converter **312** and the output from the A/D converter is fed into the comparator **306.** As will be described below, the X and Y step motors **70, 80** are driven by the output pulses from a system clock in incremental steps which, in cooperation with the gearing selected, will cause the target image on the screen to shift 1°. The output from comparator **306** is employed to terminate driving of the step motors when they have reached a position corresponding to that which was fed into register **304** in digital form.

It may be noted that in the described embodiment of the invention the digital information for a particular intended mirror position is stored on a conventional card having rows and columns of digital data and in a manner in which each column has information relating to either the X or Y position. Whether a particular seven bit digital word read by the target coordinate portion of the card reader relates to an X or Y coordinates is so identified by a bit in the column being read. Thus, card reader **300** also includes a section including output gates **302** which are set, alternatively, to a high or low state depending whether the information which relates to X or Y coordinates. It may be noted that the invention also includes manual means for positioning the target location, indicated generally at **303** and having controls at the control panel.

When operating automatically the card reader will first read a data column relating to the intended position of one of the step motors (the Y motor) and then, after that function has been carried out, the card reader will be advanced to read the next column and carry out the positioning instructions with regard to the other step motor (the X motor).

When a column of digital information is read at reader **300** or fed in at manual input **302,** it is entered into the register **304** when the register **304** is pulsed through line **314.** Line **314,** in turn, carries the output from flip-flop **316** which, in turn, is pulsed by the system clock **318** through line **320,** flip-flop **316** having been previously set by multivibrator **322.** The starting pulse from the system clock **318** is also applied, through inverter **324** to A/D converter **312** to initiate its operation. The A/D converter **312** is selectively fed with analog information from either of the follower pots **308, 310** as controlled by a switch **326.** The position of switch **326** is in turn controlled by the digital input information which also includes in each column data indicative of whether the particular column or manual input relates to positioning of X motor **80** or Y motor **90.** The "X or Y" motor identification data is applied to a pair of flip-flops **328, 330.** Digital information indicating a column of X information indicating a column of X information relating to the intended position of motor **80** will actuate X flip-flop **328** which, through line **332** operates switch **326** to connect the A/D converter **312** to the X motor follower pot **308.** In the absence of an output pulse from X flip-flop **328,** switch **326** will normally be in a position which connects the output from the Y follower pot **310** to the A/D converter **312.**

The direction in which the step motors **70, 80** are driven is controlled by output **334** of comparator **306.** Comparator output **334** controls the state of lines **340** and **342** which are connected to the X and Y step motors **80, 90,** respectively to switch the polarity of each motor in accordance with the desired drive direction. Thus, comparator output **334** is low at all times except when the digital information in register **304** is greater than that indicated by the output A/D converter **312.** The number of incremental steps which the motors **70, 80** are driven is controlled by comparator output **336** which, in turn, controls the outputs of NAND gates **344** and **346** respectively. Gates **344** and **346** are connected to the motors to drive them one increment for each output pulse. Output **336** of comparator **306** remains low at all times except when the outputs from storage register **304** and A/D converter **312** are equal, in which case comparator **306** produces a high output pulse in line **336.**

Assuming that the digital input data in register **304** relates to a Y position coordinate, switch **326** will direct the feedback of analog motor position information from the Y follower pot **310** to the A/D converter **312.** This will be compared at comparator **306** with the position data in register **304** which will be entered into the register **304** in response to the output pulse from flip-flop **316,** the A/D converter **312** being simultaneously pulsed through line **320** to begin its operation. When the Y information in register **304** if greater than the output from A/D converter **312,** the output **334** from comparator **306** will be high, which will result in a low pulse from NAND gate **338.** The other inputs to gate **338** also are high, line **413** being high when the system is not operating in vernier and line **386** being pulsed high in response to switching of Y flip-flop **330** as is the case when the digital data relates to Y positioning information. The low output from gate **338** is employed to maintain the polarity of the drive pulse applied to Y step motor **80** to drive it in one direction as will be described. Conversely, if the digital positin information in register **304** is not greater than the output from A/D converter **312,** output **334** from comparator **306** will switch low which, in turn, will switch the out-

put of gate **338** to high, thus reversing the polarity of the pulse applied to Y step motor **80** and, therefore, reversing its direction of rotation.

The number of drive pulses received by the Y step motor **80** from the system clock is controlled by NAND gate **346.** One input to gate **346** is a function of whether the machine is in a vernier sequence, and, when not, line **348** is low which, when inverted through inverter **350,** is applied as a high input to gate **346.** The other input to gate **346** is controlled by NAND gates **352, 344** and **354.** As long as the outputs from register **304** and A/D converter **312** are not equal, line **336** will be at a low state which, when inverted through inverter **346** will apply a high input to gate **354.** The other input to gate **354** is pulsed high by the system clock **318,** through line **320** and through a delay circuit **358** to cause a low output from gate **354.** This, in turn, results in a high output from gate **344** which produces a low output from gate **352.** The low output of gate **352** results in a high output pulse from gate **346** to drive the Y step motor **80** one increment. Delay circuit **358** is of conventional design and permits the analog feedback information from the follower pots **308, 310** to be fed through A/D converter **312** and converted to digital information usable in the circuit.

In the foregoing manner a high output pulse will result from gate **346** each time the clock **316** pulses to step the Y motor **90** until the information in register **304** is equal to the output from A/D converter **312.** When that occurs, the output **336** will switch to a high state, switching NAND gate **344** to a low output and thus terminating further stepping of the Y step motor **80.** In addition, when line **336** is pulsed to its high state, this pulse is applied to NAND gate **360** which then switches low, triggering monostable multivibrator **362.** The output pulse from multivibrator **362** is connected through line **364** to multivibrator **156** of the control circuitry to step the card reader to the next column of digital information which will bear data corresponding to the other (X) coordinate of the intended target image.

It may be noted that when the Y step motor **80** is stepped to its intended position in response to each high output pulse from gate **344,** that high output pulse also is directed through line **366** to the X step motor **70** to drive it simultaneously with the Y motor **80.** This mode of operation is employed because of the special construction of the mirror positioning mechanism shown in FIGS. **2–7.** The construction of that mechanism is such that operation of the Y step motor **80** alone will cause the yoke **56** to rotate which will move the mirror **26** to a position in which the reflected light beam would shift horizontally as well as vertically on the target screen. For example, rotation of the Y step motor **80** in a direction indicated by the arrow +Y in FIG. **5** and **6** would cause the yoke to rotate in the direction indicated by the arrow +Y in FIG. **4.** Because the surface of the mirror lies at an angle to the axis of rotation of the yoke, rotation of the yoke in the +Y direction will also cause the mirror to pivot to an attitude to cause the target image to be shifted not only in the +Y direction but also to the left in a −X direction on the projection screen **38** as indicated by the corresponding ±X, ±Y arrows in FIGS. **1** and **2.** By simultaneously operating the X step motor **70** in a direction opposite to that which is caused by the Y step motor (here +X), the X component of Y step motor movement can be compensated for. The positioning logic circuitry is arranged so that if the Y step motor **80** is driven a direction to shift the target location up (+Y) and to the left (−X) and the X motor **70** is also driven in a direction which will shift the target image to the right (+X). As will be described, a high output in line **340** will switch the polarity of the X step motor **70** to shift the target image to the left (−X) and a high output in line **342** is effective to switch the Y step motor **80** to shift the target image up (+Y) and to the left (−X), the outputs at lines **340** and **342** would be opposite when the mirror is being positioned to a Y coordinate. The opposite polarity in lines **340, 342** will cause the X step motor **70** to be driven in a +X or −X direction which is opposite to that component of the −Y or +Y direction of the mirror movement which would cause shifting of the target image along an X direction as the yoke is rotated.

The polarity of the pulse applied to Y step motor **80** is controlled by AND gate **368** and the polarity of the pulse applied to X step motor **70** is controlled by NAND gates **370, 372, 374.** The outputs from NAND gates **370, 372, 374** are connected in common to a termination resistor **376** which provides an OR function for that combination of gates. When not operating in the vernier mode, line **413,** which is connected to the vernier control circuitry in a manner described below, is at a high state. The high state of line **413** is inverted at inverter **382** and the resultant low state is applied to gate **374** thus maintaining its output high at times when the system is not in vernier and the mirror attitude is being determined by the digital input data. The high state of line **413** is also applied to an input of each of gates **370, 372** to enable them to be switched to high or low outputs depending on the state of the other inputs to those gates as will be described below. The high state at line **413,** when not in the vernier mode, is also applied to an input of AND gate **368** which enables the gate to be switched, depending on the output from NAND gate **338.** Switching of gates **370, 372** and **368** are dependent on the output **334** from comparator **306** and on whether the mirror mechanism **12** is being positioned to a Y coordinate or an X coordinate. When positioning the mirror to a Y coordinate and assuming that the output **334** from comparator **306** is high, all the inputs to gate **338** will be high, switching the output of gate **338** low to maintain a low output from gate **368** to set the polarity of the Y step motor **80** in a direction which will shift the target image down (−Y) and to the right (+X). The X step motor **70** is driven in a compensating direction (−X), to shift the target image to the left, because the high state at line **334** will result in a high output from each of NAND gates **370** and **372.** Conversely, if the intended Y coordinate were such that the state of line **334** was low, the output from NAND gate **338** would be high, thus switching AND gate **368** high and directing the Y step motor **80** to shift the target image up (+Y) and to the left (−X). The X step motor **70** would be driven in a compensating direction (+X), to shift the target image to the right, by a low output in line **340** which results from all high inputs to NAND gate **372,** switching its output low with a resultant low signal at line **340.**

After the mirror has been shifted to the new Y coordinate and the card reader has been advanced as a result of the pulse in line **364,** the next column on the card will include data relating to X positioning information and will trigger flip-flop **330.** This switches switch **326** to connect A/D converter **312** with the X follower

pot 308. In the manner similar to that described above, the gates 370, 372 and 374 result in an output at line 340 which is dependent on comparator output 334. However, when processing X positioning information the high output from flip-flop 328 is applied through lines 384 to an input of gate 370. A second input to gate 370 is maintained high by line 413. The output of gate 370 thus depends on the input 334 from comparator 306. Gate 372, which, during the positioning of X data, has a low input from Y flip-flop 330 will remain in a high output state at all times as will gate 338 which is also connected through line 386 to the otuput from Y flip-flop 330. Thus, when the output from comparator 306, in line 334, is high, the outputs from each of the gates 370, 372, 374 will be high which will direct the X step motor 70 to shift the target image to the left (−X). When the comparator output 334 is low, however, all the inputs to gate 370 will be high, switching its output low and resulting in a low state in line 340 which sets the polarity of the X step motor 70 to shift the target image to the right (+X).

With the polarity for the X step motor 70 set, regular pulses from the system clock will result in high output pulses from gate 344. When the feedback from the X step motor 70 indicates that the motor 70 has reached the intended position, the output from comparator 306 at line 336, switches high which will switch the output of gate 344 low thus terminating further stepping of the X step motor 70. It should be noted that when the mirror 26 is being positioned with respect to X coordinate information, the Y step motor 80 is disabled because of the low output from gate 346. This results from high input to gate 346 from inverter 350 (when not operating in vernier) and a high input to gate 346 from gate 352. The output from gate 352 is maintained high during the X coordinate positioning because of the low input to that gate by line 386 from Y flip-flop 330 which has a low output state during the processing of X coordinate information.

Where a dummy target is to be presented neither of the X or Y flip-flops 328, 330 are actuated and the positioning system remains inactive.

It may be noted that X and Y flip-flops 328, 330 are self-resetting. When the A/D converter 312 has cycled, its "busy" output at line 388 switches low which, when inverted through inverter 390 switches gate 392 which, in turn, actuates multivibrator 394. The output from multivibrator 394 operates gates 396, 398 which are effective to reset the Y flip-flop 330 and X flip-flop 332, respectively.

The foregoing description of the positioning control has related to its operation when the system is not within a vernier cycle. When in a vernier cycle the number and direction of steps for each stepper motor is controlled entirely and independently by the vernier control circuitry.

DESCRIPTION OF VERNIER LOGIC

As mentioned above when it is desired to examine more closely the regions of the subject's visual field about actually presented targets which were missed by the subject, the panel switch 122 is set to the "vernier in" mode of operation. This enables automatic operation of the vernier cycle in response to the subject having missed an actual target and disables the card reading and advancing system until the vernier target presentation has been completed. When operating in the "vernier in" mode, a signal from the decision logic indicating that the subject has missed a real target image will cause automatic actuation of the vernier control logic to automatically present a plurality of target images in a predetermined array and sequence and in close proximity to and surrounding the location of the target image which is missed. FIG. 9A shows the relative location of the vernier target images with respect to the primary target image which was missed. In the preferred embodiment, three vernier targets are presented in a triangular configuration about the primary target image location located at 400 in FIG. 9. The first of the three vernier points to be presented in the sequence V1 is located 1° directly above the primary target location 400. After vernier image V1 has been presented and the subject's eye position and movements evaluated, the vernier control circuitry causes the mirror to be repositioned to present vernier point V2 which is also spaced 1° from primary target location 400 but below and to the left of location 400 as indicated. The procedure of evaluating the subject's eye movements with respect to vernier target image V2 is performed and the vernier control logic then causes repositioning of the mirror to present vernier target image V3. Vernier image V3 is spaced 1° from the primary target image 400 and is downwardly and to the right of that location to define the triangular spacing of the three vernier points V1, V2 V3.

By presenting a plurality of vernier targets in sequence, fine mapping of the subject's visual field about the region of a missed point is achieved and may show a general boundary line of the subject's scotoma. For example, if the vernier presentation indicates that the subject missed vernier points V1 and V2 but saw vernier point V3, this would indicate that the boundary line of the particular scotoma in question would extend somewhere between vernier point V3 and a line drawn between vernier points V1 and V2 is indicated by phantom by the line 402 in FIG. 9. If the subject missed all three of the vernier targets V1, V2 and V3 this would indicate that the boundary of the scotoma was somewhere outside all of the vernier points. Conversely, if the subject saw all three vernier points this might indicate that the scotoma is quite small and is located closely about the primary target image location 400. It may be noted that while the illustrative embodiment of the invention shows a vernier pattern of only three points, a more fine mapping of the scotoma boundary could be achieved by employing more than three vernier points, as suggested in FIG. 9A in which there are six vernier points presented which would provide still further fine mapping of the scotomic boundary. However, three vernier points are adequate for most testing purpose.

The vernier sequence is begun in response to a missed target by an output pulse from multivibrator 256 (FIG. 8B) which is applied to pulse flip-flop 404 (FIG. 11) through line 266. The other input to flip-flop 404 is synchronously controlled by the system clock 318 to produce an output pulse from flip-flop 404 synchronously with the timing of the vernier system as controlled by the system clock. The output pulse from flip-flop 404 is fed into a three bit digital counter 408 having both positive and inverted outputs. It may be noted that counter 408 is rezeroed through line 409 at the beginning of each operational sequence by its connection to line 150 through gate 411. The inverted outputs are connected to the three inputs of NAND gate 410, the output of which is connected to line 413

of the control logic and position logic circuits described above. Thus, where the system is not operating in vernier or, if in vernier and a target was seen, there is no output pulse from multivibrator **256** and the flip-flop **404** remains in the low output state. As a result each of the three counter outputs *a*, *b*, *c* will be at a low state (**000**) which, when inverted and fed into NAND gate **410** will result in a low output which may be inverted through inverter **412** to a high state which is applied to line **413.** As described above, when line **413** is high gates **246** and **254** are disabled and cannot control switching of gate **242.**

When a target is missed the first vernier pulse from multivibrator **256** is applied to flip-flop **404.** The counter **408** switches to a (**001**) digital state which results in input *a* to gate **410** being switched low. This results in a high output from gate **410** which is inverted to a low state through inverter **412** to switch line **413** to a low state. As described above, when line **413** is switched low, gate **246** is switched to produce a high output which further precludes operation of the step card reader multivibrator **156** during the vernier sequence. Similarly, because the panel switch and flip-flop **248** is set to the vernier position, the output from gate **254** is high. In addition, line **413** is connected to an input of each of NAND gates **370, 372** and **338** of the position logic (FIG. **10**) to maintain their high outputs and disabling them from switching to low output during the vernier cycle. The high output from NAND gate **338** enables AND gate **368** to be controlled directly by the vernier circuitry through line **380** as will be described below. Line **380** is also connected through line **381** to an input of gate **374** to control its output in response to the vernier circuit. It should be noted that the other input to NAND gate **374** is enabled by high signal from an inverted input, through inverter **382** from line **413.** It may be noted that during operation of a vernier cycle one of the inputs *a*, *b* or *c* to gate **410** will be low, which maintains the low state in line **413.**

When counter **408** has received its first pulse from flip-flop **404** and has been switched to a (**001**) digital configuration the X and Y steps motors **70, 80** are driven to a position which will orient the mirror **26** to reflect the light target at the first vernier position V1 which, in the illustrative embodiment, is 1° above the location of the missed target **400.** This requires the Y step motor **80** to be advanced to move the mirror to reposition the image one step upwardly (+Y) and to the left (−X) and the X motor **70** to compensate one step to the right (+X). The number of pulses applied to the step motors is controlled by switching X NAND gate **414** and Y NAND gate **416** to develop output pulses in response to and for the desired number of output pulses from the system clock **318.** For example, with the counter **408** set to a (**001**) output all but input terminal *a* of NAND gate **418** will be high. When the system clock **316** pulses input *a*, through line **420,** the output from gate **418** will be switched to low which will result in an output pulse from X NAND gate **414** and, through line **424,** a high output pulse from gate **416.** The output of gate **414** is connected through line **422** to the position logic circuit. As shown in FIG. **10,** a high output in line **422** will be inverted to low at inverter **426** and that low signal switches the output of gate **344** high to pulse the X step motor **70.** The high output from gate **416** is connected through line **348,** through inverter **350** (FIG. **10**) to pulse NAND gate **346** high and drive the Y step motor **80** one increment.

The direction in which each of the step motors is driven for the first vernier point is controlled by the state of line **380.** Line **380** is connected to the output of NAND gate **428** and its state is dependent on the output from counter **408.** When counter **408** receives its first pulse to begin positioning of the first vernier point the input to gate **428** from output *b* of counter **408** will be low thus maintaining line **380** at a high state. This, in turn, results in a high output pulse from gate **368** to direct the Y step motor to drive the mirror in a +Y, −X direction (up and to the left as seen on the screen) and results also in switching of gate **374** resulting in a low output which will direct the X step motor **70** to drive the mirror in a compensating +X direction to shift the target image location to the right.

The output pulse from gate **418** also is applied to NAND gate **430** which, in turn, drives a two-bit counter **432.** When the output from gate **418** switches low in response to termination of the clock pulse, output from NAND gate **430** switches high, pulsing counter **432.** The output from counter **432** switches NAND gate **434** so that its resultant low output will be applied to an input of gate **418** through line **436** thus switching gate **418** back to its high output state which, in turn, switches vernier control gates **414, 416** back to their low output state and terminates the positioning of the mirror at the first vernier point. With the mirror having been positioned to the first vernier point V1 within the delay of multivibrator **164,** the resetting of multivibrator **164** to its low output state pulses gating circuit **170** through line **168** (FIG. **8A**) to control the projection shutter, projection light, the camera shutter, record light in the same manner and sequence described previously. The subject's response to the presentation of the first vernier point V1 is monitored by the photocells **92, 94** and the decision logic circuitry determines whether the subject saw or missed the first vernier point. Depending on whether the photographic recording system is set to record seen/record missed points, a photographic plot of the subject's response to the presentation of the first vernier target image may be recorded. Whether the subject saw or missed the first vernier point, after his response has been evaluated multivibrator **256** is then pulsed to continue the vernier sequence. This results from the output pulse from gate **258** each time either of gates **214** or **216** are switched. It should be noted that each time counter **408** is advanced from the output from flip-flop **404,** counter **432** is reset to a (**00**) state through line **44,** flip-flop **445,** inverter **446** and line **447.**

The foregoing sequence of automatically entering into the vernier mode and positioning the mirror to direct the target image to the first vernier location all takes place within the delay constant of multivibrator **164** which may be of the order of slightly over one second.

After the first vernier target image V1 has been presented, and it has been determined whether the subject has seen or missed it, and whether the response should be photographed, the second vernier point is presented. As can be seen from FIG. **9,** this requires movement of the Y step motor **80** to shift the target image two increments downwardly (−Y) and to the right (+X) and three incremental steps of the X step motor to the left (−X). When multivibrator **256** is again pulsed to cause the output from flip-flop **404** to advance counter **408** to the next digital state (**010**), the output from counter **408** switches NAND gates **438,**

428, 440 to each produce low output pulses which, in turn, switches X and Y gates 414, 416 to produce high output pulses synchronously with system clock 316. The switching of NAND gate 328 produces a low pulse in line 380 which is effective to reverse the polarity of the pulses applied to the step motors thus reversing the direction of the X and Y step motors. By switching the state of line 380 low, the output from AND gate 368 will switch low causing the polarity of the drive pulses which are directed to the Y step motor to shift the target image location downwardly (−Y) and to the right (+X). The low pulse in line 380 also is applied through line 381 to gate 374 switching its output high which, in combination with the high outputs from gates 370 and 372 result in a high state in line 340 which will direct the X step motor 70 to shift the target image location to the left (−X). The X and Y motors are pulsed in the manner described above with counter 432 being advanced for each pulse from the system clock. When the counter 432 has been pulsed twice and advanced to a (10) digital state NAND gate 442 switches from its high state to produce a low output pulse which is applied to an input of gate 440 thus switching that gate to a high output which in turn switches gate 416 low and terminates further operation of the Y step motor 80 after two incremental steps. The X drive gate 414, however, is driven one more time until counter 432 registers the third digital state (11) which causes NAND gate 448 to switch to a low output, causing a high output from gate 438 which, in turn, disables X gate 414 to terminate operation of the X step motor 70. The target is then presented at the second vernier point V2 and the decision and control logic run through their respective sequences as described above. It may be noted that when presenting the second vernier target the operation of multivibrator 164 is controlled by the output of multivibrator 256 through line 257 and not by multivibrator 156 which is disabled during vernier operation.

In order then to present the third vernier point it may be seen (FIG. 9) that the mirror must be moved to shift the target image location two increments to the right (+X). In the illustrative embodiment this requires operation of the X step motor alone. Thus, when the counter 408 has been pulsed to its next digital state (011) gate 428 will switch to a high output again reversing the polarity of the pulse which is applied to the step motors through line 380. The Y drive gate 416 remains in a low output state as all of its inputs are high. X drive gate 414 is switched through line 445 to produce a high output pulse as the output from gate 441 switches to low in response to all high inputs to gate 441, thus stepping the X motor. When counter 432 has been pulsed twice, the output from gate 442 switches to low, thus switching gate 441 to a high output which switches X drive gate 414 low and terminates further stepping of the X drive motor. With the mirror positioned to show the third vernier point, the third vernier target image is presented and the control and decision logic perform their respective functions.

After the three vernier points have been presented, it then remains for the mirror to be repositioned to the location of the original target image which was missed and which initiated the vernier sequence. This, in turn, requires that the Y motor be stepped one increment up (+Y) and to the left (−X) while the X motor is maintained inoperative. When counter 408 is pulsed, for the fourth time, and is advanced to the (100) state, the inputs to X gate 414 remain high thus maintaining X step motor inoperative. The Y drive gate 416, however, switching to a high output state because of the low input in response to the low input from fate 450. Gate 450 is switched to a low output by reason of the high input to it from counter 408. After NAND gate 430 has pulsed counter 432 to indicate one pulse, NAND gate 452 is switched high and, through line 454 resets counter 408 to its initial digital state (000). Resetting of counter 408 to the (000) digital state, returns line 413 to a high state. The (100) state of counter 408 also causes gate 453 to be pulsed and which passes through OR gate 154 switches multivibrator 156 to advance the card reader and resume the presentation of the primary targets.

DESCRIPTION OF THE DECISION LOGIC

The position and movement of the subject's eyes are monitored by the eye imaging techniques described in U.S. Pat. Nos. 3,583,794 and 3,689,135 in which the image of the subject's eye is projected onto a screen and in which photocells 92, 94 are located on the screen to be responsive to the position and movement of the eye image. The vertically spaced photocells 92 detect variations in the vertical position of the subject's eye (including movements of the eye lid) and the horizontally spaced photocells 94 detect changes in the subject's horizontal eye position. The outputs from the horizontal and vertical photocell pairs result in a signal which is indicative of both magnitude and direction of the subject's eye movement. The decision logic circuitry is designed to discriminate between photocell outputs which are characteristic of the subject having actually seen or missed the presented target, hunting eye movements and blinks.

FIG. 12A is a DC representation illustrating the relationship between the presentation of the target image and a subject's target missed response as indicated by the output from the photocells. Where the subject's eye does not move during presentation of the target there is no change in output from the photocells.

FIG. 12B illustrates an ideal response in which the subject has actually seen the target image. Typically, there will be a slight delay from the time in which the target is presented to the time in which the subject's eyes actually move and the response may be delayed, for example 200–500, milliseconds. Also, when the sighted target image is turned off a similar delay will occur in the subject's returning his eyes to the central fixation target. It may be noted that the photocell output may be positive or negative depending on the direction of movement of the subject's eyes. As will be described in connection with the decision logic circuitry, the direction of eye movement is not critical in the particular embodiment shown, the magnitude being the primary consideration.

FIG. 12C illustrates the photocell output in a situation where the subject has sighted the target but was unable to control his eye movement to direct it precisely to the target image in a single saccade. The photocell output indicates a first substantial eye movement to the general vicinity of the presented target image and a second, minor correctional movement. For example, the first saccade may be of the order of 5° or more, depending on how far the target image is from the central fixation point and the second correctional saccade may be of the order of 3° or less. FIG. 12C shows a minor correctional saccade in the same direc-

tion as the first saccade and FIG. **12D** shows a minor correctional saccade in an at least partly reversed direction. Both responses indicate an actually seen target.

FIG. **12E** shows a further response which is indicative of the subject having actually seen the target. This response may be considered as an "early return" in which the subject returned his eyes to the central fixation position before the target light was extinguished. This response also is considered as an actually seen target.

FIG. **12F** illustrates a hunting or searching eye movement in which the difference in magnitude of the photocell outputs between the first and second saccades is substantial, for example, of the order of more than 5°. This may result from a first saccade in a direction which is away from the location of the target image, as shown in FIG. **12F** or may result from an eye movement shown in FIG. **12G** in which, while the searching saccade and second saccade are in the same general direction, the second saccade is substantial, of the order of more than 5°.

FIGS. **12H** shows a typical output from the vertically spaced photocells which results from a blink. The duration of a typical blink is of the order of 30–50 milliseconds and results in a relatively short duration pulse. Of course, a blink may occur at any time, whether the target is being presented or not.

The decision logic circuitry is effective first to determine whether an output from the photocells is the result of a blink. If so, the remaining portions of the decision logic are disabled from further evaluating that photocell output.

As shown in FIG. **13** the outputs from the horizontal and vertical photocell pairs are amplified at amplifiers **460, 462** respectively. The amplified signals may be coupled to a strip chart recorder **464** if desired to provide a permanent charted D.C. record of the subject's eye movements. The outputs from amplifiers **460, 462** are fed through buffer amplifiers **466, 468** and these signals are coupled to an absolute value adder **470** through AC couple **472.** Where the amplified signals from the photocell pairs are DC, the AC couple is effective to overcome the effect of any long term drift which might be inherent in the system as well as to overcome the effect of any slight head shift of the subject during the test. The absolute value adder insures that a positive output from one pair of photocells will not be negated by a negative output from the other pair of photocells but, instead, results in an output which is the sum of the magnitude of the photocell outputs regardless of their sense. The output from absolute value adder **470** is coupled to a first sense amplifier **474** and also to a second sense amplifier **476.** Sense amplifier **474** is selected so that it will pulse line **478** when the amplitude of the input to amplifier **474** corresponds to an eye movement of more than a first predetermined magnitude, for example, 3°. Sense amplifier **476** is effective to produce an output pulse in line **480** in response to an input from adder **470** having an amplitude corresponding to a change in the direction of eye movement of more than a second predetermined magnitude, for example, 5°.The outputs at lines **478** and **480** are employed in the decision logic circuitry to discriminate between the various saccadic movements illustrated in FIGS. **12A–12H** in a manner described below.

The decision logic includes three channels including a primary saccade detection channel **479,** a secondary saccade detection channel **481** and a blink detection channel **493.** Each signal resulting from the output of either or both of the photocell pairs **92, 94** is applied to each of the three channels simultaneously. If the photocell output was the result of a blink the blink detection channel **493** disables the primary and secondary channels **479, 481** from further operation thus disregarding the effect of the blink. If the resulting signal from the photocells **92, 94** was caused by a genuine saccade this is detected by the primary channel **479** which, in turn, is connected to the secondary channel **481** to enable the secondary channel to thereafter detect existence of a second saccade within a predetermined time interval after the first saccade. The output from the first channel is also connected to an output decision gate **506** (as will be described) in a manner which causes that gate to be enabled at a fixed, predetermined time interval after the detection of the first saccade. The state of the other input to decision out gate **506** is dependent on whether the primary and secondary channels **479, 481** have detected the existence of only two or more saccades and the timed relationship of the saccades with respect to the presentation of the target image as well as their magnitude.

More particularly in order to discriminate blinks from other eye movements, the signal from the vertical photocells is connected through buffer amplifier **468** to a sample and hold circuit **482** and also to a comparator **484,** the output from the sample and hold circuit **482** also being fed into comparator **484.** Comparator **484,** in turn, drives a pair of sense amplifiers **486, 488** which produce an output pulse when the output from the comparator is positive and negative respectfully. When an output signal results from the photocells, the decision logic circuit first evaluates whether the output was the result of a blink. If so, the decision logic circuitry is disabled and there is no change in its output. The blink detection circuitry includes a NAND gate **490** having its inputs fed by sense amplifiers **485, 488.** The output from NAND gate **490** is inverted at inverter **492.** The inputs to NAND gate **474** are normally high which results in a normally high output from inverter **492.** The output from inverter **492** thus may be switched by any change of state to either input to gate **490** resuling from a pulse from either of sense amplifiers **486, 488.** The output from the inverter **492** is connected directly to an input of NAND gate **494** and also to the other input of gate **494** through a multivibrator **496** having a delay constant of, for example, approximately 330 milliseconds. When either input to NAND gate **490** is low as a result of a signal from the vertical photocells input of gate **494** will remain low, to preclude switching of gate **494** while monostable multivibrator **496** will switch to a high output state.

If the triggering input to NAND gate **490** was the result of a blink, which typically lasts between 30–50 milliseconds, the low output of inverter **492** and input *a* of gate **494** will switch back to high before multivibrator **496** has returned to its low output state. The all high inputs switch gate **494** to a low output which triggers monostable multivibrator **498,** switching it to a high output state and switching the output of NAND gate **500** to low. A low state at the output of NAND gate **500** indicates the presence of a blink and disabled NAND gates **502** and **504** which, in turn, precludes any change in output of the decision out gate **506** as will be

apparent from the further following description. If, on the other hand, the input to NAND gate **490** was the result of a genuine saccade in which the subject's eye remain fixated for considerably more than 30–50 milliseconds, the direct input to gate **494** will remain low at all times during and after the delay of multivibrator **496** thus leaving gate **94** unactuated and maintaining the output from gate **500** in its normally high state which, in turn, maintains the inputs to gates **502, 504** high and in an enabled state.

If the blink detection channel **493** has detected that the input pulse was the reset of aa genuine saccade, the remaining primary and secondary channels **479, 481** evaluate whether the saccade was the result of the subject's actual perception of the target image or whether it was the result of "hunting" or searching eye movements. When an added pulse from one or both pairs of photocells is fed into sense amplifiers **474, 476** those amplifiers, respectively, evaluate whether the saccade (here the first saccade) was of a magnitude of more than 3° and whether the saccade was a change in eye movement of more than 5°. For example, assuming that a target was presented and was seen, the subject's eye movement of more than 3° results in an input pulse to monostable multivibrator **505** switching its output high. Multivibrator **505** has a 330 millisecond delay function and serves to delay further operation of the portions of the primary channel **479** for a time sufficient to enable the blink detection channel **493** to evaluate whether the pulse resulted from an eye movement or a blink. When multivibrator **505** switches back to its low, stable state, that actuates monostable multivibrator **508** switching its output momentarily to a high state. If the target light was on at the time of the saccade then all three inputs to NAND gate **502** are switched to high. This is accomplished by applying a pulse in line **510** indicating that the target light is on and passing it through inverter **512** and NAND gate **514** to produce a high pulse at input of gate **502,** thus enabling that gate as long as the target light is on. It may be noted that while the first saccade may have been of a magnitude which would have also switched the output from sense amplifier **476** to a high state, gate **524** is, at that time, in a disabled state because of the low input, through line **518** from the monostable multivibrator **522** as will be described.

In order to evaluate whether the first saccade was the first of a series of eye movements indicating true perception of the target or whether it was a "hunting" saccade, the decision logic awaits subsequent signals from the photocells to determine whether only a second saccade follows or whether both a second and third saccade follows. Also, where there are three saccades, their relative magnitudes must be evaluated to discriminate between hunting movements (FIGS. **12F, 12G**) and acceptable correctional movements (FIGS. **12C, 12D**). As described above, saccadic movements of less than a predetermined magnitude for example 3°, are considered to be mere correctional movements. Thus, a pulse resulting from photocells **92, 94** which corresponds to an eye movement of less than 3° will be isolated from the primary and secondary channel, **479, 481** by the sense amplifiers **474, 476** respectively. There being no signal applied to the primary and secondary channels, an eye movement of less than 3° has the same effect as if there had been no eye movement at all thus completely disregarding mere correctional movements.

As indicated at FIGS. **12A–12G,** where there has been a first saccade there will always be a second saccade. The second saccade may result from the subject's returning his eyes to the central fixation target (FIGS. **12B, 12E**) in which case the second saccade is a final saccade indicating that the subject actually saw the target. However, the second saccade may have been the result of the first time that the subject actually saw the target, in which case the second saccade would be only an intermediate saccade which would indicate that the first saccade would have been a hunting or searching movement (FIGS. **12F, 12G**). In order to discriminate between these saccadic movements the invention employs a technique in which the subject's eyes are monitored to detect the existence and magnitude of at least three saccades in which the intermediate saccade or saccades was more than 5° which would indicate that the first saccade was a hunting movement and that the subject did not actually see the presented target.

The foregoing functions are enabled by the switching of gate **502** to a low output state which is the case when the first saccade is not a blink, as described above. The low output from gate **502** is inverted to a high state through inverter **520** and that pulse is applied to monostable multivibrator **522.** Multivibrator **522** is switched to its high output state when the output from multivibrator **508** retuns to its low state after generating its short pulse. When multivibrator **522** is switched, its high output is applied to the input of NAND gate **524** which enables that gate and, consequently, the secondary channel **481** to be actuated when the remaining low input of gate **524** receives a high pulse from sense amplifier **476.** Multivibrator **522** has a time delay which will maintain its high output state, thus maintaining the secondary channel **481** in an enabled state for a time sufficient to include that in which a second, intermediate saccade would be made. For example, the delay of multivibrator **522** may be of the order to 450 milliseconds. Thus, if the photocells **92, 94** produce a signal indicating a saccade which was a change of more than 5° and during the enabled interval of secondary channel **481,** gate **524** will be actuated to switch its output low to low thus actuating blink delay monostable multivibrator **526** which also has a time delay constant of 330 milliseconds. This enables the block detection logic to again evaluate whether the second input signal to gate **524** was the result of a blink or a genuine second saccade. If a blink, the low output at gate **500** of the blink detection logic is applied to an input of gate **504** thus disabling that gate and the secondary channel **481.** However, if the signal was not a blink gate **504** will be enabled. When multivibrator **526** switches back to low state, after its 330 millisecond delay, and that pulse triggers monostable multivibrator **528** to produce a short output pulse switching gate **504** low which triggers monostable multivibrator **530** switching its output high. This high output is applied to an input of NAND gate **532** which enables that gate. Multivibrator **530** has a delay constant sufficient to maintain gate **532** in an enabled state for an extended interval ending shortly after the target light has been extinguished. By way of example the delay may be of the order of 2.75 seconds. As described below the other input to gate **533** depends on whether or not there was a third saccade which, in turn, controls the output of gate **532** and the input to decision out gate **506.**

The detection of a third saccade is effected by the primary channel **479.** After the 450 millisecond delay

of multivibrator **522,** its output switches low which switchs multivibrator **536** to a high output state. This, in turn, enables one of the inputs to gate **534.** Multivibrator **536** has a delay constant which also extends beyond the time that the target lights is extinguished in order to be able to detect return eye movements which often occur after the extinguishment of the target light. It may be noted that multivibrator **530** has a delay slightly longer than multivibrator **536** so that gate **532** may remain enabled and be switchable in the event that gate **534** is switched. If a third pulse is emitted from the photocells, it will, as is the case for each such pulse, be directed to the sense amplifiers **474, 476** as well as to the blink detection circuitry. Multivibrator **505** delays functioning of the primary channel **479** stages until the blink detection channel **493** has an opportunity to evaluate whether the photocell output was the result of a saccade or a blink. Assuming that it was not a blink and that a third saccade was made by the subject, the signal resulting from the third saccade switches the output from inverter **520** high which is applied through line **538** to the other input of gate **534** switching its output low which, is inverted at inverter **540** and is fed as high pulse into an input of NAND gate **532.** This results in a low output from gate **532** which switches multivibrator **542** to produce a high output which is inverted at inverter **544** and is fed into decision out gate **506.** This will not switch and its **164** in the control logic andits output will remain low thus indicating a "missed target."

When there is no third saccade during the delay of multivibrator **536,** this indicates that the second saccade was in fact a final saccade to the central fixation point and was thus an actually seen target. When there is no third saccade the input to decision out gate **506** from inverter **544** is high thus enabling that gate. When multivibrator **536** switches back to its low stable output state this switches multivibrator **546** and the high output pulse from multivibrator **546** switches decision out gate **506** to a low output which, in turn, actuates multivibrator **164** and indicates a target seen.

In some mass testing situations it may be desirable to make a more coarse test, for example, to detect only whether the subject responded at all to presentation of the target image. This may be accomplished by disabling the second channel **481** so that the output from inverter **544** will remain high at all times thus maintaining decision out gate **506** enabled continuously. Any non-blinking eye movement during presentation of the target image will result, ultimately, in a pulse from multivibrator **546** which will switch decision out gate **506** low indicating a response by the subject during presentation of the target image. While this mode of operation does not discriminate between hunting eye movements and true perceptions, it does give a rapid more coarse testing procedure. The second channel may be disabled by switch **126** on the control panel which switches flip-flop **550** to enable or disable gate **524** as desired.

When the subject has actually perceived the target and makes a "normal" response (FIG. **12B**) his eyes will fixate on it as long as it is presented (approximately 2.2 seconds). In this event there will be no detected eye movement during the 450 milliseconds that the multivibrator **522** is in its high state. Thus, even though gate **522** is in readiness to be actuated in response to sensed eye movement during the 450 millisecond interval, there is no movement and the input to gate **532** remains low. When the subject's eyes do return to the reference fixation target shortly after the target light has been extinguished from the subject's view the pulse resulting from the saccade, which is channeled to gate **502** causes multivibrator **522** to be pulsed. The high output from multivibrator **522** is inconsequential at this time because multivibrator **536** already is in its high state. When the multivibrator **536** switches back to its low state multivibrator **546** is pulsed to apply a high input to decision out gate **506.** The other input of the decision out gate **506** is also high at this time because as multivibrator **536** was switched to its low state, gate **534** switched to a high state which is inverted to low through inverter **540** which maintains gate **532** at a high state thus precluding actuation of multivibrator **542** whose normally low output is inverted at **544** to a high state which is applied to the decision out gate **506.** The resulting low pulse from gate **506** is applied through line **470** to the control logic as previously described. As described previously, there may be some instances in which the subject has perceived the target but returns his gaze to the general region of the central fixation target before the target light has been extinguished. Such early return is detected by the foregoing decision logic as a perceived target. Here, the subject's eye movement usually will be after the 450 millisecond delay of multivibrator **522** but before multivibrator **536** has switched back to its low state. This has the same effect as a "seen" response described above.

In order to insure that gate **502** is enabled through line **516** during the extended time interval which includes the interval during which the target is actually presented and a short time thereafter, the output from multivibrator **522** is connected through inverter **548** to an input of gate **514** and the output from multivibrator **536** is connected through inverter **550** to the other input of gate **514** thus insuring a high state in line **516** at all times during operation of the decision logic.

The foregoing mode of operation of the decision logic may be considered as employing a technique in which the extended time interval during which the subject's eye positions and movements are monitored may be considered as divided into successive portions in which each portion begins with eye movement. The number and duration of each such portion of the extended time interval will, of course, depend on the time in which the subject moves his eyes. In addition, an initial segment of each portion of the extended time interval is employed to evaluate whether the particular eye movement was a blink, in which case the eye movement is disregarded as described above.

It should be understood that the foregoing description of the invention is intended merely to be illustrative thereof and that other modifications and embodiments of the invention may be apparent to those skilled in the art without departing from its spirit.

Having thus described the invention what I desire to claim and secure by Letters Patent is:

1. A method of objectively testing the visual field of a subject:

providing reference fixation target within the subject's visual field;

thereafter presenting a target image to said subject, at a selected location within the subject's visual field and at a selected angular distance from said reference target, said target image being presented for a determined time interval;

monitoring the position and movement of the subject's eye at least during an extended time interval which includes and which extends beyond said predetermined time interval; and

determining whether the subject actually visually detected the presented target image by electronically detecting the number and magnitude of the subject's eye movements during said extended time interval.

2. A method as defined in claim **1** wherein said step of determining whether the subject actually visually detected the presented target image comprises, at least in part:

detecting, within said extended time interval, those of the subject's eye movements having at least three saccades and in which the magnitude of an intermediate of said saccades is more than a predetermined magnitude thereby indicating a hunting eye movement and a missed target.

3. A method as defined in claim **2** wherein said predetermined magnitude comprises approximately 3°.

4. A method as defined in claim **1** wherein said step of determining whether the subject actually visually detected the presented target image comprises, at least in part:

detecting, within said extended time interval, those of the subject's eye movements having at least three saccades and in which the magnitude of the first of said saccades does not differ from said selected angular distance by more than a predetermined magnitude and in which the magnitude of an intermediate of said saccades is no more than a predetermined angle.

5. A method as defined in claim **1** wherein said step of determining whether the subject actually visually detected the presented target image comprises, at least in part:

detecting, within said extended time interval, those of the subject's eye movements having only two saccades, each of which is of a magnitude substantially equal to said selected angular distance.

6. A method as defined in claim **1** wherein said step of determining whether the subject actually visually detected the presented target image comprises:

detecting, within a first portion of said extended time interval, the existence of an initial saccade of a magnitude greater than a first predetermined magnitude;

detecting, within a second portion of said extended time interval, the existence of a subsequent saccade of a magnitude greater than a second predetermined magnitude;

detecting, within a third portion of said extended time interval, the existence of a subsequent saccade of a magnitude greater than said first predetermined magnitude; and

discriminating between those groups of saccadic movements which include said second saccade and those which do not.

7. A method as defined in claim **6** further comprising:

detecting within a first segment of each of said portions of said extended time interval, the existence of double eye movements having a short duration characteristic of a blink; and

discriminating between said saccadic movements and said blink movements.

8. An apparatus for objectively testing the visual field of a subject comprising:

means for presenting a reference fixation target within the subject's visual field;

means for presenting a target image to the subject at a selected location within the subject's visual field at a selected angular distance from said reference target and for a predetermined time interval;

means for monitoring the position and movement of the subject's eye at least during an extended time interval which includes and which extends beyond said predetermined time interval, said monitoring means being constructed and arranged to provide an electrical output signal of an amplitude corresponding to the magnitude of movement of the subject's eye; and

circuit means having an input connected to the output of said monitoring means and having an input from said target image presentation means for determining whether the subject actually visually detected a presented target image by electronically detecting the number and magnitude of the subject's eye movements during said extended time interval.

9. An apparatus as defined in claim **8** wherein said circuit means comprises, at least in part:

means for detecting, within said extended time interval, groups of at least three output signals from said monitoring means and in which the amplitude of an intermediate of said signals is more than a predetermined amount.

10. An apparatus as defined in claim **9** wherein said predetermined amplitude corresponds to a subject's eye movement of approximately 3°.

11. An apparatus as defined in claim **8** wherein said circuit means comprises, at least in part:

means for detecting, within said extended time interval, groups of at least three output signals from said monitoring means and in which the amplitude of the first of said signals corresponds to an eye movement which does not differ from said selected angular distance by more than a predetermined amount and in which the amplitude of the succeeding of said signals is no greater than that which would correspond to an eye movement which is no more than said predetermined amount.

12. An apparatus as defined in claim **8** wherein said circuit means comprises, at least in part:

means for detecting, within said extended time interval, the existence of only two output signals from said monitoring means, each of said two output signals being of an amplitude which corresponds to an eye movement of a magnitude substantially equal to said selected angular distance.

13. An apparatus as defined in claim **8** wherein said circuit means comprises:

a primary channel having an output connected to an output gate, said primary channel being constructed and arranged to apply a pulse to said output gate and in response to an input signal to said primary channel and at the end of said extended time interval;

said monitoring means including an output connected to the input to said primary channel;

said primary channel including, at its input, means for enabling only those of the output signals from said monitoring means which have an amplitude more than that which corresponds to a predetermined magnitude of eye movement to be applied to the input of said primary channel;

means for enabling said output gate, at least at the end of said extended time interval; and

whereby an eye movement of a magnitude at least equal to said predetermined magnitude will switch the output of said output gate at the end of said extended time interval.

14. An apparatus as defined in claim **8** wherein said circuit means further comprises:

a primary channel having an output connected to an output gate, said primary channel being constructed and arranged to apply a pulse to said output gate in response to an input signal to said primary channel and at the end of said extended time interval;

said monitoring means including a first output connected to the input to said primary channel;

said primary channel including, at its input, means for enabling only those of the output signals from monitoring means which have an amplutude of more than that which corresponds to a predetermined magnitude of eye movement to be applied to the input to said primary channel;

a second channel having an output connected to said output gate, said second channel being constructed and arranged to disable said output gate in response to an input signal to said second channel;

said monitoring means including a second output connected to the input to said second channel;

said second channel including, at its input, means for enabling only those of the output signals from said monitoring means which have amplitude more than that which corresponds to a second predetermined magnitude of eye movement, which second predetermined magnitude is greater than said first predetermined magnitude, to be applied to the input of said second channel;

means responsive to an initial signal to said primary channel for enabling said second channel for a predetermined time interval after said first signal; and

means connecting said primary and second channels for reenabling said output gate in response to a third signal applied to said primary channel within said extended time interval.

15. An apparatus as defined in claim **14** further comprising:

means for manually and independently disabling said second channel whereby said circuit means will be responsive solely to the first and said eye movements.

16. An apparatus as defined in claim **14** further comprising:

a third channel having an input connected to an output from said monitoring means, said third channel having an output connected to said primary channel for selectively enabling or disabling said primary channel;

said third channel being constructed and arranged to disable said primary channel in response to a pulse signal from said monitoring means in which said signal has a period of up to approximately 50 milliseconds and being characteristic of a blink; and

said primary and second channels including means for delaying operation of said channels until after said third channel has selectively enabled or disabled said primary channel.

17. A method for determining the visual field of a subject comprises:

providing a reference fixation target within the subject's visual field;

thereafter presenting a target image to the subject at a location spaced from said reference fixation target but within his expected visual field;

electronically determining whether the subject actually visually detected said presented target image; and

in response to an indication that the subject did not actually visually detect said presented target image, thereafter automatically and sequentially presenting a plurality of individual secondary target images, each of said secondary target images being presented at equally spaced locations with respect to the location of said first presented target image, and determining, by electronic detection of the eye movements of the subject, which of said secondary targets were actually seen.

18. A method as defined in claim **17** wherein said sequentially presentation of said secondary target images includes presentation of at least three such images disposed in a generally triangular pattern surrounding the location of said first presented target.

19. A method as defined in claim **18** wherein said secondary target images are each spaced approximately 1° from the location of the first presented target image.

20. An apparatus for determining the visual field of the subject comprising:

means for displaying a reference fixation target within the subject's expected visual field;

means for presenting a target image to the subject within his expected visual field and at a location spaced from that of said reference fixation target;

means for monitoring the subject's eye positions and movements;

means for detecting those of the subject's eye positions and movements which display at least one characteristic indicative of whether the subject actually visually detected said presented target image;

means responsive to detection by said detection means of the subject's having failed to visually detect an actually presented target for thereafter sequentially presenting a plurality of individual, secondary target images, each of said secondary target images being presented at equally spaced locations with respect to the location of said first presented target image; and said means for monitoring the subject's eye positions and movements including means for electronically monitoring the subject's position and eye movements for each of said presented secondary target image to determine whether said subject actually visually detected said secondary target images.

21. An apparatus as defined in claim **20** further comprising:

said means for presenting said target image including means for directing a beam of light toward a surface within the subject's expected visual field;

directional control means for varying the direction of said beam to enable a plurality of target images to be presented at various locations;

digital input information means constructed and arranged to receive digital information corresponding to selected locations of said target image and being operatively associated with said directional

control means to sequentially position the direction of said beam to said selected locations;

means for monitoring the subject's eye positions and movements in response to presentation of said target images and for detecting and discriminating between those of the presented targets which the subject has actually visually detected and those which he has not;

means responsive to detection of the subject's having failed to actually visually detect a presented target for disabling said operative association between said digital input information means and said directional control means; and

means for thereafter sequentially presenting a plurality of individual secondary target images at equally spaced locations with respect to the location of said target image which the subject failed to actually visually detect, and including secondary target positioning means operatively associated with said directional control means for controlling the direction of said light beam independently of said digital input information means.

22. An apparatus as defined in claim **21** further comprising:

said secondary target positioning means including means for operating said directional control means to reposition the location of said target image to the position within the subject's visual field in which said last target image was presented, after completion of the presentation of said individual secondary target images; and

means for disabling said operative association between said secondary target positioning means and said directional control means and for reestablishing the operative association between said digital input information means and said directional control means.

RETROFOCUS WIDE-ANGLE OBJECTIVE LENS SYSTEM OF LARGE RELATIVE APERTURE

This is a continuation of application Ser. No. 387,038 filed Aug. 9, 1973, now abandoned.

DETAILED DESCRIPTIION OF THE INVENTION

This invention relates to a retrofocus ultrawide-angle camera objective which has a relative aperture of less than 2.8 in F-number with an field angle of at least 75°, and which also is so designed that the back focus length is sufficient long to permit the quick-return pivoting operation of the reflecting mirror incorporated in a single lens reflex camera.

In retrofocus wide-angle objectives of the conventional type, it is often unavoidable that the curvature of field at the lateral or outer portions of the viewing field is over-corrected with the result of a considerable drop in image sharpness at the edge regions of the image. Particularly when this known construction is modified so as to provide a furthermore increased relative aperture and simultaneously a short total length, the resulting drawback is so intensified as to abandon its use.

Accordingly, the present invention has for a general object to provide an optical objective system designed so as to have a wide-angle of field and compact structure while nevertheless being well corrected for various aberrations.

Further objects and advantages will become apparent during the course of the following description with reference to the accompanying drawings in which:

FIG. 1 is a diagrammatic view of one example of a practical wide-angle objective in accordance with the present invention.

FIG. 2 is a graphic representation of spherical aberrations, sine condition, astigmatism and distortion in the corrected objective shown in FIG. 1.

FIG. 3 is a diagrammatic view of a further example of a practical wide-angle objective in accordance with the present invention.

FIG. 4 is a graphic representation of spherical aberrations, sine condition, astigmatism and distortion in the corrected objective shown in FIG. 3.

Now referring to FIGS. 1 and 3, in order to accomplish the foresaid object, the lens system constructed in accordance with the present invention comprises eight optically aligned lens components, of which the first component designated by Roman character I counting from the front is a concave meniscus lens of rearward concavity, component II is a convex lens, component III is a concave meniscus lens of rearward concavity, component IV is a concave lens of which the strongly curved surface, or the surface with a smaller radius of curvature than that of the other faces toward the object, component V is a convex lens of strong rearward convexity, component VI is a double concave lens, components VII is a convex meniscus doublet consisting of a concave lens and a convex lens cemented together, and component VIII is a double convex lens, and having a diaphragm interposed between components V and VI.

In the eight-component lens system, the symbols for lens parameters denote the following:

f: The equivalent focal length of the entire system

r: The radii of curvature of the individual refracting surfaces

d: The axial separations between the retracting surfaces

N: The refractive indices of the individual lens glasses

ν: The Abbe number of the individual lens glasses

Thus, the wide-angle objective of the present invention is characterized by good aberration correction effected by satisfying the following conditions in combination:

$$0.35f < d_7 + d_8 + d_9 < 0.8f \quad (1)$$

$$0.5 \left| r_{13} \right| / r_{12} < 2.0 \; ; \; r_{13} < 0 \quad (2)$$

$$0.03f < d_{12} < 0.13f \quad (3)$$

$$1.73 < \frac{N_8 + N_9}{2} \quad (4)$$

$$\nu_4 < 35.0 \quad (5)$$

$$2.0 < \nu_6 - \nu_7 < 20.0 \quad (6)$$

The meanings of the above specified conditions and their limit values will be explained herebelow.

Condition (1) defines the limits for permitting the design of an objective so as to cover a wide-angular field of view and simultaneously shorten the total length while still maintaining a good state of correction for field curvature at the outer regions of the viewing field. As the deviation down from the lower limit increases, the field curvature at the outer portions rapidly increases to result in a strong over-correction, whilst as the upper limit is exceeded, the total length increases with an increase in the diameter of the front lens assembly so that the bulk of the complete lens system cannot be minimized in good proportion.

Condition (2) has an effect on the optical performance of an air lens intervening between components VI and VII. As far as the lens system of the type described is concerned, the provision of the air lens is effective for the correction of distortion ascribable to the concave lenses on the object side of the air lens, but this effect is remarkably reduced, as the relative aperture of the lens system increases. In order to secure the effect sufficiently even in a greatly increased relative aperture range, condition (2) is required. When the upper limit is exceeded, or when r_{12} is far smaller than the absolute value of r_{13}, spherical aberrations increase. When the lower limit is violated, or when r_{12} is far longer than the absolute value of r_{13}, the correction for negative distortion is difficult to be achieved. From the standpoint of severer lens design specification, it is desirable for $\left| r_{13} \right| / r_{12}$ to lie between 0.7 and 1.5.

Condition (3) provides the adjustment of the axial thickness of the air lens in order to compensate residual distortion and astigmatism resulting from the dependence of aberration correction for completeness upon not only conditions (2) but also the balancing with other elements of the objective. When the upper limit is violated, a remarkable under-correction of distortion is effected. When the lower limit is violated, a remarkable under-correction of astigmatism is effected.

Condition (4) is concerned with a range in the effective reduction of field curvature at the intermediate portions under the above-mentioned condtions (1), (2) and (3) and it is also effective for the purpose of facilitating the correction of spherical aberrations ascribable to the convex lenses of components VII and VIII. When

the limit is violated, it is impossible to secure these effects.

As far as the lens system of the type described, the correction of chromatic aberrations is achieved usually by virtue of the choice of lowly dispersive glasses for the concave lenses arranged on the object side of the diaphragm and highly dispersive glasses for the convex lenses arranged thereon. However, the use of such convex lenses causes color coma and color distortion to be strongly over-corrected.

Condition (5) prevents such over-corrections of color aberrations. Inasmuch as condition (5) is satisfied, due correction for chromatic aberrations can be achieved by increasing the dispersive power of component IV and decreasing the dispersive power of component V while avoiding increases in color coma and color distortion ascribable to the strong rearward convexity of the component V. When ν_4 is increased from the specified limit value, ν_5 must be decreased for the maintenance of the equivalent chromatic aberration correction, or otherwise color coma and color distortion increase. The practical upper limits of conditions (4) and (5) depend on the characteristics of available glasses, whereby it is preferred that $(N_8 + N_9)/2$ and ν_4 are deviated from the above-specified limit values as much as possible.

Condition (6) works effectively on the correction for color coma and color distortion ascribable to the lens components arranged on the image side of the diaphragm. When the lower limit is violated, color coma and color distortion ascribable to the front surface of the air lens formed between components VI and VII in accordance with conditions (2) and (3) increase. When the upper limit is violated, color astigmatism ascribable to the rear surface of the air lens increases.

By satisfying the above-specified conditions, the retrofocus wide-angle objective can be constructed as represented by the numerical data in Table 1 or Table 3 for the radii of curvature of the individual refracting surfaces, r_1 to r_{17}, the negative sign indicating that the surface is concave to the front, the axial thickness of the individual elements, or the axial air separation between the components, d_1 to d_{16} along with the corresponding refractive indices, N_1 to N_9 and the Abbe numbers ν_1 to ν_9 of which the individual lens elements are made. The numerical data of the first practical example in Table 1 are related to the lens system of FIG. **1**. The aberration curves of the corrected lens system shown in FIG. **1** are illustrated in FIG. **2***a*, **2***b* and **2***c*. The numerical data of the second practical example in Table 3 are related to the lens system of FIG. **3**, and its aberration curves are illustrated in FIGS. **4***a*, **4***b* and **4***c*.

As far as the present invention is concerned, the permissible limit of variation for the parameters of the lens system from the values stated in respect of each of the two examples, are ±5% for the inverse number of the radius of curvature ($1/r$), ±5% for the thickness or separation (d), ±0.03 for the refractive index, and ±5% for the dispersive power ($1/\nu$).

What is claimed is:

1. A retrofocus wide-angle objective lens system with large relative aperture comprising eight optically aligned lens components of which the first component is a concave meniscus lens of rearward concavity, the second component is a convex lens, the third component is a concave meniscus lens of rearward concavity, the fourth component is a convex lens of strong forward convexity, the fifth component is a convex lens of strong rearward convexity, the sixth component is a bi-concave lens, the seventh component is a convex meniscus doublet consisting of a concave lens and a convex lens cemented together and the eighth component is a bi-convex lens, and having a diaphragm interposed between the fifth and sixth components, and said objective lens system being characterized by the following relationships in combination:

$$0.4f<d_7+d_8+d_9<0.75f \quad (1)$$

$$0.68 < \frac{|r_{13}|}{r_{12}} < 1.75,\ r_{13} < 0 \quad (2)$$

$$0.05f<d_{12}<0.105f \quad (3)$$

$$1.73<(N_8+N_9)/2 \quad (4)$$

$$\nu_4<35 \quad (5)$$

$$2.5<\nu_6-\nu_7<17 \quad (6)$$

wherein f is the equivalent focal length of the entire lens system, d_7 is the axial thickness of the fourth component, d_8 is the axial air separation between the fourth and fifth components, d_9 is the axial thickness of the fifth component, r_{12} is the radius of curvature of the rear refracting surface of the sixth component, r_{13} is the radius of curvature of the front refracting surface of the seventh component, d_{12} is the axial air separation between the sixth and seventh components, N_8 is the refractive index of the convex lens of the seventh doublet lens component for the sodium d-line of the spectrum, N_9 is the refractive index of the eighth convex lens component for the sodium d-line of the spectrum, ν_4 is the Abbe number of the fourth convex lens component, ν_6 is the Abbe number of the sixth bi-concave lens component, and ν_7 is the Abbe number of the concave lens of the seventh doublet lens component.

2. A retrofocus wide-angle objective lens system with large relative aperture comprising eight optically aligned lens components of which the first component is a concave meniscus lens of rearward concavity, the second component is a convex lens, the third component is a concave meniscus lens of rearward concavity, the fourth component is a convex lens of strong forward convexity, the fifth component is a convex lens of strong rearward convexity, the sixth component is a bi-concave lens, the seventh component is a convex meniscus doublet consisting of a concave lens and a convex lens cemented together and the eighth component is a bi-convex lens, and having a diaphragm interposed between the fifth and sixth components, and said objective lens system being characterized by the following relationships in combination:

$$0.35f < d_7 + d_8 + d_9 < 0.8f \quad (1)$$

$$0.5 < \frac{|r_{13}|}{r_{12}} < 2.0 \ ;\ r_{13} < 0 \quad (2)$$

$$0.03f < d_{12} < 0.13f \quad (3)$$

$$1.73 < \frac{N_8 + N_9}{2} \quad (4)$$

$$\nu_4 < 35.0 \quad (5)$$

$$2.0 < \nu_6 - \nu_7 < 20.0 \quad (6)$$

wherein f is the equivalent focal length of the entire lens system, d_7 is the axial thickness of the fourth component, d_8 is the axial air separation between the fourth and fifth components, d_9 is the axial thickness of the fifth component, r_{12} is the radius of curvature of the rear refracting surface of the sixth component, r_{13} is the radius of curvature of the front refracting surface of the seventh component, d_{12} is the axial air separation between the sixth and seventh components, N_8 is the refractive index of the convex lens of the seventh doublet lens component for the sodium d-line of the spectrum, N_9 is the refractive index of the eighth convex lens component for the sodium d-line of the spectrum, ν_4 is the Abbe number of the fourth convex lens component, ν_6 is the Abbe number of the sixth bi-concave lens component, and ν_7 is the Abbe number of the convex lens of the seventh doublet lens component, the characteristics of the various lenses of the components and their special relationships to each other being of the proportions indicated by the numerical data in the following table,

[57] **ABSTRACT**

A wide angle lens of the retrofocus type comprising six lens groups in front and rear groupings. The rear grouping is movable forward while the front grouping is stationary to focus the lens to within ten equivalent focal lengths of the lens.

WIDE ANGLE OBJECTIVE

This application is a continuation-in-part of application Ser. No. 392,120, filed Aug. 27, 1973, now abandoned.

This invention relates to lenses and more particularly to those known as wide angle lenses.

Wide angle lenses may be defined as those in which the diameter of the film frame with which the camera is used is substantially equal to or greater than the effective focal length of the lens. Generally, wide angle objectives and particularly those of the retrofocus type are well corrected for ordinary aberrations for only one magnification. Wide angle lens of the retrofocus type are generally used with single lens reflex cameras and have a back focal length (BFL) greater than the equivalent focal length (EFL). This is generally dictated by design considerations which must permit room for the viewing mirror behind the last lens element.

Where the lens is designed for close focusing applications, the magnification will change slightly and such objectives then have considerably degraded performance due to the introduction of astigmatism, coma and other aberrations. One technique often employed to compensate for this change of aberration is to change an axial separation between lens elements as a function of focusing distance independent of focusing travel of the overall lens. While this technique has theoretical merit and can often be used to produce satisfactory results over a large range of focusing distances, the power of the lens elements for this type of objective is often large, and together with the nature of the lens element aberration contributions, the group of elements moving independent of the focusing travel is often very sensitive to deviations in mechanical centration. The resulting image is thus often degraded due to decentration more than to the effects of astigmatism, the dominant aberration due to focusing.

Accordingly, the present invention provides a new and improved wide angle lens of the retrofocus type which corrects the aberrations generally encountered in close focusing, decreases or eliminates the sensitivity to decentration resulting from focusing motion of the lens elements, and may also provide a lens barrel in which the length is not elongated during focusing. This construction may be quite useful in environments potentially damaging to the lens.

Briefly stated, the invention in one form thereof comprises a lens utilizing a front grouping of elements which are fixed in location with respect to the image plane and are generally afocal. The remaining lens elements move as a unit for focusing. since the front element grouping in combination is nearly afocal, the sensitivity to decentration resulting from the focusing motion is considerably reduced. With the proper selection of lens elements the effect of focusing the rearward group is merely to provide a constant correction for astigmatism.

An object of this invention is to provide a new and improved wide angle lens of the retrofocus type.

Another object of this invention is to provide a wide angle lens of the retrofocus type which can be focused very close distances without degradation of the image.

A further object of this invention is to provide a wide angle lens in which the front vertex distance of the lens does not change during focusing.

The features of the invention which are believed to be novel are particularly pointed out and distinctly claimed in the concluding portion of this specification. However, the invention both as to its organization and operation, together with further objects and advantages thereof, may best be appreciated by reference to the following detailed description taken in conjunction with the drawings, wherein:

FIG. 1 is a representation of elements of a first lens embodying the invention;

FIG. 2 is a side elevation, partially in half section of a lens utilizing the elements of FIG. 1;

FIG. 3 is a side elevation, partially in half section of another lens utilizing the invention; and

FIG. 4 is a representation of another lens embodying the invention.

Reference is now made to FIG. 1 which exemplifies a wide angle lens of the retrofocus type adapted to be utilized with a 35 millimeter camera (24 millimeter × 36 millimeter frame size) and which has a relative aperture of f/1.9 and an equivalent focal length (EFL) of 28 millimeters.

The lens **10** comprises elements L1 – L9 having surfaces defined by radii R1 – R16 as shown. The aperture is placed between elements L3 and L4. Elements L1 and L2 form a first group which is fixed in relation to a lens housing and, hence, the film plane FP. The elements L3 – L9 are held in fixed relation to each other but move axially for focusing.

The lens of FIG. 1 comprises from the object end a first negative group L1, L2; a second negative group L3 in the form of a meniscus having a convex object side surface; a third positive group L4 having a convex object side surface; a fourth positive group L5, L6 having a convex image side surface; a fifth negative group L7; and a sixth positive group L8, L9 having convex object and image side surfaces.

The lens of FIG. 1 for the frame size specified is defined substantially by the data of Table I, as scaled to an equivalent focal length of 28.7mm;

TABLE I-continued

Lens	Radius	Axial Distance Between Surfaces	N d	V d
		41.687		

Film Plane

EFL = 28.7mm

The aperture stop is located between elements L3 and L4. The focal length of elements L1 and L2 is −329.5mm, or nearly twelve times the EFL of the lens. The spacing between elements L2 and L3 varies from 0.20mm to 4.72mm for focusing from infinity to 178.4mm. N_d is the index of refraction and V_d is the Abbe number.

The lens disclosed may, of course, be scaled for other image frame sizes and EFL.

FIG. **2** exemplifies the lens **10** of FIG. **1** in a lens mount **11** which includes a lens barrel or housing **12,** a lens mount **13,** and a focusing ring **14.** Barrel **12** is provided with a camera mount in the form of threads **15,** and has a longitudinal slot **16** defined therein. A pin **17** is received in mount **13** and extends through slot **16** into barrel **12** into an annular groove **18** in ring **14.** Ring **14** has internal threads **19** engaging mating external threads **20** on barrel **12.** As ring **14** is rotated, pin **17** in slot **16** inhibits rotation of mount **13,** and axial movement is imparted to mount **13** for focusing travel.

FIG. **3** exemplifies a sealed lens construction, where there is no change in the front vertex distance of the lens during focusing. The first group comprising elements L1 and L2 is fixed in a lens barrel on housing **25,** a movable lens mount **26** carrying a pin **27** therein which extends into an internal axially directed slot **28** in barrel **25.** The image end of the barrel **25** is adapted to be coupled to a camera body **29** as by means of threads **30,** mating with mounting threads **31** of the camera body. A focusing sleeve **32** is disposed within barrel **25,** and has internal threads **33** engaging external threads **34** on mount **26.** A pin **35** carried by barrel **25** extends into an annular groove **36** in sleeve **26** and prevents axial motion thereof. A gear **37** is defined on the end of sleeve **26,** and meshes with a pinion **38** on a shaft **39** journaled in body **29.** A focusing knob **40** is coupled to shaft **39.**

To focus the lens, knob **40** is rotated imparting rotational movement to pinion **38** and sleeve **37.** As sleeve **32** rotates, mount **26** travels axially in barrel **25** over the focusing range of the lens.

The barrel **25** has a continuous uninterrupted outer surface with the exception of an aperture for pin **35,** which may be suitably sealed. A seal **41** may be provided between the rear side of lens element L1 and barrel **35.** Also a seal **42** may be provided in an annular groove **43** in mounting flange **44** on barrel **25.**

This construction provides a sealed lens which may be utilized in underwater applications without the necessity of placing the camera body and lens in a sealed container.

Table II sets forth data of another lens embodying the invention as scaled to an equivalent focal length of 35mm for a 24 × 36mm frame size, and with a relative aperture of F/1.9. The lens of Table II is exemplified in FIG. **4.**

TABLE II

Lens		Radius(mm)	Axial Distance Between Surfaces(mm)	N_d	N_d
L1	R_1	30.600	7.000	1.487	70.4
	R_2	170.290	.300		
	R_3	34.231	2.985	1.487	70.4
L2	R_4	11.567	6.000		
	R_5	67.235	2.000	1.569	56.0
L3	R_6	25.201	6.171		
	R_7	46.077	3.200	1.806	40.7
L4	R_8	−644.608	7.931		
	R_9	−34.424	2.358	1.762	26.6
L5	R_{10}	−829.911	1.350		
	R_{11}	−47.763	4.832		
L6	R_{12}	−19.289	4.70–.10	1.757	47.7
	R_{13}	41.514	3.000	1.667	33.1
L7	R_{14}	35.544	1.900		
	R_{15}	64.725	8.000	1.717	48.0
L8	R_{16}	−22.414	2.700	1.805	25.5
L9	R_{17}	−56.648			

The BFL varies from 39.56mm to 44.16mm as the lens is focused from infinity to 258mm, and the spacing between Groups IV and V varies as shown. The aperture stop is located 1.59mm behind element L4. Groups I-IV are fixed with respect to the film plane.

In this arrangement only the grouping of elements L7, L8 and L9 move while the grouping of elements L1 – L6 as shown in FIG. **4** are stationary in the lens housing. There is thus no change in the front vertex distance and the lens barrel may be completely sealed.

Table III exemplifies a lens also as represented in FIG. **4** as scaled for a 28.5mm equivalent focal length for a 24 × 36mm image frame in which the grouping elements L7, L8 and L9 move relative to the image frame while the grouping of elements L1 – L6 are in fixed relation to the image frame and there is no change in the front vertex distance of the lens when focused as close as 203mm or 7.25 EFL's.

TABLE III

Lens		Radius(mm)	Axial Distance Between Surfaces(mm)	N_d	V_d
L1	R_1	54.600	5.700	1.487	70.4
	R_2	937.48	.300		
L2	R_3	28.640	2.800	1.487	70.4
	R_4	11.392	4.474		
L3	R_5	28.640	2.000	1.517	64.2
	R_6	15.990	13.502		
L4	R_7	41.450	3.200	1.689	31.2
	R_8	840.70	3.342		
L5	R_9	−70.750	2.164	1.805	25.5
	R_{10}	106.030	1.900		
L6	R_{11}	−71.649	4.549	1.804	46.5
	R_{12}	−21.220	4.098 –.10		
L7	R_{13}	48.140	2.700	1.741	27.8
	R_{14}	35.430	1.212		
L8	R_{15}	53.960	9.159	1.639	55.5

TABLE III-continued

Lens		Radius(mm)	Axial Distance Between Surfaces(mm)	N_d	V_d
L9	R_{16}	−20.430	2.700	1.805	25.5
	R_{17}	−44.190			

The aperture stop is located 11.5mm behind L3. Groups V and VI move from a BFL of 39.2mm to 43.2mm for focusing from infinity to 203mm while Groups I –IV are fixed with respect to the film plane.

The lens groupings of the lenses are set forth in Table IV.

TABLE IV

Lens		Stationary Grouping	Movable Grouping
Table	I	L1 , L2	L3 – L9
	II	L1 – L6	L7 – L9
	III	L1 – L6	L7 – L9

The absolute value of the EFL (F_s) of the stationary grouping is is substantially greater than the EFL (F_o) of the overall lens, the EFL of the stationary grouping being at least three times the focal length of the overall lens or

$$| F_s | \geq 3F_o$$

It is preferred that the following relations are maintained:

$$3.7\ F_o \geq F_{56} \geq 1.5\ F_o$$

where F_o is the EFL of the lens and F_{56} is the combined equivalent focal length of Groups V and VI, and

$$1.5\ F_o \geq F_{34} \geq 1.0\ F_o$$

where F_{34} is the combined equivalent focal length of Groups III and IV.

The disclosed lens have the following relationships:

LENS	F_s/F_o	F_{56}/F_o	F_{34}/F_o	Focuses To	
Table I	−11.54	3.61	1.26	$6.20F_o$	(7.01")
Table II	4.89	1.57	1.31	$7.12F_o$	(10.15")
Table III	3.19	2.18	1.46	$7.25F_o$	(7.99")

It is possible to focus even closer by moving the overall lens after the movable grouping has reached the end of its travel. This is merely a conjugate shift, which is accomplished after the primary focusing movement.

For example the lens of Table III can be arranged so that after L7–L9 move forward from an object distance of infinity to an object distance 209mm (8.23 EFL) through 3.9mm of forward travel, the entire lens may be moved 1.3mm to focus to an object distance 149.7mm or 5.89 EFL. This may easily be accomplished mechanically by making movement of the overall lens responsive to the moving group reaching the end of its close focusing travel.

The described arrangements provide wide angle lens of the retrofocus type which give excellent image quality while focusing to less than 10 EFL's from the front element and capable of focusing within 8 EFL's while maintaining a relatively small front vertex distance.

It may thus be seen that the objects of the invention set forth as well as those made apparent from the foregoing description are efficiently attained. While preferred embodiments of the invention have been set forth for purposes of disclosure, modification to the disclosed embodiments of the invention as well as other embodiments thereof may occur to those skilled in the art. Accordingly, the appended claims are intended to cover all embodiments of the invention and modifications to the disclosed embodiments which do not depart from the spirit and scope of the invention.

What is claimed is:

1. A wide angle lens of the retrofocus type comprising a housing, said housing having means for detachable mounting to a camera, a plurality of lens groups in said housing comprising from the object end to the image end, a first negative group, a second negative group in the form of a meniscus having a convex object side surface, a third positive group having a convex object side surface, a fourth positive group having a convex image side surface, a fifth negative group, and a sixth positive group having convex image and object side surfaces, said lens groups arranged in said housing in first and second groupings, said first grouping including said first group and mounted in said housing in fixed relation thereto, said second grouping residing on the image side of said first grouping and being of positive overall power, means for moving said second grouping with all groups therein in said housing in fixed relation to each other toward said first grouping while said first grouping remains stationary in said housing to focus said lens to within ten equivalent focal lengths of said lens.

2. The lens of claim **1** wherein said second grouping comprises said second, third, fourth, fifth and sixth groups.

3. The lens of claim **1** wherein said second grouping comprises said fifth and sixth groups.

4. The lens of claim **1** wherein

$$1.5\ F_o \geq F_{34} \geq 1.2\ F_o$$

where F_{34} is the combined equivalent focal length of the third and fourth groups and F_o is the equivalent focal length of the overall lens.

5. The lens of claim **1** wherein

$$3.7\ F_o \geq F_{56} \geq 1.5\ F_o$$

where F_{56} is the combined equivalent focal length of the fifth and sixth groups and F_o is the equivalent focal length of the overall lens.

6. The lens of claim **1** defined substantially by the following data where the elements L1 and L2 comprise said first grouping:

Lens		Radius(mm)	Axial Distance Between Surfaces(mm)	N_d	V_d
	R1	38.387mm			
L1			2.435mm	1.5168	64.2

[57] **ABSTRACT**

An objective system for motion picture cameras wherein a zoom lens is installed in a barrel and the barrel is surrounded by two ring-shaped selectors. The rear selector is rotatable to change the focal length of the lens by moving the optical elements of the rear group of optical elements of the lens with and relative to each other in the direction of the optical axis. The front selector is rotatable within a first angle to focus the image of a subject which is located at a distance of 5 ft. or more from the barrel, and within a second angle to focus the image of a subject prior to the making of close-up shots. The front selector moves the optical elements of the front group of optical elements of the lens during rotation within the first angle and the optical elements of the second group during rotation within the second angle. The focussing for close-up shots can be made after the focal length of the lens is reduced to a minimum value.

OBJECTIVE SYSTEM WITH ZOOM LENS FOR PHOTOGRAPHIC APPARATUS

BACKGROUND OF THE INVENTION

The present invention relates to objectives or objective systems for photograhic apparatus, and more particularly to improvements in objectives which comprise variable-focus or zoom lenses. Still more particularly, the invention relates to objectives having variable-focus lenses and means for focussing during the making of exposures at close range or at a greater distance (including infinity) from the subject. As used in the specification and claims, the expression "objective" or "objective system" is intended to denote a picture taking lens (preferably a zoom lens), a tubular barrel or mount for the lens, and means for moving selected optical elements of the lens with respect to the barrel in the direction of the optical axis.

In certain presently known objectives with variable-focus lenses, the focussing of the image of a subject which is close to the lens is effected by actuating a first selector and the focussing of the image of a subject which is located at a larger distance from the lens (e.g., at a distance exceeding 1.5 meters) is effected by actuating a second selector. In an objective having a pancratic lens, the first selector (for focussing prior to the making of close-up shots) can also serve as a means for changing the focal length of the lens. The provision of two discrete selectors (one of which enables the user to focus at close range and the other of which allows for focussing at a greater distance from the subject) is likely to confuse an inexperienced photographer. Thus, the photographer must be on the alert to distinguish between focussing for close-up shots and focussing for normal shots. The likelihood of confusion is increased due to that fact that one of the selectors performs a dual function, namely focussing at close range and changing the focal length of the lens. Thus, a novice or an unskilled amateur will make many unsatisfactory exposures or will miss many unique shots because the first selector is mistakenly actuated to focus at a normal distance from the subject, the second selector is actuated by mistake to change the focal length, or the first selector is actuated in a wrong direction for the purpose of focussing at close range.

SUMMARY OF THE INVENTION

An object of the invention is to provide a novel and improved objective with variable-focus lens wherein a single selector serves for focussing the image of a subject at close range or at a greater distance from the camera.

Another object of the invention is to provide an objective which comprises a zoom lens and wherein the manipulation of means for changing the focal length and for focussing at any desired distance from the subject is simpler and less confusing to the user than in heretofore known objectives.

A further object of the invention is to provide novel and improved means for shifting the optical elements of a zoom lens in the objective of a motion picture camera.

An additional object of the invention is to provide a novel and improved operative connection between the focussing means and the means for changing the focal length of a zoom lens.

The invention is embodied in an objective system for photographic apparatus, especially motion picture cameras, which comprises a tubular mount or barrel, a picture taking lens (preferably a variable-focus lens) having a plurality of optical elements disposed in and movable axially of the barrel to thereby focus the image of a subject, selector means (e.g., a ring-shaped member which is rotatable on the barrel), and means for connecting the selector means with the plurality of optical elements so as to move selected optical elements axially in response to movement of the selector means with respect to the barrel. The selector means is movable between a first plurality of positions to thereby move at least one first optical element (e.g., the front group of optical elements of the lens) during focussing of the image of a subject which is located within a range of greater first distances from the barrel (e.g., within a range of distances from about 5 ft. to infinity), and the selector means is movable beyond the first plurality of positions to any one of a second plurality of positions to thereby move at least one second optical element (e.g., a rear group of optical elements of the lens) during focussing of the image of a subject which is located within a range of shorter second distances (e.g., not exceeding 5 ft.) from the barrel. Such shorter second distances correspond to the making of close-up shots.

The connecting means preferably comprises a cam which serves to effect axial movements of the second optical element while the selector means moves between the second plurality of positions.

The objective system preferably further comprises second selector means (e.g., a ring-shaped member which surrounds and is rotatable on the barrel behind the first selector means) and means for connecting the second selector means with selected optical elements of the lens (preferably with the aforementioned rear group of optical elements). The second selector means is movable with respect to the barrel to thereby move at least one optical element of the lens (e.g., the aforementioned second optical element) axially of the barrel and to thus change the focal length of the lens. The arrangement is preferably such that the first mentioned selector means can focus the image of a subject for the making of a close-up shot when the focal length of the lens is reduced to a minimum value.

The novel features which are considered as characteristic of the invention are set forth in particular in the appended claims. The improved objective system itself, however, both as to its construction and its mode of operation, together with additional features and advantages thereof, will be best understood upon perusal of the following detailed description of certain specific embodiments with reference to the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a fragmentary axial sectional view of an objective system with zoom lens which embodies the invention; and

FIG. 2 is a fragmentary sectional view substantially as seen in the direction of arrows from the line II—II of FIG. 1.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The drawing shows an objective which comprises a tubular barrel or mount 1 assumed to be rigidly secured

to the housing or body of a photographic apparatus, not shown. The barrel **1** contains a variable-focus picture taking lens or zoom lens having two groups **2** and **3** of optical elements. The rear group or variator system **2** is movable axially in the barrel **1** in order to adjust the focal length of the lens as well as for focussing prior to the making of close-up shots. The front group **3** is movable axially in the barrel **1** for the purpose of focussing in the normal range of distances from the subject. The group **2** comprises four optical elements **2***a*, **2***b*, **2***c*, **2***d* and the group **3** comprises three optical elements **3***a*, **3***b*, **3***c*.

The elements **2***a*–**2***c* of the rear group **2** are fixedly mounted in a ring **4** which is axially movable in a sleeve **5**. The latter is rotatable in the barrel **1** to thereby effect a movement of the ring **4** and optical elements **2***a*–**2***c* in the direction of the optical axis of the picture taking lens. The ring **4** receives motion from a follower here shown as a screw **6** whose head extends through a cam slot **10** in the sleeve **5** and into a longitudinally extending guide groove **7** in the internal surface of the barrel **1**. The rearmost optical element **2***d* of the group **2** is mounted in a discrete ring **8** which is fixedly mounted in the sleeve **5**. A second follower **11** is threadedly connected with and extends radially outwardly from the sleeve **5** in the region between the rings **4** and **8**; this follower extends through and outwardly beyond a cam slot **12** (FIG. **2**) of the barrel **1** so that its outermost portion extends into a longitudinally extending internal guide groove **13** of an annular focal length selector **15**. The latter is rotatable on the barrel **1** and has a radially outwardly extending handle **14**. When the user of the photographic apparatus rotates the selector **15** through the medium of the handle **14**, the cam slots **10** and **12** cause the rings **4**, **8** and the optical elements **2***a*–**2***d* of the group **2** to move in the direction of the optical axis of the lens in accordance with a predetermined pattern which is calculated to establish desirable optical characteristics of the lens. The optical element **2***d* rotates with the sleeve **5** but the optical elements **2***a*–**2***c* merely move in the axial direction of the barrel **1** because the outer end portion of the follower **6** extends into the groove **7**. The shortest focal length is selected when the followers **6**, **11** assume the illustrated positions, i.e., when the ring **4** is located at a maximum distance from the ring **8**.

The optical elements **3***a*–**3***c* of the front group **3** are installed in a ring **150** which is movable axially of the barrel **1** in response to manual rotation of a second annular selector **16**. The latter surrounds and extends forwardly of the barrel **1** and is separably but rigidly affixed to the ring **150** by one or more screws **17** or analogous fasteners. FIG. **1** further shows two intermediate rings **18** and **19** which are installed between the ring **150** and the selector **16**. The inner intermediate ring **18** is threadedly connected to the ring **150** and is non-rotatably secured thereto in a selected axial position by a screw **20**. The outer intermediate ring **19** is axially adjustably connected with the barrel **1** by a screw **21**. The rings **18** and **19** are respectively provided with mating external and internal threads **18***a*, **19***a*. When the ring **19** is being adjusted axially of the barrel **1**, it transmits motion to the rings **18**, **150** and to the selector **16**. Such adjustment is effected by rotating the screw **21** which is received in a tapped radial bore of the barrel **1** and has a conical inner end portion extending into a conical socket or recess **22** in the periphery of the ring **19**. If the screw **21** is rotated to move toward the optical axis of the lens the rings **18**, **19**, **150** and the selector **16** will move rearwardly. The screw **21** further serves as a means for non-rotatably connecting the ring **19** to the barrel **1**.

The rear end portion of the inner intermediate ring **18** has an inwardly extending annular portion **23** which includes two cams **24** and **25** (see FIG. **2**) facing the ring **4** for the optical elements **2***a*–**2***c*. The cam **24** or **25** is engaged by a motion transmitting slide **27** which is movable in parallelism with the optical axis in ways **26** provided therefor in the barrel **1**. The front end portion **28** of the slide **27** has a semicylindrical shape and abuts against the cam **24** or **25** under the bias of a helical spring **29**. The latter surrounds a stud **30** of the slide **27** and a stud **31** in the barrel **1**. The foremost convolution of the spring **29** bears against a crosshead **32** which forms part of the slide **27** and is disposed between the end portion **28** and stud **30**. The rearmost convolution of the spring **29** bears against a retainer **33** which is a bracket forming part of the barrel **1** and carrying the stud **31**.

FIG. **2** shows that the slide **27** has a cutout or slot **34** which extends substantially transversely of the ways **26** and can receive the head of the follower **11**. The width of the slot **34** equals or approximates the width of the cam slot **12** in the barrel **1**. In the illustrated axial position of the slide **27**, the slot **34** is in exact register with the cam slot **12**, i.e., the follower **11** can enter the slot **34** as soon as the sleeve **5** assumes that axial position which corresponds to the shortest focal length of the lens.

The barrel **1** is formed with an internal groove **35** which extends in parallelism with the optical axis and communicates with the cam slot **12**. The groove **35** permits axial movements of the group **2** for the purpose of focussing prior to the making of a close-up shot when the focal length of the lens has been reduced to a minimum value. Thus, the follower **11** can move in the groove **35** when the sleeve **5** assumes the position shown in FIG. **1**. The distance between the optical elements **2***a*–**2***c* on the one hand and the optical element **2***d* on the other hand (i.e., between the rings **4** and **8**) remains unchanged when the follower **11** extends into and moves in the groove **35** of the barrel **1**. The sleeve **5** is then movable by the selector **16** while the latter causes the cam **25** of the annular portion **23** of the intermediate ring **18** to move with respect to the slide **27**. The annular portion **23** can reach the front end portion **28** of the slide **27** subsequent to an angular displacement through the angle alpha (focussing prior to the making of shots at close range), i.e., the cam **25** can engage the slide **27** only after the ring **18** has been rotated beyond the plurality of angular positions (angle alpha) in which the slide **27** bears against the cam **24**. The plurality of angular positions of the selector **16** in which the cam **25** engages the slide **27** is shown at beta. The inclination of the cam **25** is selected in such a way that the spring **29** is free to expand and to move the slide **27** forwardly when the cam **25** engages the end portion **28** and the ring **18** is rotated in a direction to move the cam **24** away from the slide **27**. The slide **27** then causes the group **2** to move toward the group **3** because the surface bounding the slot **34** moves the follower **11** forwardly and the latter is free to slide in the longitudinally extending groove **35** of the barrel **1**. The forward movement of the group **2** toward the group **3** is a composite movement including a first movement which is caused by the spring **29** (the latter

urges the slide **27** forwardly while the end portion **28** engages the cam **25** and the cam **25** moves upwardly, as viewed in FIG. **2**) and a second movement which is caused by the inner intermediate ring **18** (the latter moves forwardly because its threads **18***a* mesh with the threads **19***a* of the ring **19** which is fixed to the barrel **1**). The ring **18** is rotated by the selector **16** through the medium of the ring **150**, and the ring **19** causes the ring **18** to move forwardly when the cams **24**, **25** move upwardly, as viewed in FIG. **2**.

The inclination of the cam **24** is identical to the pitch of the threads **18***a*, **19***a*. Therefore, the axial position of the slide **27** remains unchanged when its end portion **28** tracks the cam **24** while the selector **16** rotates the ring **18** and its annular portion **23**. This insures that the follower **11** can enter the slot **34** of the slide **27** when the sleeve **5** is moved to the axial position of FIG. **1** (shortest focal length of the lens).

During assembly of the objective, the rings **150**, **18** and **19** are threadedly connected to each other and inserted into the barrel **1** in such a way that the end portion **28** of the slide **27** abuts against the cam **24** of the annular portion **23** at the rear end of the ring **18**. Thus, the ring **18** can assume the angular position which is shown in FIG. **2**. The screw **21** is thereupon rotated in a direction to introduce its conical inner end portion into the socket **22** and to adjust the axial position of the rings **18**, **19**, **150** in such a way that the slot **34** of the slide **27** is in exact register with the cam **12**. As the screw **21** moves radially inwardly, its conical end portion slides along the right-hand side of the conical surface bounding the socket **22** so that the rings **18**, **19**, **150** move rearwardly against the opposition of the spring **29**, i.e., the spring **29** permanently urges the surface surrounding the socket **22** against the screw **21**. The exact axial position of the ring **150** and group **3** can be selected thereafter by loosening the screw **20**, by rotating the ring **150** through the medium of the selector **16** (the ring **150** meshes with the ring **18**), and by thereupon tightening the screw **20**.

The operation:

If the user of the camera wishes to focus for the purpose of making normal exposures (i.e., other than close-up shots), the selector **16** is rotated to move the ring **18** within the angle alpha so that the slide **27** engages the cam **24**. For example, such angular adjustment of the ring **18** enables the user to focus the image of a subject which is located at a distance between 1.5 meters and infinity. As a result of the just mentioned rotation of the selector **16**, the ring **18** moves axially of the barrel **1** because it rotates with the selector **16** (it receives torque via screw **17**, ring **150** and screw **20**) and because its threads **18***a* mesh with the threads **19***a* of the ring **19** which is secured to the barrel **1** by the screw **21**. The end portion **28** of the slide **27** bears against the cam **24** under the action of the spring **29** but the axial position of the sleeve **5** (and hence of the group **2**) remains unchanged because the slope of the cam **24** is identical with the pitch of threads **18***a*, **19***a*.

If the user wishes to change the focal length of the picture taking lens, the selector **15** is rotated by moving the handle **14** about the barrel **1**. The selector **15** rotates the sleeve **5** through the medium of the follower **11** (because the latter extends into the longitudinally extending groove **13** of the selector **15**) whereby the follower **11** travels in the cam slot **12** and moves the sleeve **5** in the barrel **1** through a relatively short distance, as considered in the direction of the optical axis. As the sleeve **5** turns with the selector **15**, the follower **6** slides in the cam slot **10** and causes the ring **4** to move axially of the sleeve. The cam slot **10** causes the ring **4** and the optical elements **2***a*–**2***c* to approach the ring **8** and optical element **2***d* while the focal length increases.

In order to focus prior to the making of close-up shots, the focal length of the lens must be reduced to the minimum value, i.e., the selector **15** must be rotated in a direction to increase the distance between the rings **4**, **8** to the maximum value shown in FIGS. **1** and **2**, whereby the slot **34** of the slide **27** registers with the cam slot **12**. The follower **11** has entered the slot **34** and its outermost portion extends into the groove **35** of the barrel **1**. Thus, the slide **27** can move the sleeve **5** lengthwise (through the medium of the follower **11** and the surface surrounding the slot **34**) whereby the follower **11** slides in the groove **35**. Ths slide **27** moves lengthwise in response to rotation of the selector **16** and ring **18** beyond that plurality of angular positions (angle alpha) in which the ring **18** focuses prior to the making of exposures at a distance from the subject which exceeds 1.5 meters. In order to enable the user to detect or sense the movement of the ring **18** beyond the angular positions for normal focussing (angle alpha), the cams **24**, **25** of the annular portion **23** are separated from each other by a pronounced protuberance or lobe **40** (FIG. **2**) which must be caused to bypass the slide **27** before the latter can engage the cam **25**. Thus, the focussing is always effected by rotating the selector **16** whereby, in order to focus prior to the making of close-up shots, the user must rotate the selector **16** beyond that range of angular positions (angle alpha) which are provided for focussing at a distance between 1.5 meters and infinity in order to move the selector **16** to one of a second plurality of angular positions (angle beta) which are provided for focussing at a close range. When the selector **16** is rotated in a direction to move the lobe **40** beyond the end portion of the slide **27**, the latter begins to move forwardly under the action of the spring **29** because the cam **25** slopes forwardly as considered in the circumferential direction of the annular portion **23** (and assuming that the selector **16** moves the ring **18** and annular portion **23** upwardly, as viewed in FIG. **2**). The sleeve **5** shares the lengthwise movement of the slide **27** in the ways **26** but the distance between the rings **4** and **8** remains unchanged because the sleeve **5** does not rotate about the optical axis. Thus, the optical element **2***d* is separated from the optical elements **2***a*–**2***c* by a (maximum) distance, which corresponds to the minimum focal length of the lens, whenever the slide **27** engages the cam **25**.

An important advantage of the improved objective is that a single selector **16** can be manipulated to focus at any distance of the subject from the photographic apparatus. Thus, the user need not actuate different selectors for the same purpose (focussing); all the user has to know is that focussing at close range must be preceded by the selection of a predetermined focal length, and the focal length is changed by manipulating one and the same selector **15**. As mentioned above, such simplification of the manipulation of a relatively complex objective is especially important when the photographic apparatus embodying the improved objective is used by a novice or an inexperienced amateur photographer. However, the simplification of manipulation of the objective is equally beneficial to professionals or skilled amateur photographers.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features which fairly constitute essential characteristics of the generic and specific aspects of our contribution to the art and, therefore, such adaptations should and are intended to be comprehended within the meaning and range of equivalence of the claims.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims:

1. In an objective system for photographic apparatus, a combination comprising a barrel; a variable-focus picture-taking lens having a plurality of optical elements disposed in and movable axially of said barrel to thereby focus the image of a subject; a focus selector element movably mounted on said barrel; first connecting means for connecting said selector element with said plurality of optical elements so as to move selected optical elements axially in response to movement of said selector element relative to said barrel, said selector element being displaceable between a first plurality of positions to thereby move at least one first optical element of said plurality of optical elements through the medium of said connecting means during normal focusing of the image of a subject which is located within a range of first distances from the barrel, and said selector element being displaceable beyond said first plurality of positions to any one of a second plurality of positions to thereby move at least one second optical element of said plurality of optical elements through the medium of said connecting means during close-up focussing of the image of a subject which is located within a range of shorter second distances from the barrel such as correspond to the making of close-up shots, said connecting means comprising a cam, a motion transmitting member engaging said cam and operatively connected with said second optical element in each of said plurality of second positions of said selector element, and means for biasing said motion transmitting member against said cam, said motion transmitting member including a slide which is reciprocable in said barrel in parallelism with the optical axis of said lens; selector means and second connecting means for connecting said selector means with said second optical element, said selector means being movable with respect to said barrel to thereby move said second optical element axially and to thus change the focal length of said lens, said second connecting means comprising a second cam in said barrel and a follower operatively connected with said first optical element, tracking said second cam and rotatable by said selector means, said barrel further having a longitudinally extending groove and said slide having a slot into which said follower extends in a predetermined axial position of said second optical element, said follower further extending into said groove in response to movement of said second optical element to said predetermined axial position whereby said slide can move said second optical element axially in response to movement of said selector element between said second plurality of positions, said first connecting means comprising a third cam which is engaged by said slide in each of said plurality of first positions of said selector element, the slope of said third cam being such that the axial position of said second optical element remains unchanged while said selector element moves between said plurality of first positions, said first connecting means further comprising a ring which surrounds said first optical element and is rotatably and axially movably mounted in said barrel, said first mentioned and third cams being provided on said ring, and said ring comprising a protuberance disposed between said first mentioned and third cams and over which said slide rides against the opposition of said biasing means during movement of said selector element beyond said plurality of first positions; and means for confining said selector element to a single type of movement with respect to said barrel both during its displacement between said first plurality of positions and during its displacement between said second plurality of positions.

2. A combination as defined in claim **1,** wherein said connecting means further comprises means for connecting said ring to said selector element so that said ring moves axially of said barrel at least while said selector element moves between said first plurality of positions, said first optical element being mounted in and being movable with said ring and said additional cam being rigid with said ring.

3. A combination as defined in claim **2,** further comprising means for adjusting the axial position of said ring with respect to said barrel.

4. A combination as defined in claim **2,** wherein said ring has a first set of threads and further comprising a second set of threads supported by said barrel and meshing with said first set of threads, said selector element being rotatable with said ring relative to said barrel to thereby rotate said ring and said first optical element while moving between said first plurality of positions whereby said threads move said ring and said first optical element axially.

5. A combination as defined in claim **4,** wherein said confining means comprises a second ring normally rigid with said barrel, said first set of threads constituting external threads on said first mentioned ring and said second set of threads constituting internal threads of said second ring.

6. A combination as defined in claim **1,** further comprising selector means, and means for connecting said selector means with selected optical elements of said lens, said selector means being movable with respect to said barrel to thereby move at least one of said optical elements axially of said barrel through the medium of said last mentioned connecting means and to thus change the focal length of said lens.

7. A combination as defined in claim **6,** wherein said one optical element is said second optical element and said last mentioned connecting means comprises a device for moving said one optical element to a predetermined axial position corresponding to a predetermined focal length of said lens, said one optical element being movable axially by said first mentioned connecting means from said predetermined axial position in response to movement of said selector element between said second plurality of positions.

8. A combination as defined in claim **7,** wherein said last mentioned connecting means further comprises a sleeve surrounding said one optical element and being rotatable and axially movable in said barrel, a cam on said barrel, and a follower constituting said device, said follower being connected with said sleeve and tracking said cam in response to rotation of said sleeve by said selector means.

9. A combination as defined in claim **8,** wherein said barrel has a longitudinally extending groove into which said follower extends in said predetermined axial posi-

tion of said one optical element, said motion transmitting member moving said follower in said groove in response to movement of said selector element between said plurality of second positions.

10. A combination as defined in claim **9**, wherein the focal length of said lens is reduced to a minimum value in said predetermined axial position of said one optical element.

11. In an objective system for photographic apparatus, a combination comprising a barrel; a variable-focus picture-taking lens having a plurality of optical elements disposed in and movable axially of said barrel to thereby focus the image of a subject; a focus selector element movably mounted on said barrel; connecting means for connecting said selector element with said plurality of optical elements so as to move selected optical elements axially in response to movement of said selector element relative to said barrel, said selector element being displaceable between a first plurality of positions to thereby move at least one first optical element of said plurality of optical elements through the medium of said connecting means during normal focusing of the image of a subject which is located within a range of first distances from the barrel, and said selector element being displaceable beyond said first plurality of positions to any one of a second plurality of positions to thereby move at least one second optical element of said plurality of optical elements through the medium of said connecting means during close-up focussing of the image of a subject which is located within a range of shorter second distances from the barrel such as correspond to the making of close-up shots, said connecting means comprising a cam, a motion transmitting member engaging said cam and operatively connected with said second optical element in each of said plurality of second positions of said selector element, said motion transmitting member including a slide which is reciprocable in said barrel in parallelism with the optical axis of said lens means for biasing said motion-transmitting member against said cam, an additional cam which is engaged by said slide in each of said plurality of first positions of said selector element and having a slope which is such that the axial position of said second optical element remains unchanged while said selector element moves between said plurality of first positions, a ring which surrounds said first optical element and is rotatably and axially movably mounted in said barrel, said cams being provided on said ring, and said ring comprising a protuberance disposed between said first cams and over which said slide rides against the opposition of said biasing means during movement of said selector element beyond said plurality of first positions; and means for confining said selector element to a single type of movement with respect to said barrel both during its displacement between said first plurality of positions and during its displacement between said second plurality of positions.

[57] **ABSTRACT**

An objective lens comprising a front positive meniscus element, a middle negative biconcave element and a rear positive biconvex element. Improved optical performance at a relative aperture of f/1.70 is achieved by the incorporation of an asphere on the rear surfaces of the first and second elements.

THREE ELEMENT OBJECTIVE LENS

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to photographic objective lenses and in particular to such lenses that comprise three air spaced elements.

2. Description of the Prior Art

Triplet lenses for use in photographic apparatus are well known and have been used for many years. Moreover, high relative aperture lenses have also been in use for many years in the photographic industry. However, with the advent of available light photography, the use of high relative aperture lenses has spread to photographic apparatus designed to be mass produced for the amateur market. The price of such lenses then becomes of great concern and the relatively complex, well corrected, high relative aperture lenses known in the art are too costly.

Another trend in the photographic industry is toward compact designs to provide convenience in storage, handling and transportation. Large, complex lenses represent a sizable percentage of the camera's volume and place a lower limit on the size of the photographic apparatus. A reduction in the number of elements in a lens will generally aid in reducing the size and cost of the lenses to be incorporated in the photographic apparatus.

SUMMARY OF THE INVENTION

In accordance with the present invention, there is provided a three element air spaced objective lens comprising a front positive meniscus element, a middle negative biconcave element and a rear positive biconvex element, with a diaphragm positioned to the rear of the lens. Good optical performance is achieved by incorporation of an asphere on the rear surfaces of the first two elements of the lens, and by the use of glass having a very high index of refraction for all three elements.

BRIEF DESCRIPTION OF THE DRAWING

In the detailed description of the preferred embodiment of the invention presented below, reference is made to the accompanying drawing which is a diagrammatic axial cross-section of a lens according to the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENT

For all purposes of describing or claiming of the invention, the term lens will be used to describe the complete lens and not the elements thereof. In the drawing, the elements are numbered from left to right with Arabic numerals. In each of the examples, the elements, indices of refraction N, Abbe numbers V, radii of curvature R, thicknesses T and air spaces S are numbered to correspond with the drawing. The indices of refraction are for the 0.5876 micron helium d line of the spectrum. The Abbe numbers are calculated utilizing this d line index and, as the dispersion, the index difference between the 0.4861 micron hydrogen F line and the 0.6563 micron hydrogen C line. Radii of curvature having centers of curvature to the right of the surface are considered positive; those with centers of curvature to the left of the surface are considered negative.

In all embodiments of the invention as illustrated in the drawing, the lens comprises three air spaced elements. Element 1 is a front positive meniscus element. Element 2 is a middle negative biconcave element. Element 3 is a rear positive biconvex element. D is a diaphragm.

The use of aspheric surfaces in a lens design provides additional parameters for correction of aberrations. Incorporation of an aspheric surface is particularly useful in a high relative aperture lens, because it permits a better correction of spherical aberration than is otherwise obtainable. In the design of the present invention, the improved spherical aberration correction and the reduction of other aberrations, along with the high relative aperture, are achieved by the use of aspheres on surfaces 2 and 4 of the lens.

A general aspheric surface may be described by the following equation:

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1 + K)C^2y^2}} + Dy^4$$

This equation describes a surface in terms of its surface sag x at a semi-aperture distance y from the axis of the lens. The constat C is the vertex curvature, that is, the surface curvature at the vertex of the lens, equal to the reciprocal of the vertex radius of curvature R. The constant K is the conic constant and is defined by the equation $K = -e^2$ where e is the eccentricity of the surface. Certain values of K describe conic sections or surfaces of revolution about the optical axis of the lens. The coefficient D determined the first term of higher order aspheric sag of the surface and is selected to achieve the higher order corrections that are desired. Terms higher than the quartic in the equation for x may also be included, if desired.

Lenses may be made according to this invention by following the specification in the preferred embodiment presented below:

EXAMPLE I

Element	N	V	Radius mm	Thickness or Separation mm
			R_1=13.506	
1	2.01940	34.21		T_1=6.000
			R_2=Asphere	
				S_1=1.210
			R_3=−185.19	
2	1.90893	19.31		T_2=1.200
			R_4=Asphere	
				S_2=1.340
			R_5=25.258	
3	2.01940	34.21		T_3=6.000
			R_6=−25.258	
				S_3=.500

Example I is an all glass triplet objective which is characterized by a relative aperture of f/1.70, with an effective focal length of 25.00 and a semifield angle of 23.70°. The lens is relatively compact with a total length of 15.750mm. In order to achieve the high relative aperture and good optical quality, aspheric surfaces have been incorporated on the rear surfaces of Elements 1 and 2. The asphere on Surface 2 represents a higher order correction to a spherical surface whereas the asphere on Surface 4 represents a hyperboloid of revolution around the optical axis. The re-

spective coefficients for defining the two aspheres are given in the following table:

Table I

Surface	R=1/C	K	D
2	36.338	0	0.12283×10^{-3}
4	9.4853	−1.6218	0

The invention has been described in detail with particular reference to a preferred embodiment thereof, but it will be understood that variations and modifications can be effected within the spirit and scope of the invention.

I claim:

1. A three element objective lens comprising, from front to rear, a positive meniscus element, a negative biconcave element and a positive biconvex element, each of said elements being formed of a glass having an index of refraction in excess of 1.90 and said lens including an aspheric surface on the rear surfaces of said positive meniscus element and said negative biconcave element, said aspheric surfaces being represented by the following formula and parameters:

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1 + K)C^2y^2}} + Dy^4$$

Surface	R=1/C	K	D
2	36.338	0	0.12283×10^{-3}
4	9.4853	−1.6218	0

wherein x is the sag of the aspheric surface from a plane reference surface at a radial distance y from the axis of the lens, C is equal to the reciprocal of the vertex radius of curvature R and K is the conic constant.

2. A three element objective lens comprising, from front to rear, a positive meniscus element, a negative biconcave element and a positive biconvex element, each of said elements being formed of a glass having an index of refraction in excess of 1.90 and said lens including an aspheric surface on the rear surfaces of said positive meniscus element and said negative biconcave element, said lens having a focal length of 25.00mm when constructed according to the parameters in the following table:

Element	N	V	Radius mm	Thickness or Separation mm
			R_1=13.506	
1	2.01940	34.21		T_1=6.000
			R_2=Asphere	
			R_3=−185.19	S_1=1.210
2	1.90893	19.31		T_2=1.200
			R_4=Asphere	
			R_5=25.258	S_2=1.340
3	2.01940	34.21		T_3=6.000
			R_6=−25.258	
				S_3=.500

wherein, from front to rear, the elements are numbered from 1 to 3, the corresponding indices of refraction, N, and Abbe' numbers, V, are listed for each of the lens elements, the radii are numbered from R_1 to R_6, the thicknesses are numbered from T_1 to T_3 and the air spaces are numbered from S_1 to S_3, and wherein R_2 and R_4 represent the radius of curvature at the vertex of aspheric surfaces defined by the following formula and parameters:

$$x = \frac{Cy^2}{1 + \sqrt{1 - (1 + K)C^2y^2}} + Dy^4$$

Surface	R=1/C	K	D
2	36.338	0	0.12283×10^{-3}
4	9.4853	−1.6218	0

wherein x is the sag of the aspheric surface from a plane reference surface at a radial distance y from the axis of the lens, C is equal to the reciprocal of the vertex radius R and K is the conic constant.

[57] **ABSTRACT**

A mechanism for transmitting the position of a diaphragm ring of a camera interchangeable lens to an exposure control device in the camera interchangeable viewer, a mechanism is mounted on the housing and includes a fixed gear, a mounting arm swingable about the fixed gear and having a sector shaped outer end which supports a rotatable gear which is coupled to the fixed gear by an idler gear carried by the mounting arm. A connector arm has one end connected to and moveable and rotatable with the rotatable gear, and is provided at its outer end with a coupling pin which separably engages a coupling element carried by the diaphragm ring. A flexible line extends from the outer end of the mounting arm along the periphery of the arm sector shaped end to the exposure control device and is spring loaded. The fixed and rotatable gears may be replaced by pulleys coupled by a flexible belt. The end of the connector arm traverses a circular path corresponding to that of the diaphragm ring coupling element.

INTERCHANGEABLE OBJECTIVE LENS DIAPHRAGM EXPOSURE CONTROL COUPLING MECHANISM

BACKGROUND OF THE INVENTION

The present invention relates to improvements in diaphragm coupling or interlock devices for use in an interchangeable lens type camera, by which the aperture value set by the lens diaphragm setting member which operates to preset the diaphragm aperture in the interchangeable lens, is transmitted to an exposure control mechanism located in the camera body.

Among the known interlocking devices of the present type is one which is provided with a coupling element secured to a diaphragm setting ring which is rotatable relative to the interchangeable objective lens barrel, and a pantograph mechanism which may be interlocked with the coupling element, or one which is provided with a pin engageable with the coupling element and an arcuate rail concentric with the center of rotation of the coupling element.

However, both the pantograph mechanism and the arcuate rail occupy considerable space, and thus considerably increase the size and bulk of the camera. In addition, great difficulties are encountered in the connection of an exposure control mechanism which is mounted in a finder casing removable from a camera body. Furthermore, the pin engaged with the rail has to slidingly rotate relative to the camera body or relative to the finder casing on the camera body, so that a smooth rotation in association with the movement of the diaphragm setting ring is not achieved.

SUMMARY OF THE INVENTION

It is a principal object of the present invention to provide a diaphragm interlocking or coupling device for use in an interchangeable lens type camera, in which a connecting member moves in accordance with the extent of displacement of the diaphragm setting member of an interchangeable lens and the displacement of the connecting member is transmitted as an aperture value to an exposure control mechanism.

It is another object of the present invention to provide a diaphragm interlocking device for use in a lens interchangeable type camera, in which a connecting member which is connectable with the diaphragm setting member of an interchangeable objective lens is secured to a revolving member which revolves around a fixed member and rotates about its own axis, thereby reducing the space occupied by the diaphragm interlocking mechanism housed in the camera body, contributing to a compact camera size and affording a smooth operation of the diaphragm interlocking device.

It is a further object of the present invention to provide a diaphragm interlocking device for use in an interchangeable objective lens type camera, in which, even if the diaphragm interlocking device is provided within an interchangeable pentaprism viewer removeable from the camera body, the extent of manipulation of the diaphragm setting member may be positively transmitted to an exposure control means.

The above and other objects and features of the present invention may be readily attained in a diaphragm interlocking device of the type described, which comprises a fixed member provided on the body of a camera, a revolving member which revolves around the fixed member and rotates on its own axis, a connecting member secured to the revolving member and connectable with a diaphragm setting member of an interchangeable lens, and means for transmitting the displacement of the connecting member to an exposure control means.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a perspective view, partly broken away, of the essential parts of one embodiment of the present invention;

FIG. **2** is a front elevational view of the coupling mechanism of the embodiment of FIG. **1**, showing the interchangeable lens and the finder casing properly mounted on the body of the camera;

FIG. **3** is a front view of the coupling mechanism, showing the finder casing removed from the camera body;

FIG. **4** is a front view of the coupling mechanism, showing the condition of the mechanism set for properly mounting the finder casing to the camera body;

FIG. **5** is a diagram illustrating the operation of the coupling mechanism;

FIG. **6** is a diagram showing the relationship between an angle θ_1 and an angle θ_2; and

FIG. **7** is a front view of another embodiment of the present invention.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawings, particularly FIGS. **1** to **4** thereof which illustrate a preferred embodiment of the present invention, the reference numeral **1** generally designates a camera body which is provided with an objective lens barrel **2** interchangeably mounted thereon and a finder casing **4** removeably mounted on the camera body in communication with the objective lens.

When the interchangeable objective lens **2** and the finder casing **4** are properly mounted on the camera body **1**, a coupler element or pawl **3***a* affixed to a diaphragm setting ring **3**, which is rotatable relative to the lens barrel, is engageable with an engaging or coupling pin **9***a* located on a connecting member **9** which will be hereinafter described, the connecting member **9** being disposed within the finder casing **4**.

A fixed or stationary gear **5** is rigidly mounted on the finder casing **4** and is substantially housed therein. A rotatable gear **6** is drive coupled by way of an idle gear **8** to the fixed gear **5**. A sector member or arm **7** is pivoted to a pivot **5***a* which is mounted at the center of the fixed gear **5**. The revolving gear **6** and idle gear **8** are both pivoted to the sector arm **7** by means of a pivot **6***a* and a pivot **8***a*, respectively. Accordingly, when the revolving gear **6** revolves together with the sector arm **7** around the fixed gear **5**, the gear **6** rotates on its axis **6***a*. The gear ratio of the gear **6** to the fixed gear **5** is set to a ratio which will be hereinafter described.

A flexible wire or line **10** has one end thereof secured to the sector arm **7** by means of a fastening piece **7***a* and extends along a cam groove **7***b* formed in the peripheral portion of the sector arm **7**, the other end of the line **10** being connected to an exposure control means which is provided within the finder casing. The line **10** is normally pulled in a direction toward the exposure control means, thereby resiliently loading or biasing the sector arm **7** so as to rotate in the counterclockwise direction.

A connecting arm or member **9** is secured at one end to the revolving gear **6** and is formed with an engaging pawl **9***b* at one edge thereof and is provided at its opposite end with an engaging pin **9***a* engageable with the coupler pawl **3***a*.

With the coupler pawl **3***a* in engagement with the engaging pin **9***a*, when the diaphragm setting ring **3** is rotated in the clockwise direction, then the coupler pawl **3***a* urges the engaging pin **9***a* in the same direction. This causes gear **6** to rotate on its axis in the counter-clockwise direction, so that it revolves in the clockwise direction around the fixed gear **5** by way of the idle gear **8,** and the sector arm **7** rotates in the clockwise direction about the pivot **5***a* to pull the wire **10** opposite to the direction in which the wire is spring drawn. On the other hand, when the diaphragm setting ring is rotated in the counter-clockwise direction, then the tendency of the wire to be pulled under the spring influence rotates the sector arm **7** in the counter-clockwise direction, so that the gear **6** revolves about gear **5** in the counter-clockwise direction, but rotates in the clockwise direction on its own axis, and the engaging pin **9***a* follows the coupler pawl **3***a*. As is clear from the foregoing, the clockwise and counter-clockwise rotations of the setting ring **3** draws the wire **10** against the spring pull thereon and pays out the wire **10,** respectively, thereby transmitting diaphragm aperture information to the exposure control means.

A pin **11** serves as a stop which limits the clockwise rotation of the connecting member **9** due to the spring influence on wire **10** when the engaging pin **9***a* is disengaged from the coupler pawl **3***a*.

For transmitting the aforesaid operation to the exposure control means irrespective of the aperture value set by the setting ring **3,** it is necessary that the coupler pawl **3***a* and the engaging pin **9***a* maintain an engaging relationship, independently of the position of the revolving gear **6.** Furthermore, for maintaining the aforesaid relationship, it is necessary that a predetermined gear ratio be maintained between the fixed gear **5** and the revolving gear **6,** as has been earlier set forth.

Now, a more detailed description will be given of the aforesaid gear ratio relationship, by referring to FIGS. **5** and **6.** In FIG. **5,** the point O represents the center of rotation of the coupler pawl **3***a*, and the coupler pawl **3***a* follows an arc *i* having a radius *r* (OC_1, OC, OC_0, OC_2) about the center O; the pivot **5***a* of the fixed gear **5** is shown at point A; the revolving radius of the revolving gear **6** has a length l_1 (AB_1, AB, AB_0); the distance between the pivot **6***a* on the connecting member **9** and the engaging pin **9***a* is represented as a length l_2 (B_1C_1, BC, B_0C_0); the revolving angle of the revolving gear **6** is represented as an angle θ_1, i.e., the rotational angle of the sector arm **7;** the rotating angle of the revolving gear **6** on its axis is represented as an angle θ_2; and the distance from the center of rotation to the pivot **5***a* of the fixed O **5** is represented as a length *a*.

Still referring to FIG. **5,** suppose a four joint link consisting of four link members $\overline{OA}$ (*a*), $\overline{AB}$ (l_1), $\overline{BC}$ (l_2), $\overline{CO}$ (*r*), then

$$a + l_1 = l_2 + r$$

wherein the link member $\overline{OA}$ is a fixed link member, assume the point O which is the original point of the coordinates, fixed link $\overline{OA}$ which is represented by the y axis, and the intersection B_0 of the link $\overline{AB}$ with the *y* axis, and

$$< BAB_0 = \theta_1$$

$$< ABC = \theta_2,$$

then the point C (X_c, Y_c) is given as follows:

$$X_c = l_1 \sin \theta_1 + l_2 \sin (\theta_2 - \theta_1) \quad (1)$$

$$Y_c = d + l_1 \cos \theta_1 - l_2 \cos (\theta_2 - \theta_1)$$

Thus,

$$\gamma^2 = X_c^2 + Y_c^2 = d^2 + l^2 + l_2^2 + Zdl_1, \cos \theta_1 - Zl_1 l_2 \cos \theta_2 - 2dl_2 \cos (\theta_2 - \theta_1) \quad (2)$$

When the relationship between θ_1 and θ_2 is determined by selecting *r*, *a*, l_1, l_2 at suitable values, the relationship shown by the solid line in FIG. **6** may be obtained. As is clear from FIG. **6,** if the angle θ_1, remains within a certain angular range, the aforesaid relationship approximates the following linear relationship:

$$\theta_2 = \lambda\theta_1$$

This demonstrates that, even if the aforesaid four joint link is devoid of the link member $\overline{OC}$, the tip C_{BC} of the arm $\overline{BC}$ will describe an arc approximately the arc described by the tip C_{OC} of the link member $\overline{OC}$, if the relationship $\theta_2 = \lambda\theta_1$ is maintained. This further indicates that, for defining the arc described by the coupler pawl **3***a* commensurate with the diaphragm setting as being an arc C_1C_2 within a given rotational angle as well as for causing the engaging pin **9***a* of the connecting member **9** to move within the locus approximating the aforesaid arc C_1C_2, the gear ratio Z1/Z2 of the fixed gear **5** to the revolving gear **6** should be $\lambda = \theta_2/\theta_1$, i.e., $\lambda = \theta_2/\theta_1 = Z_1/Z_2$,

In addition to the aforesaid relationship, since the interchangeable lens **2** and finder casing **4** are both removeable from the camera body **1,** when the interchangeable lens **2** and finder casing **4** are both mounted on the camera body **1,** the relationship between the coupler pawl **3***a* and the engaging pin **9***a* should be such that the pin **9***a* engages the righthand portion of the coupler pawl **3***a*, as shown in FIG. **2.** Conversely, when the relationship of the both members are reversed as shown in FIG. **3,** then there results a failure to transmit an aperture value set by the diaphragm setting ring **3** to the exposure control means by means of the wire **10.** To avoid the aforesaid failure, the present embodiment permits proper mounting of the finder casing **4** on the camera body **1** in the case as shown in FIG. **3.**

Specifically, an angular locking lever **12** is pivoted at its elbow on the finder casing by means of a shaft **14** and loaded by means of a spring **13** so as to be biased to rotate in the clockwise direction. The locking lever **12** has formed on one arm a locking pawl **12***a* which is engageable with an engaging hook **9***b* and on its other arm with a shoulder portion **12***b*. A guide screw **19** is positioned on the locking pawl **12.**

An adjusting member **18** is provided with a guide groove **18***b*, with which the guide screw **19** is engaged, and the adjusting member **18** is rigidly fixed, with its position being adjusted in the lengthwise direction. The adjusting member **18** is formed with a slope **18***a* positioned on the same side of the pivot **14** as the shoulder portion **12***b*.

A selecting lever **15** is pivoted on the finder casing by means of a pivot **17** and is loaded by a spring **16** so as to be biased to rotate in the counter-clockwise direction. The selecting lever **15** has formed on one arm a bent piece which is engageable with the shoulder portion **12***b*, and a projecting portion **15***b* projects downwards from the other arm thereof.

As shown in FIG. **3**, the bent piece in engagement with the shoulder portion **12***b* stops the clockwise rotation of the selecting lever **15** against the action of the spring **16**. On the other hand, as shown in FIG. **4**, when the aforesaid engagement is released, then the selecting lever **15** is allowed to rotate in the clockwise direction. However, when the selecting lever **15** is rotated in the clockwise direction against the action of the spring **16**, then the bent piece **15***a* will engage the slope **18***a*, thereby rotating the locking lever **12** in the counter-clockwise direction against the action of the spring **13**.

Shown at **1***a* is a base plate which is provided within the camera body **1** and adapted to engage the aforesaid projecting portion **15***b*, when the finder casing **4** is mounted on the camera body **1**.

As shown in FIG. **3**, when the finder casing **4** is to be mounted on the camera body **1**, with the bent piece **15***a* in engagement with the shoulder portion **12***b*, then the projecting portion **15***b* will abut the base plate **1***a* so that the clockwise rotation of the selecting lever **15** is interrupted. Thus, the finder casing is prevented from being mounted on the camera body **1**.

When the connecting member **9** is rotated in the counter-clockwise direction against the spring loaded pull of the wire **10**, and hence the sector arm **7** is rotated in the clockwise direction manually, then the engaging pawl **9***b* will engage the locking pawl **12***a* at its final step of the rotation, so that the locking lever **12** is rotated in the counter-clockwise direction against the action of the spring **13**, and the shoulder portion **12***b* will be retracted from the bent piece **15***a*, and thus the engagement of both will be released. As a result, when the projecting portion **15***b* abuts the base plate **1***a*, with the finder casing **4** being mounted on the camera body **1**, then the selecting lever **15** is rotated in the clockwise direction, and the projecting portion **15***b* is moved upwards, so that the finder casing **4** may be properly mounted on the camera body **1**. The bent piece **15***a* which rotates in the clockwise direction will engage the slope **18***a* to thereby advance the same so that the engaging pawl **9***b* is disengaged from the locking pawl **12***a*. Accordingly, the connecting member **9** is rotated in the clockwise direction under the pulling force of the wire **10**, while its engaging pin **9***a* engages the righthand portion of the coupler pawl **3***a*, as shown in FIG. **2**.

The aforesaid arrangement completely prevents the finder casing **4** from being mounted on the camera body **1** in a manner that the engaging pin **3***a* is positioned on the lefthand side of the coupler pawl **3***a*, as shown in FIG. **3**.

FIG. **7** shows another embodiment of the present invention in which the gear meshing arrangement of the first embodiment is replaced by a fixed pulley **20** and a belt **22** trained therearound, and about a revolving member **21** which rotates about the center pivot **20***a* of the fixed member **20**. Specifically, the pulley **20** which is affixed to the finder casing takes over the place of and defines the fixed member. In addition, there is provided a sector arm **7** which is identical to that shown in the first embodiment and which is rotatable about the center pivot. Furthermore, the manner in which the wire **10** is secured to the fastening metal piece **7***a* of the sector arm **7** is the same as that in the first embodiment. The pulley **21** serving as a revolving member is pivoted on the sector arm **7** by means of a pivot **21***a*. Journalled on the pivot **21***a* is a connecting member **9** which rotates integrally with the revolving pulley **21**. A belt **22** is trained around the revolving pulley **21** and fixed pulley **20**, so that the revolving pulley **21** may be revolved about the pivot **20***a* around the fixed pulley **20** and rotates on its own axis. The other structural details of the present arrangement are the same as those shown in the first embodiment.

In the last described embodiment as well, when the interchangeable lens **2** and the finder casing **4** are properly mounted on the camera body **1**, the engaging pin **9***a* of the connecting member **9** should maintain the engaging relationship with the righthand portion of the coupler pawl **3***a*. In this case, the following relationship may be obtained. $\lambda = \theta_2/\theta_1 = Z/Z_2$ at the gear ration of Z_1/Z_2 of the fixed gear **5** to the revolving gear **5** in the first embodiment, and number of teeth $Z = D/m$, thus

$$\lambda = \theta_2/\theta_1 = Z_1/Z_2 = D_1/D_2,$$

wherein $D = a$ diameter, m= module, $D_1 = a$ diameter of the fixed pulley **20**, and $D_2 = a$ diameter of the revolving pulley **21**.

In other words, even if the fixed gear is replaced by the fixed pulley and the revolving gear is replaced by the revolving pulley, there remains no difference in principle. Thus, it suffices that a specific relationship between the both only be maintained when replacing the gear ratio λ in the first embodiment with the diameter ratio.

While in the aforesaid embodiments there is shown a pentaprism view of the interchangeable type, even if the viewer is of a fixed type, the extent of manipulation of the diaphragm setting member may positively be transmitted to the exposure control means. In addition, the present invention is not intended to limit the arrangement as far as such compensation is effected during the time in which the extent of rotation of the diaphragm setting member is transmitted to the final exposure control means.

While there have been described and illustrated preferred embodiments of the present invention, it is apparent that numerous alterations, omissions and additions may be made without departing from the spirit thereof.

I claim:

1. A lens interchangeable type camera including a camera body, an objective lens interchangeably mounted on said camera body and having a rotatable diaphragm ring, and a finder housing, comprising:

an exposure control means;

a fixed member disposed in said camera;

a revolving member rotatable around said fixed member through an interlocking means and rotatable about its own axis;

a connecting member having one end connected to and rotatable with said revolving member and its other end connectable with said diaphragm ring and moveably interlocking with the movement of said diaphragm ring for moving said diaphragm ring;

a transmitting means for transmitting the movement of said revolving member to said exposure control means; and

an arm member rotatably pivoted at one end to said fixed member, said revolving member being pivoted to said arm member.

2. The camera as set forth in claim **1** wherein said arm member includes a sector shaped section, a peripheral portion of said sector shaped section defining a cam forming part of said transmitting means.

3. The camera as set forth in claim **1** including a shaft rotatably mounting said revolving member and said connecting member to said arm member.

4. The camera as set forth in claim **1** wherein said finder housing is interchangeable, and said exposure control means, said fixed member, said revolving member, said connecting member and said transmitting means are disposed in said finder housing.

5. The camera as set forth in claim **1** wherein said fixed member and said revolving member comprise a fixed gear and a revolving gear respectively, and said interlocking means comprises an interlocking gear meshed with said fixed gear and said revolving gear.

6. The camera as set forth in claim **1** wherein said fixed member and said revolving member comprise a fixed pulley and revolving pulley respectively, and said interlocking means comprises a belt trained around said fixed pulley and revolving pulley.

7. In a camera including an interchangeable objective lens having a diaphragm control ring and an adjustable exposure control device, a mechanism for transmitting the angular position of said diaphragm control ring to said exposure control device comprising a first gear rotatable about a first axis thereof and swingable about a second axis parallel to and offset from said first axis, means including a second gear coaxial with said second axis and a mounting arm swingable about said second axis and rotatably supporting said first gear and means drive coupling said first gear to said second gear for rotating said first gear about its first axis in response to its swinging about said second axis, a connector arm having one end connected to said first gear and being rotatable and moveable therewith and an opposite end coupled to and moveable with said diaphragm control ring and motion transmission means connecting said first gear to said exposure control device.

8. A lens interchangeable type camera including a camera body, an objective lens interchangeably mounted on said camera body and having a rotatable diaphragm with a coupler pawl, and a finder housing, comprising,

an exposure control means;

a fixed gear disposed in said camera;

a revolving gear rotatable around said fixed gear and revolvable about its own axis, and an interlocking gear intercoupling said fixed and revolving gears;

a connecting member having one end connected to said revolving gear and being moveable with said revolving gear and its other end connectable with said coupler pawl of said diaphragm ring and moveably interlocking with the movement of said diaphragm ring for moving said revolving gear;

a mounting arm swingable about said fixed gear and rotatably supporting said revolving gear and interlocking gear; and

a transmitting means for transmitting the movement of said revolving gear to said exposure control means.

9. The camera of claim **8** wherein said mounting arm includes a sector shaped section, a peripheral portion of said sector shaped section defining a cam forming part of said transmitting means.

10. The camera of claim **8** including a shaft rotatably mounting said revolving gear and said connecting member to said connecting arm.

11. The camera of claim **8** wherein said finder housing is interchangeable, and said exposure control means, said fixed gear, said revolving gear said connecting member and said transmitting means are disposed in said finder housing.

[57] **ABSTRACT**

An objective system for motion picture cameras wherein the focal length of a zoom lens is variable by rotating a ring-shaped selector about the optical axis through the medium of a radially extending handle, and focussing prior to the making of exposures at close range is effected by rotating the handle about its own axis. Prior to rotation of the handle about its axis, the selector must be moved to an angular position corresponding to the shortest focal length of the lens and the handle is thereupon depressed radially inwardly against the opposition of a spring so that an eccentric pin at its inner end enters a socket in a slide which is reciprocable in the lens barrel and is coupled to a sleeve for the optical elements of the lens by means of a follower which also serves to couple the sleeve to the selector. The handle can be depressed in a single angular position and can be moved outwardly to become disengaged from the slide only after it reassumes the single angular position. The selector may be completely or nearly completely concealed in the interior of a tubular extension of the front wall of the camera body.

OBJECTIVE SYSTEM WITH ZOOM LENS FOR MOTION PICTURE CAMERAS

CROSS-REFERENCE TO RELATED APPLICATION

Certain features of our objective system are disclosed in the commonly owned copending application Ser. No. 505,601 filed Sept. 12, 1974 by Reinsch and Körner.

BACKGROUND OF THE INVENTION

The present invention relates to objective systems for photographic apparatus, and more particularly to improvements in objective systems which comprise variable-focus or zoom lenses. Still more particularly, the invention relates to objective systems having variable-focus lenses and means for focussing during the making of exposures at close range or at a greater distance (including infinity) from the subject. As used in the specification and claims, the term "objective system" is intended to denote a variable-focus lens, a tubular barrel or mount for the lens, and means for moving selected optical elements of the lens with respect to the barrel in the direction of the optical axis.

It is already known to provide an objective system for use in motion picture cameras with a variable-focus lens and with a rotary ring-shaped selector which can be displaced by means of a radially extending handle. When the handle is moved in a direction to rotate about the optical axis, the selector changes the focal length of the lens. In order to enable the selector to allow for focussing at close range, the handle is moved in the direction of the optical axis whereby such movement of the handle does not influence the positions of the optical elements but merely serves to disengage the selector from a further ring-shaped member which is connected with the optical elements of the lens. When the axial movement of the selector with the handle **1** is completed, the selector is rotated again to thereby focus prior to the making of exposures at close range. Such rotation causes a predetermined axial adjustment of certain optical elements of the lens.

It is further known to provide an objective system which includes a variable-focus lens with a selector which is rotatably and axially movably mounted on the barrel for the optical elements. When the selector is rotated in one axial position, it changes the focal length of the lens. Rotation of the selector in another axial position results in focussing prior to the making of exposures at close range.

Each of the just described prior solutions employs a single selector which must be rotated for the purpose of changing the focal length as well as for the purpose of focussing at close range. As a rule, the selector must be provided with a relatively wide annular knurled portion so that it may be readily gripped and conveniently manipulated by the user prior to and/or during picture taking. This is not possible when the selector is relatively small (e.g., if the manufacturer wishes to reduce the overall dimensions of the photographic apparatus) and/or when the selector is partly or nearly fully concealed in a forwardly extending part (e.g., a sleeve) of the camera body. In such instances, the selector is invariably provided with a radially extending handle which replaces the aforementioned knurled portion and enables the user to move the selector axially and/or about the axis of the lens.

SUMMARY OF THE INVENTION

An object of the invention is to provide an objective system for photographic apparatus, especially for motion picture cameras, wherein the optical elements of the variable-focus lens can be moved by novel and improved means which facilitates convenient manipulation even if the diameter of the selector (which forms part of such moving means) is very small and/or if the selector is fully or nearly fully concealed in the body of the photographic apparatus.

Another object of the invention is to provide the objective system with a versatile handle which facilitates the shifting of selected optical elements of the variable-focus lens with and/or relative to the selector.

A further object of the invention is to provide the objective system with novel and improved means for moving selected optical elements of the variable-focus lens for the purpose of focussing prior to the making of exposures at close range.

An additional object of the invention is to provide novel and improved motion transmitting connections between the handle for a ring-shaped selector and the optical elements of the variable-focus lens in the objective system of a motion picture camera. The objective system of the present invention comprises a tubular barrel, a variable-focus picture taking lens having a variator system including a plurality of optical elements disposed in the barrel one behind the other and being movable axially of the barrel to thereby focus the image of a subject (preferably at close range) and to change the focal length of the lens, and novel and improved means for moving the optical elements. Such moving means includes a handle which extends outwardly (preferably radially outwardly) from the barrel and is movable in a first direction about the optical axis of the lens (i.e., about the barrel) and in a different second direction (preferably about an axis extending radially of the barrel), first motion transmitting means for moving the optical elements in response to movement of the handle in the first direction to thereby change the focal length of the lens, and second motion transmitting means for moving the optical elements in response to movement of the handle in the second direction to thereby focus the image of a subject.

The first motion transmitting means may comprise a ring-shaped selector which comprises a sleeve or an analogous carrier or holder for the handle, a sleeve which is mounted in the barrel and surrounds the optical elements of the lens, and means (e.g., a follower) for connecting the selector with the sleeve. The second motion transmitting means preferably comprises a slide which is reciprocable in parallelism with the optical axis in guide means provided therefor in the barrel, a coupling which can connect the slide to the handle in response to movement of the handle substantially radially of the barrel from a first to a second position, and means for connecting the slide to the aforementioned sleeve in the barrel. Such connecting means may constitute the aforementioned follower which couples the sleeve to the slide in a predetermined angular position of the selector.

The novel features which are considered as characteristic of the invention are set forth in particular in the appended claims. The improved objective system itself, however, both as to its construction and its mode of operation, together with additional features and advantages thereof, will be best understood upon perusal of

the following detailed description of certain specific embodiments with reference to the accompanying drawing.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 is a fragmentary axial sectional view of an objective system with zoom lens and a handle which embodies the invention; and

FIG. 2 is a fragmentary view substantially as seen in the direction of arrows from the line II—II of FIG. 1.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

FIG. 1 shows an objective system which comprises a tubular barrel or mount 1 fixedly mounted in the body of a motion picture camera. The barrel 1 contains a variable-focus picture taking lens or zoom lens having two groups of optical elements including a front group (not shown) and a rear group or variator system 2 including four discrete optical elements 2*a*, 2*b*, 2*c* and 2*d*. The optical elements 2*a*–2*d* of the group 2 are disposed one behind the other, as considered in the direction of the optical axis, and are movable axially of the barrel 1 in order to adjust the focal length of the lens as well as for the purpose of focussing prior to the making of close-up shots. The front group of optical elements is shown at 3 in the copending application Ser. No. 505,601. Such front group can be moved axially by rotating the selector 16 of Ser. NO. 505,601 which selector is coupled to the ring 150 of Ser. No. 505,601. The threads of the ring 150 of Ser. No. 505,601 mesh directly with the barrel 1 of our objective system. Thus, the intermediate rings 18 and 19 of Ser. No. 505,601 can be omitted. Reference may also be had to U.S. Pat. No. 3,259,044 to MacMillin et al. which discloses a suitable adjusting device for the front group of optical elements in a variable-focus lens.

The optical elements 2*a*–2*c* are fixedly mounted in a ring 3 which is axially movably installed in a sleeve 4. The sleeve 4 is rotatable in the barrel 1 to thereby effect a movement of the ring 3 and optical elements 2*a*–2*c* in the direction of the optical axis of the picture taking lens. The ring 3 receives motion from a follower here shown as a screw 5 whose head extends through a cam slot 7 in the sleeve 4 and into a longitudinally extending guide groove 6 in the internal surface of the barrel 1. The rearmost optical element 2*d* of the variator system 2 is mounted directly in the rearmost portion of the sleeve 4. The sleeve 4 is further threadedly secured to a connecting means or follower 8 which extends radially outwardly in the region of the optical elements 2*b*, 2*c* so that its outermost portion projects into and is movable lengthwise of an internal groove 10 of a ring-shaped motion-transmitting selector 11. The selector 11 is rotatably mounted on the barrel 1 and its internal groove 10 is parallel to the optical axis of the lens. An intermediate portion of the follower 8 extends through an arcuate cam slot 9 of the barrel 1. The major portion of the selector 11 is confined in a tubular extension or sleeve 12 of the front wall (not shown) of the camera body. The means for rotating the selector 11 about the barrel 1 comprises a novel handle 13 which extends radially outwardly at the front end of the extension 12.

When the handle 13 is grasped by hand and is caused to rotate the selector 11 about the barrel 1, i.e., about the optical axis, the cam slots 7 and 9 cause the ring 3 and the optical elements 2*a*–2*d* of the variator system 2 to move in the direction of the optical axis in accordance with a predetermined pattern which is calculated to establish desirable optical characteristics of the lens. The optical element 2*d* rotates with the sleeve 4 but the optical elements 2*a*–2*c* merely move in the axial direction of the barrel 1 because the outer end portion of the follower 5 extends into the groove 6. The shortest focal length is selected when the followers 5 and 8 assume the illustrated positions, namely when the ring 3 (with the optical elements 2*a*–2*c*) is located at a maximum distance from the optical element 2*d*.

The barrel 1 is formed with an internal groove 14 (FIG. 2) which extends in parallelism with the optical axis and communicates with the cam slot 9. The groove 14 permits axial movements of the variator system 2 for the purpose of focussing prior to the making of close-up shots when the focal length of the lens has been reduced to a minimum value. The follower 8 is then in register with the slot 14 (as shown in FIG. 2) so that the sleeve 4 can be moved forwardly. During such movement of the sleeve 4 (i.e., when the follower 8 moves in the groove 14 of the barrel 1), the distance between the optical elements 2*a*–2*c* and 2*d* remains unchanged. The just described movement of the sleeve 4 is effected by rotating the handle 13 about its own axis. In addition, the handle 13 is movable axially, i.e., radially of the extension 12, selector 11 and barrel 1, between a first or extended position and a second or depressed position.

The handle 13 comprises a shaft 15 which is rotatably and axially movably mounted in a sleeve-like guide or carrier 16 of the selector 11. The outer end portion of the shaft 15 has a tapped bore for the shank of a screw 17 serving as a means for fastening the shaft 15 to a cupped handgrip portion 18 which surrounds the carrier 16. The outer end face 19 of the carrier 16 constitutes a retainer for the inner end convolution of a helical spring 21 which bears against an annular internal shoulder 20 of the handgrip portion 18 and serves to urge the shaft 15 to the extended position, i.e., away from the extension 12. The extended positions of the shaft 15 and handgrip portion 18 are shown in FIG. 1.

The inner end portion 22 of the shaft 15 has a larger diameter and constitutes a cylindrical plunger which is rotatable and axially movable in a counterbore at the inner end of the carrier 16. The inner end face of the plunger 22 has an eccentric projection or pin 23 which constitutes a first coupling means and can be introduced into a complementary second coupling means here shown as a socket or aperture 32 provided in a motion transmitting slide 25. The projection or pin 23 can enter the socket 32 in response to deformation of the spring 21. The slide 25 can transmit motion from the handle 13 (and more particularly from the shaft 15 and handgrip portion 18) to the optical elements 2*a*–2*d* of the variator system 2.

As shown in FIG. 2, the slide 25 is reciprocable in a guide groove 24 which is machined into the internal surface of the barrel 1 and is parallel to the optical axis of the lens. This slide is located inwardly of the groove 14 and is biased rearwardly (i.e., in a direction to the right, as viewed in FIG. 1 or 2) by a helical spring 26 which reacts against the foremost portion of the barrel 1; this foremost portion of the barrel has a radially extending surface 31 against which the foremost convolution of the spring 26 abuts. Furthermore, the surface 31 is formed with a projection or post 29 which is surrounded by the foremost convolutions of the spring

26. The rearmost convolutions of the spring 26 surround a similar projection or post 28 extending forwardly from a crosshead 30 of the slide 25. The spring 26 urges the slide 25 to a predetermined starting position in which the rear end of the slide abuts against an adjusting device here shown as a disk 27 which is eccentrically mounted on the shank of a screw 27*a* secured to the barrel 1. The angular position of the adjusting disk 27 (and hence the starting position of the slide 25 in the groove 24) can be changed by inserting a suitable tool into a peripheral notch 27*b* of the disk 27 and by thereupon turning the disk about the axis of the screw 27*a*. The slide 25 normally abuts against the disk 27 under the action of the spring 26; however, it can be moved forwardly and away from the disk 27 when the pin 23 of the plunger 22 extends into the socket 32 and the handgrip portion 18 is rotated about its axis to thereby displace the pin 23 through the medium of the shaft 15.

The socket 32 has a substantially rectangular shape and extends circumferentially of the barrel 1. The slide 25 is further formed with an open-ended slot 33 which can receive the follower 8. The width of the slot 33 approximates the width of the cam slot 9 in the barrel 1 and slightly exceeds the diameter of the follower 8. When the slide 25 assumes the starting position shown in FIG. 2, the slot 33 is in exact register with the slot 9, i.e., the follower 8 can enter the slot 33 as soon as the variator system 2 assumes the position of FIG. 1 which corresponds to the shortest focal length of the lens. The follower 8 thereupon moves forwardly in response to forward movement of the slide 25, i.e., in response to depression and subsequent rotation of the hand-grip portion 18 about the axis of the shaft 15.

The selector 11 has a blocking pin 34 which is parallel to the axis of the barrel 1 and extends through the carrier 16 and into a peripheral groove 35 of the plunger 22. The groove 35 is parallel to the axis of the shaft 15.

When the handgrip portion 18 is in the extended position of FIG. 1, the blocking pin 34 extends into the radially outermost portion of the groove 35 and holds the plunger 22, shaft 15 and handgrip portion 18 against rotation about the axis of the shaft 15. However, if the operator depresses the handgrip portion 18 to stress the spring 21, the outer end of the groove 35 moves inwardly beyond the blocking pin 34 so that the handgrip portion 18 is free to rotate about the axis of the shaft 15. At the same time, the pin 23 enters the socket 32 of the slide 25 so that rotation of the handgrip portion 18 entails a lengthwise movement of the slide 25 in the guide groove 24. If the handgrip portion 18 is turned only slightly from the angular position shown in FIG. 1 (while the pin 23 extends into the socket 32, the blocking pin 34 engages the outer end face or shoulder 22*a* of the plunger 22 and automatically holds the handgrip portion 18 in the depressed position against the opposition of the spring 21. Thus, the handgrip portion 18 is free to return to the extended position of FIG. 1 only when the shaft 15 and its plunger 22 assume the predetermined angular position of FIG. 1 in which the groove 34 can receive the blocking pin 34.

The operation is as follows:

If the user of the motion picture camera wishes to change the focal length of the lens, the selector 11 is rotated, preferably by way of the handle 13. Such angular movement of the selector 11 and of its internal groove 10 causes the follower 8 to move about the optical axis and to move the sleeve 4. An intermediate portion of the follower 8 travels in the cam slot 9 of the barrel 1 whereby the follower 8 causes the sleeve 4 to move axially. Also, as the sleeve 4 rotates in response to rotation of the selector 11, the cam slot 7 moves relative to the follower 5 whereby the latter moves the ring 3 and the optical elements 2*a*–2*c* in the direction of the optical axis. The configuration of the cam slot 7 is such that the optical elements 2*a*–2*c* move away from the optical element 2*d* while the user reduces the focal length of the lens.

In order to focus for the making of close-up shots, the user must reduce the focal length of the lens to the minimum value in a first step, i.e., the follower 8 must enter the slot 33 of the slide 25 and must be in register with the internal groove 14 of the barrel 1. The user thereupon depresses the handgrip portion 18 against the opposition of the spring 21 so that the groove 35 moves inwardly beyond the blocking pin 34 of the selector 11 and the pin 23 penetrates into the socket 32 of the slide 25. The user then rotates the handgrip portion 18 about the axis of the shaft 15 whereby the pin 23 causes the slide 25 to move in the guide groove 24 toward the post 29 on the foremost portion of the barrel 1. The direction in which the handgrip portion 18 can rotate the shaft 15 and its plunger 22 in order to move the slide 25 forwardly is indicated by the arrow 40 (FIG. 2). The slide 25 entrains the follower 8 which in turn entrains the sleeve 4, the follower 5 and ring 3, i.e., the optical elements 2*a*–2*d* are moved forwardly as a unit because the angular position of the sleeve 4 remains unchanged. Thus, the distance between the optical elements 2*a*–2*c* and optical element 2*d* remains unchanged while the slide 25 moves away from the adjusting disk 27. The just described lengthwise movement of the slide 25 results in focussing for the making of close-up shots. The user can release the handgrip portion 18 in the selected angular position (proper focussing for the making of close-up shots) because the friction between moving parts suffices to prevent accidental changes in angular position of the shaft 15 and its plunger 22. The handgrip portion 18 remains in the depressed position because the blocking pin 34 engages the outer end face or shoulder 22*a* of the plunger 22 and the plunger thereby bears against the pin 34 under the action of the spring 21. Such engagement between the plunger 22 and blocking pin 34 suffices to prevent unintentional angular displacements of the handle 18 under the action of the spring 26 which tends to move the slide 25 back into abutment with the disk 27.

If the camera is thereupon to make one or more normal exposures, the user rotates the handgrip portion 18 back to the angular position of FIG. 1 whereby the spring 21 expands and moves the plunger 22 radially outwardly so that the groove 35 receives the blocking pin 34. The pin 23 is withdrawn from the socket 32 whereby the spring 29 automatically returns the slide 25 into abutment with the adjusting disk 27. The focal length of the lens can be increased by rotating the selector 11 about the barrel 1.

The groove 35 is preferably located substantially diametrically opposite the pin 23. Thus, the pin 23 must be located in the rearmost position (as considered in the direction of the optical axis) in order to enter the socket 32 while the slide 25 abuts against the disk 27.

An advantage of the blocking means including the pin 34 and the plunger 22 with its groove 35 and shoul-

der 22*a*, and of the spring 21 is that such parts reduce the likelihood of improper manipulation of the means for moving the optical elements 2*a*–2*d*. Thus, the pin 34 prevents rotation (movement in the second direction) of the handgrip portion 18 about the axis of the shaft 15 when the handle 13 dwells in the extended position of FIG. 1 or in any other position except in the fully depressed position. Also, the pin 34 automatically blocks the movement of the handle 13 from the depressed position except when the handle assumes that angular position (with respect to the axis of the shaft 15) in which the pin 34 is in register with the groove 35 of the plunger 22. Thus, the optical elements 2*a*–2*d* automatically assume those positions which correspond to the shortest focal length of the lens when the slide 25 can be engaged by or disengaged from the pin 23 of the handle 13.

Without further analysis, the foregoing will so fully reveal the gist of the present invention that others can, by applying current knowledge, readily adapt it for various applications without omitting features which fairly constitute essential characteristics of the generic and specific aspects of our contribution to the art and, therefore, such adaptations should and are intended to be comprehended within the meaning and range of equivalence of the claims.

What is claimed as new and desired to be protected by Letters Patent is set forth in the appended claims.

We claim:

1. In an objective system for photographic apparatus, a combination comprising a tubular barrel; a variable-focus picture taking lens having a variator system including a plurality of optical elements disposed in said barrel one behind the other and being movable axially of said barrel to thereby change the focal length of said lens and to focus the image of a subject; and means for moving said optical elements, including a handle extending outwardly from said barrel and being movable in a first direction substantially circumferentially of said barrel and in a different second direction, first motion transmitting means for moving said optical elements in response to movement of said handle in said first direction to thereby change the focal length of said lens, and second motion transmitting means for moving said optical elements in response to movement of said handle in said second direction to thereby focus the image of a subject, said handle being further movable substantially radially of said barrel between first and second positions, said handle and said second motion transmitting means comprising complementary first and second coupling means which are engaged with each other only in one of said positions of said handle to move said second motion transmitting means in response to movement of said handle in said second direction while said handle assumes said one position.

2. A combination as defined in claim 1, wherein said handle has an axis which extends substantially radially of said barrel and said movement in said second direction constitutes a rotary movement about said axis.

3. A combination as defined in claim 1, further comprising means for biasing said handle to the other of said positions.

4. A combination as defined in claim 1, wherein said second motion transmitting means further comprises a slide which is reciprocable in parallelism with the axis of said barrel and said second coupling means comprises a socket in said slide, said first coupling means comprising a projection which enters said socket in response to movement of said handle to said one position.

5. A combination as defined in claim 4, wherein said barrel has guide means for said slide and further comprising means for biasing said slide to a predetermined position from which said slide is shifted in response to movement of said handle in said second direction in said one position of said handle.

6. A combination as defined in claim 4, wherein said handle has an axis extending substantially radially of said barrel and said movement in said second direction constitutes an angular movement about said last mentioned axis, said projection being laterally offset with respect to said last mentioned axis.

7. A combination as defined in claim 6, wherein said first motion transmitting means comprises a hollow carrier and said handle further comprises a shaft which is reciprocable in said carrier between said first and second positions and is rotatable in said carrier about said last mentioned axis, and a handgrip portion rigid with said shaft and surrounding said carrier.

8. A combination as defined in claim 7, further comprising means for biasing said handle to the other of said positions, including a spring reacting against said carrier and bearing against said handgrip portion.

9. A combination as defined in claim 1, further comprising means for blocking the movement of said handle in said second direction in response to movement of said handle from said one position.

10. A combination as defined in claim 1, wherein said second movement is an angular movement about an axis extending sbstantially radially of said barrel and further comprising means for blocking the movement of said handle from said one position thereof except in a single angular position of said handle.

11. A combination as defined in claim 10, wherein said blocking means comprises a device which also blocks the angular movement of said handle in response to movement of said handle from said one position.

12. A combination as defined in claim 11, further comprising means for biasing said handle to said other position, said blocking means comprising a groove provided in said handle and extending in parallelism with said axis, an annular shoulder provided on said handle at one end of said groove, and a pin provided on said first motion transmitting means and extending into said groove except in said one position of said handle, said pin engaging said shoulder in said one position of said handle and when said handle is rotated from said predetermined angular position, said biasing means storing energy in response to movement of said handle from said other to said one position to thereupon bias said shoulder against said pin in said one position of said handle and to return said handle to said other position when said handle assumes said single predetermined angular position so that said pin can reeneter said groove.

13. A combination as defined in claim 12, wherein said handle further comprises a plunger and said groove is provided in the periphery of said plunger, said plunger having an end face which constitutes said shoulder.

14. A combination as defined in claim 1, wherein said first motion transmitting means comprises a ring-shaped selector surrounding said barrel and being rotatable by said handle about the axis of said barrel.

15. A combination as defined in claim 14, wherein said lens further comprises a sleeve for said optical elements and said first motion transmitting means further comprises means for connecting said sleeve to said selector.

16. A combination as defined in claim 15, wherein said means for connecting said sleeve to said selector is connected to said second motion transmitting means in a predetermined angular position of said selector.

[57] **ABSTRACT**

In a method for focusing a reproducing objective, such as may be used for measuring distances, wherein multiplication of the image of the entrance pupil is achieved by image-splitting optical elements mounted in the plane of the object image, the improvement comprising:

projecting the light fluxes from different parts of the pupil image plane on separate sets or groups of photoelectric receivers, deriving a signal from the comparison of the output signals from these receiver groups and using this signal as a criterion for focusing as a function of magnitude and sign. Apparatus for performing the method includes a grid of prisms or pyramids, and a beam splitter for directing light through two separate photoelectric receiver masks.

METHOD AND APPARATUS FOR FOCUSING AN OBJECTIVE

CROSS REFERENCE TO A RELATED APPLICATION

Applicant claims priority under 35 U.S.C. 119 for application Ser. No. P 22 60 474.6, filed Dec. 11, 1972 in the Patent Office of the Federal Republic of Germany.

BACKGROUND OF THE INVENTION

The invention relates to a method for focusing a reproducing objective, for instance for distance measurements, wherein multiplication of the image of the entrance pupil or iris is achieved by means of image splitting optical elements located in the plane of the object image.

The state of the art of follow up systems for focusing the slide in a slide projector may be ascertained by reference to U.S. Pat. Nos. 3,399,595 and 3,517,992, and the follow up systems are useful in focusing the objective of the present invention. The disclosures of these patents are incorporated herein.

With regard to photographic cameras, it is known to mount pyramidal grids or rasters on the pane of the viewer for the purpose of focusing the objective or for visual assessment of the same. For each direction of surface inclination of the trilateral or quadrilateral pyramid, there will be a laterally shifted reproduction of the objective pupil, provided a lens reproducing the object pupil is mounted in the vicinity of the grid plane. The observing (ocular) puil covers part of the domain of the overlapping pupil images. However, since the ocular pupil is of a different relative position in each of the pupil images, many object images shifted by parallax and corresponding in number to that of the pupil images will occur when the focusing plane is moved out of the screen plane. Errors in camera objective setting therefore are noted by the fuzzy, fringy nature of the transitions in image contrasts.

Under such conditions, it becomes difficult to subjectively assess focus, especially if there is great depth of field of the reproduction through the camera objective.

SUMMARY OF THE INVENTION

The object of the present invention therefore is to create a method for focusing a reproducing objective such as is used in photographic cameras and the like, wherein there will not be the above-described difficulty relating to known visual-subjective methods, which will not require accurate objective setting at the edges of the images, and which will allow the use of automatic objective setting devices.

The object of the present invention is achieved by applying light fluxes from different parts of the pupil plane to separate photoelectric receiver groups and deriving a signal from the latter to serve as a criterion for focus as a function of magnitude and sign.

Advantageous systems for implementing the method of the present invention are also disclosed herein.

The special advantage of the novel method of the present invention consists in its many faceted applicability. If electronic automatic control is dispensed with, the novel devices of the invention may also be used as an improved, visual, static display. The setting criterion in this instance is the equality in brightness of two test fields.

BRIEF DESCRIPTION OF THE DRAWINGS

The new method and the corresponding devices and systems are best described by reference to the appended drawings, wherein:

FIG. 1 shows schematically an embodiment of the elements of the present invention for focusing an objective;

FIG. 2 shows schematically another embodiment of the elements of the present invention for focusing an objective;

FIG. 3 shows schematically still another embodiment of the elements of the present invention for focusing an objective using a beam splitter;

FIG. 4 shows schematically yet another embodiment of the elements of the present invention for focusing an objective having an arrangement for the visual observation of a pupil sector near the axis;

FIG. 5 shows schematically an embodiment of the elements of the present invention having reflecting pupil stops, a polarizing beam splitter and two quarter-wave plates;

FIG. 6 is a side view of a prism useful in the present invention having a photoelectric differential receiver; and

FIG. 7 is a detailed showing of the differential receiver of FIG. 6 along the line VII—VII.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

As shown in FIG. **1**, a light source **1** illuminates a narrow light slit **1'** normal to the plane of the drawing. Light slit **1'** is reproduced in the region of a dividing mirror **2** by means of an objective **1''**, for instance at location **3**. The parts of the split beam are applied by means of condensing lenses (**4, 5**) mounted downstream dividing mirror **2** to two photoelectric receiver sets **6, 7** and **8,9**. Shifting objective **1''** along the optical axis allows the displacement of the image location **3** of slit **1'** in front of and behind dividing mirror **2.**

If location **3,** as shown, lies in front of dividing mirror **2,** then receivers **7** and **9** will be illuminated, while receivers **6** and **8** will not be. When the image location **3** is moved beyond mirror **2,** illumination passes to the photoelectric receivers **6** and **8.** The change in signal at the outputs of the receiver sets **6, 7** and **8, 9** occurring when the location of focusing is passing the front edge of mirror **2** therefore is a criterion for the focusing of the slit image.

Such a change in signal will also be obtained from the arrangement of FIG. **2.** A luminous object, not shown, is to be focused by means of objective **1''** which is followed by a prism **10** having its front edge **21** as well as its rear edge aligned to the optical axis of said objective. A beam splitting prism **11** is located behind prism **10,** the exit surfaces of prism **11** being provided with two complementary stops **12, 14** for blocking light fluxes passing the device close to the axis and away from the axis respectively. The rays leaving beam splitter **11** and passing through lenses **15, 16** and **17, 18** are collected respectively at photoelectric receivers **19** and **20.**

The method of operation of the arrangement described so far is as follows:

If the object is focused in front of edge **21** of prism **10,** for instance at location **3,** the refracting power of prism **10** is concentrating the image of the entrance pupil reproduced by objective **1''** close to the optical

axis. Therefore, only receiver **20** will be illuminated as light fluxes emitted from said image and deflected by the splitting surface of beam splitting prism **11** will be blocked by stop **12**, while light fluxes penetrating beam splitter **11** will pass stop **14**.

Yet if the object is focused behind edge **21**, for instance at location **13**, the image of the entrance pupil is formed away from the optical axis as a result of the refracting power of prism **10**, thus causing the illumination of receiver **19** only as light fluxes deflected by beam splitter **11** will pass stop **12** but will be blocked by stop **14** after penetrating prism **11**. Therefore, the image position with respect to the edge **21** of prism **10** is shown by the ratio of the photoelectric receiver outputs. Exact focus signified by coincidence of edge **21** and the focus of objective **1''** is represented by equality of signals.

As regards the arrangement of FIG. **3**, prism **10** of FIG. **2** is replaced by a grid of prisms **10'**. The remaining components are denoted by the same reference numerals and operate as in FIG. **2**. The grid of prisms **10'** may also be replaced by a grid of pyramids of known kind. Stops **12, 14** must be adapted to the grid geometry.

The arrangement of FIG. **4** differs from that of FIG. **3** in being provided with a polarizing beam splitter **11'**. The object, not shown, is reproduced in the region of the grid plate **10'**. Collecting optical elements project the light passing through the grid plate to the polarizing splitter **11'**. Stop **12'**, corresponding to stop **12** of FIG. **3**, in this instance is made reflecting and separated from splitter **11'** by means of a quarter-wave plate **24**, so that the reflected light rays far from the axis are projected on the photoelectric receiver **19** by means of lenses **15, 16**. Ocular **25** is located behind stop **12'**, allowing visual observation of the rays being transmitted. Components **14, 17, 18, 20** are analogous to those of FIG. **3**.

In the arrangement of FIG. **5**, both stops **12'** and **14'** are reflecting and separated from the polarizing splitter **11'** by quarter-wave plates **24, 26** so that the light rays away from the axis reflected at stop **12'** and the paraxial rays reflected at stop **14'** reach via the ocular **25** an observer's eye. The ray portions passing the stops **12', 14'** reach the photoelectric receivers **19, 20** as in FIG. **3**.

In the variation of the invention shown in FIG. **6**, splitting of the light beams onto different photoelectric receivers is achieved by designing these receivers proper as a photoelectric differential receiver group **27**, as shown in detail in FIG. **7**. This group is mounted in the rear of the grid of pyramids **10''** at a spacing corresponding to the deviation angle of this pyramid grid **10''** and to the aperture of objective **1''**. The receiver group **27** is so designed that its subdivision corresponds to that of grid **10''** and that the limited field of one set of receivers **28** is located behind each peak of a grid element, while the adjacent receiver elements are combined into a group or set of receivers **29** for the rays more removed from the peaks. Equality of signal at the receiver outputs here to is the criterion for focusing the object image on the grid plate **10''**.

The arrangement shown in FIGS. **6** and **7** is particularly well suited for photographic cameras.

Following focusing adjustment, the distance between object and adjustment component may be read off, for instance from a suitable scale on the objective setting.

I claim:

1. A method for focusing an objective of an object projecting light fluxes consisting of said objective having an entrance pupil receiving said light fluxes and reproducing the image of said entrance pupil at an image plane, splitting optical elements mounted in the range of said image plane for achieving multiplication of said image of said entrance pupil, selecting from said light fluxes predetermined ones passing through different parts of said entrance pupil, applying said fluxes to first and second photoelectric receiver means for generating output signals corresponding to said light fluxes passing through said different pupil parts, comparing said signals of said receiver means, deriving a signal from said comparison, and using said signal for focusing said objective according to magnitude and sign of said signal.

2. The method of claim **1**, further consisting of separating said image plane into two planes of spatially different location by means of a beam splitter (**11**), said different planes corresponding to said photoelectric receiver means.

3. A system comprising an objective with an optical axis and an entrance pupil, said objective being adjustable for focusing an object image in a plane along said optical axis, ray splitting optical elements mounted in said image plane selecting light fluxes from different parts of said entrance pupil, first and second photoelectric receiver means receiving said light fluxes from said different part of said entrance pupil and generating output signals depending on the amount of light received, means for comparing said output signals and generating a comparison signal and means responsive to said comparison signal for focusing said objective according to magnitude and sign of said comparison signal.

4. The system of claim **3**, further comprising a beam splitter (**11**) located along said optical axis producing together with a field lens and said ray splitting optical elements on respectively each exit surface of the splitter, two spatially separate double images of said entrance pupil in spatially separate planes corresponding to said first and second photoelectric receiver means, said two spatially separate double images having first and second separate axes, first and second stops **12, 14** located along said first and second separate axes at said double images, said stops being matched to the geometrical form of said image splitting elements and having apertures corresponding respectively to the paraxial part of said entrance pupil and to the complementary part of said entrance pupil, and one objective and one condensing lens each located along said first and second separate double image axes for collimating the light fluxes passing said apertures onto said receiver means.

5. The system of claim **3**, wherein said ray splitting optical elements comprise a grid of pyramids (**10''**) mounted in said plane of the image of the object.

6. The system of claim **3**, wherein said ray splitting optical elements comprise a grid of prisms (**10'**) mounted in said plane of the image of the object.

[57] **ABSTRACT**

A photographic objective lens system for adaption with a diaphragm located in front of the entire system. The lens system comprises positive front and rear lenses and a negative intermediate lens in optical alignment with each other. The front lens is in the form of a positive meniscus doublet composed of a double convex lens and double concave lens cemented together at their adjoining surfaces. The intermediate lens is a double concave singlet. The rear lens consists of a positive meniscus front singlet of rearward convexity and a positive meniscus rear singlet of forward convexity. This objective is so designed as to have a relative aperture of at most two in F-number and a field angle as wide as 44° while nevertheless preserving an excellent state of correction of various aberrations.

LARGE APERTURE PHOTOGRAPHIC OBJECTIVE

BACKGROUND OF THE INVENTION

This invention relates to photographic objective lens systems having a relative aperture of at least *f*/2.0 and field angle as wide as 44°, and more particularly to a photographic objective lens system adapted for use with a diaphragm located outwardly of the entire lens system while nevertheless an excellent state of correction of the image aberrations is preserved even in such situation.

The commonly known photographic objective lens systems are designed so that the diaphragm is located within an air space of the lens system, and, therefore, the entrance and exit pupils lie inside of the lens system. In some special photography, however, it is required for the objective lens to have a pupil lying outwardly thereof. For example, with specially designed cameras, it is desired because of the arrangement and construction of the mechanism thereof to position the shutter, diaphragm and the like in front of the objective lens. In this case, there is required the front diaphragm type of objective lens.

SUMMARY OF THE INVENTION

The lens design parameters of such an objective lens system are seriously limited in the possibility of establishing certain relationships because of the high tendency of producing various aberrations, so that a high degree of correction of the image aberrations are considerably difficult to accomplish. Particularly with an objective lens having an abnormally large relative aperture compared to an ordinary objective, such a difficulty is remarkably intensified. The present invention is adapted to overcome the above-mentioned problem. Accordingly, the object of the invention is to provide a photographic objective lens system having a large relative aperture along with an excellent state of correction of the image aberrations.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a diagrammatic view of an objective lens system according to a preferred embodiment of the present invention.

FIGS. **2A, 2B** and **2C** are curves illustrating various aberrations of the lens of FIG. **1.**

FIG. **3** is a diagrammatic view of an objective lens system according to another preferred embodiment of the present invention.

FIGS. **4A, 4B** and **4C** are curves illustrating various aberrations of the lens of FIG. **3.**

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIGS. **1** and **3,** the objective lens system according to the present invention is illustrated as comprising four optically aligned lens components with five lens elements. Character A indicates a diaphragm position. The first component I is in the form of a positive meniscus doublet composed of a double convex lens element and a double concave lens element which has a first refracting surface R1 of a convex curvature forwardly directed toward the object side. The second component II is a double concave singlet which has a front surface R4 of stronger concave curvature, or having a smaller radius of concave curvature than that of the rear surface thereof and is rearwardly spaced in an axial distance D3 from Component I. The third component III is a positive meniscus singlet which has a rear surface R7 of convex curvature rearwardly directd toward the image plane, and is spaced in an axial distance D5 from Component II. The fourth component IV is a positive convex singlet which has a front surface R8 of stronger convex curvature or having a smaller radius of convex curvature forwardly directed toward the object side. The adjacent surfaces R7 and R8 of Components III and IV are characterized in that the surface R8 of Component IV is flatter than the surface R7 of Component III. Further, the axial distance from the first surface R1 of Component I to the first surface R4 of Component II or the sum of the axial thicknesses D1 and D2 of the front and rear lens elements of Component I and the axial separation D3 between Components I and II is longer than the axial distance from the second surface of Component II to the second surface of Component III, or the sum of the axial separation D5 between Components II and III and the axial thickness D6 of Component III. The arrangement and construction of the components of the lens system according to the present invention may be considered to be of modified triplet type from the standpoint of the basic lens design, for which the rear lens component of the triplet type objective is formed by two convex lenses. By the provision of the two convex lenses in the rear lens component it is made possible to decrease the refractive powers of each surface with decrease in residual spherical aberrations. However, these two convex lenses, namely, Components III and IV, are spaced apart from the diaphragm at so long distance that extra-axial pencils of rays pass practically through the marginal portions thereof to cause the production of extra-axial image aberrations. In order to minimize such image aberrations, the relationship between the adjacent surfaces of Components III and IV is set forth as $R7 < R8$. Component II of a concave lens plays a roll of cancelling various residual aberrations of the positive lens of Component I. As far as the extraaxial aberration correction is concerned, it is preferred to place component II near Component III. From this point of view, the relationship $D1 + D2 + D3 > D5 + D6$ is herein set forth. To impart a refractive power of a predetermined magnitude to Component II, the front surface R4 rather than the rear surface R5 is provided with a smaller radius of curvature, thereby contributing a large proportion of the refractive power to Component II, or otherwise residual aberrations are deteriorated as the incident angles of extra-axial pencils of rays impinging upon the rear surface R5 increases. Under the condition that $D1 + D2 + D3 < D5 + D6$, the axial separation between Components I and II is relatively long. In order to effect a high degree of correction of chromatic aberrations under such situation, Component I is constructed in the form of a doublet of lens elements cemented together at their adjoining surfaces. The present invention in its broader aspects has been described with respect to the optical constructional principle. In the practice of the present invention, however, good image quality can be obtained by the use of certain relationships set out in more detail below which define the limits for an optimum lens design.

$$(1)\ 0.55f < \Sigma D > 0.9f$$

$$(2)\ 1.70 < \bar{N}_{convex}$$

$$(3)\ 1.4 < \frac{R_8}{|R_7|} < 2.5;\ R7<0$$

$$(4)\ 0.12f < (D1 + D2 + D3) - (D5 + D6) < 0.3f$$

$$(5)\ 0.6f < R5 < 1.2f$$

$$(6)\ 0.005 < \left(\frac{1}{V_2} - \frac{1}{V_1} \right) < 0.020$$

wherein f is the overall focal length of the entire lens system; ΣD is the total physical length of the entire lens system; R5, R7 and R8 are the radii of curvature of the fifth, seventh and eighth refracting surfaces counting from the front respectively; D1, D2, D3, D5 and D6 are the first, second, third, fifth and sixth axial distances between successive refracting surfaces respectively; $\overline{N}_{convex}$ is the mean value of the refractive indices of materials of which all the convex lens element are made; and V1 and V2 are the Abbe numbers of the convex and concave lens elements respectively constituting said first component.

As the pupil of an objective of front diaphragm type lies outwardly of the lens system, the diameter of the rear lens is unavoidably increased and a high degree of correction of extra-axial aberrations is more difficult to accomplish. These problems may be neglected when designing objectives of the type having, though large relative aperture, a small field angle, and objectives of the type having, though relatively wide field angle, a small relative aperture. On the other hand, as an objective has a large relative aperture of at least $f/2.0$ and field angle as great as 44° as in the present invention, the solution of aberrational problems is made complicated.

Relationship (1): The diameter of the rear lens may be decreased with decrease in the total length of the complete objective. As the total length is shortened, however, the refractive powers of each lens element are necessarily strengthened to thereby make it difficult to correct particularly spherical aberrations, so that an objective having a large relative aperture is hardly obtainable. Relationship (1) is set out for the purposes of facilitating the minimization of the diameter of the rear lens of a large aperture objective adapted for use with a diaphragm located in front of the objective while permitting the objective to have a field angle of as great as 44°. When the upper limit of relationship (1) is violated, the required diameter of the rear lens is increased so that a difficulty is created in assembling the resultant objective with a given camera body. When the lower limit is violated, the solution of aberrational problems can not be facilitated even by the use of relationships to be subsequently described.

Relationship (2): Spherical aberrations and the Petzval sum tend to over-correction when the total length of the complete objective is restricted in the range defined by relationship (1). For this reason, a relatively high refractive indices of glasses have to be selected for employment in the convex lens elements. For facilitating a high standard correction of spherical aberrations and the Petzval sum with an objective having a large aperture of more than $f/2.0$, it is necessary that the mean value of the refractive indices of all the convex lens elements satisfies at least relationship (2). The upper limit of relationship (2) is not given, but it may be the presently available maximum refractive index of glass.

Relationship (3): The reason why the surfaces R7 and R8 of strong convex curvature of Components III and IV are particularly selected for subject to relationship (3) is to define the surfaces R7 and R8 of such configurations that extra-axial aberrations and particularly coma aberration are minimized. When the lower limit is violated, coma aberration is intensified. When the upper limit is violated, the spherical aberrations are intensified.

Relationship (4): When the lower limit is violated, a high degree of correction of extra-axial aberrations are more difficult to accomplish and the diameter of the rear lens is increased. When the upper limit is violated, spherical aberrations are deteriorated.

Relationship (5): A preferable balance of astigmatism is effected with the rear surface R5 of controlled curvature of the concave lens of Component II. When the upper limit is violated, under-correction of astigmatism results. When the lower limit is violated, over-correction of astigmatism results.

Relationship (6): determines the range of acceptable differences between the dispersive indices of the convex and concave lens elements of Component I, When the lower limited is violated, the concave lens of Component II has to compensate for chromatic aberrations to so large extent that when longitudinal chromatic aberrations are over-corrected, lateral chromatic aberrations are caused to result in over-correction. When the upper limit is violated, the situation is reversed. Thus, in any case, good states of correction of longitudinal chromatic aberrations as well as lateral chromatic aberrations can not be effected simultaneously.

Two examples of a specific objective of the present invention may be constructed in accordance with the numerical data given in Tables 1 and 2 below wherein;

- R: the radii of curvature of each lens surface with the respective refracting surfaces being numbered from the front to the rear of the objective and being identified respectively by a subscript numeral for each R
- D: the axial spacings between successive refracting surfaces with each D being identified by its numerical subscript successively from front to rear
- N: the refractive indices of each lens element for the spectral D line of sodium with each N being identified by its numerical subscript successively from front to rear
- V: the dispersive indices of each lens element with each V being identified by its numerical subscript successively from front to rear.

(6)	0.0094	0.0137

Relationships (1) – (6) may be modified as follows without causing appreciable deteriolation of aberrations from the states shown in FIGS. 2 and 4.

(1') $0.55f < \Sigma D < 0.8f$

(2') $1.7 < \bar{N}_{convex}$

(3') $1.6 < \frac{R8}{|R7|} < 1.75$

(4') $0.15f < (D1+D2+D3) - (D5+D6) < 0.25f$

(5') $0.7f < R5 < 0.95f$

(6') $0.005 < \left(\frac{1}{\nu 2} - \frac{1}{\nu 1} \right) < 0.018$

What is claimed is:

1. A large aperture photographic objective lens system adapted for use with a diaphragm located forwardly thereof, said objective comprising in order from the object side:

a first positive meniscus doublet lens component which is convex toward the object side and is composed of a double convex lens and a double concave lens cemented together at their adjoining surfaces;

a second double concave single lens component a strong concave curvature directed forwardly toward the object side and being rearwardly spaced from said first component;

a third positive meniscus singlet lens component which is convex toward the image side and lying substantially in edge contact with said second component; and

a fourth convex singlet lens component having a refracting surface of strong convex curvature directed toward the object side and being spaced from said third component; said refracting surface of strong convex curvature of the fourth component being flatter than the adjacent surface of said third component; and the axial length from the first surface of said first component to the first surface of said second component being longer than the axial length from the second surface of said second component to the second surface of said third component.

2. A large aperture photographic objective as described in claim 1, wherein said fourth component has a second surface of concave curvature rearwardly directed toward the image side.

3. A large aperture photographic objective lens system for use with a diaphragm located forwardly thereof, said objective comprising in order from the object side:

a first positive meniscus doublet lens component which is convex toward the object side and is composed of a double convex lens and a double con-

cave lens cemented together at their adjoining surfaces;

a second double concave single lens component having a strong concave curvature directed forwardly toward the object side and being rearwardly spaced from said first component;

a third positive meniscus singlet lens component which is convex toward the image side and lying substantially in edge contact with said second component; and

a fourth convex singlet lens component having a refracting surface of strong convex curvature directed toward the object side and being spaced from said third component,

said fourth component also having a second surface of concave curvature rearwardly directed toward the image side;

said refracting surface of strong convex curvature of the fourth component being flatter than the adjacent surface of said third component; and the axial length from the first surface of said first component to the first surface of said second component being longer than the axial length from the second surface of said second component to the second surface of said third component, wherein the characteristics of the various lenses of the four lens components and their spatial relationships to each otehr being substantially of the proportions indicated by the numerical data in the following table

The focal length of the entire system f = 26.0
F-number = 2.0
The field angle 2ω = 44.7°

$R_1 = 15.445$		
$D_1 = 3.0$	$N_1 = 1.77250$	$V_1 = 49.6$
$R_2 = -44.635$		
$D_2 = 1.85$	$N_2 = 1.64769$	$V_2 = 33.8$
$R_3 = 45.846$		
$D_3 = 4.23$		
$R_4 = -15.233$		
$D_4 = 1.63$	$N_3 = 1.68893$	$V_3 = 31.1$
$R_5 = 21.407$		
$D_5 = 1.2$		
$R_6 = -33.113$		
$D_6 = 2.73$	$N_4 = 1.77250$	$V_4 = 49.6$
$R_7 = -12.198$		
$D_7 = 0.15$		
$R_8 = 20.022$		
$D_8 = 2.1$	$N_5 = 1.77250$	$V_5 = 49.6$
$R_9 = 66.210$		
$\Sigma D = 16.89$		

wherein R denotes the radii of curvature of each lens surface with the respective refracting surfaces being numbered from front to rear and being identified respectively by a subscript numeral for each R; D denotes the axial spacings between successive refracting surfaces with each D being identified by its numerical subscript successively from front to rear; N denotes the refractive indices of each lens for the spectral D line of sodium with each N being identified by its numerical subscript successively from front to rear; and V denotes the dispersive indices of each lens with each V being identified by its numerical subscript successively from front to rear.

4. A large aperture photographic objective lens system for use with a diaphragm located forwardly thereof, said objective comprising in order from the object side:

a first positive meniscus doublet lens component which is convex toward the object side and is composed of a double convex lens and a double concave lens cemented together at their adjoining surfaces;

a second double concave single lens component having a strong concave curvature directed forwardly toward the object side and being rearwardly spaced from said first component;

a third positive meniscus singlet lens component which is convex toward the image side and lying substantially in edge contact with said second component; and

a fourth convex singlet lens component having a refracting surface of strong convex curvature directed toward the object side and being spaced from said third component, said fourth component also having a second surface of concave curvature rearwardly directed toward the image side; said refracting surface of strong convex curvature of the fourth component being flatter than the adjacent surface of said third component; and the axial length from the first surface of said first component to the first surface of said second component being longer than the axial length from the second surface of said second component to the second surface of said third component, wherein the characteristics of the various lenses of the four lens components and their spatial relationships to each other being substantially of the proportions indicated by the numerical data in the following table

The focal length of the entire system f = 26.0
F-number = 1.8 The field angle 2ω = 44.7°

HIGH NUMERICAL APERTURE INTERMEDIATE WIDE ANGLE OBJECTIVE

BACKGROUND OF THE INVENTION

The present invention relates to a high numerical aperture intermediate wide angle lens system of image angle ranging from 55° to 60°, which is small in size and suitable for use in a single lens reflex camera as a retro focus type objective.

SUMMARY OF THE INVENTION

The present invention involves high numerical aperture intermediate wide angle objective lens system whose aberration is corrected to a high degree of excellence and which is a retro focus lens system consisting of a 7 group 8 lens system characterized in that the image angle is 55° or greater and which satisfies the following conditions:

$$F / 1.4 < |F_{1.2}| < F / 0.8 \ , \ F_{1.2} < 0 \qquad 1$$

$$F / 1.4 < |F_{1.2.3.4}| < F / 0.9 \qquad 2$$

$$0.8 < \frac{(d_1 + d_2 + d_3 + \cdots + d_6 + d_7)}{(d_8 + d_9 + d_{10} + \cdots + d_{13} + d_{14})} < 1.3 \qquad (3)$$

$$1.1 < (\nu_1 + \nu_2) / (\nu_3 + \nu_4) < 1.6 \qquad 4$$

where;

F:	is the resultant focal length of the whole optical system;
$F_{1.2...i}$:	is the resultant focal length of the first to the i-th lenses;
n_i:	is the d-line index of refraction of the i-th lens;
ν_i:	is the Abbe's number of the i-th lens;
r_k:	is the radius of curvature of the k-th surface;
d_j:	is the j-th lens spacing or lens thickness.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows the lens system of example 1;

FIG. 2 shows graphs of the aberration curves of example 1;

FIG. 3 shows the lens system of example 2;

FIG. 4 shows graphs of the aberration curves of example 2;

FIG. 5 shows the lens system of example 3; and

FIG. 6 shows graphs of the aberration curves of example 3.

DESCRIPTION OF THE PREFERRED EMBODIMENT

The first and the second lenses 1 and 2 are of negative meniscus type whose concave surfaces are directed to the image side; the third and the fourth lenses 3 and 4 are of positive type and are positioned opposite to the fifth lens with a diaphragm (not shown) positioned therebetween. The fifth lens 5 is of negative type. In example 3 (FIG. 5), the fifth lens 5 and the sixth lens 6 are cemented together. In examples 1 and 2, the sixth lens 6 is of negative type and is cemented to the seventh lens 7. In all examples, the seventh and eighth lenses 7 and 8 are of positive type. Each example is of 7 group 8 lens structure.

In the conditions indicated below, the characters denote as follows:

F:	is the resultant focal length of the whole optical system;
$F_{1.2...i}$:	is the resultant focal length of the first to the i-th lenses;
n_i:	is the d-line index of refraction of the i-th lens;
ν_i:	is the Abbe's number of the i-th lens;
r_k:	is the radius of curvature of the k-th surface;
d_j:	is the j-th lens spacing or lens thickness.

In accordance with the present invention, the optical system is characterized with the following conditions:

$$F / 1.4 < |F_{1.2}| < F / 0.8 \ , \ F_{1.2} < 0 \qquad 1$$

$$F / 1.4 < |F_{1.2.3.4}| < F / 0.9 \qquad 2$$

$$0.8 < \frac{(d_1 + d_2 + d_3 + d_4 + d_5 + d_6 + d_7)}{(d_8 + d_9 + d_{10} + d_{11} + d_{12} + d_{13} + d_{14})} < 1.3 \qquad (3)$$

$$1.1 < (\nu_1 + \nu_2) / (\nu_3 + \nu_4) < 1.6 \qquad 4$$

Condition 1 indicates the power of the front group negative lenses of the retro focus lens system. Naturally, for small size, it is necessary to increase the power of the negative lenses and diminish the spacing. However, if the negative value of the focal length $F_{1.2}$ is too much smaller than $F / 1.4$, the desired result is obtained but aberration is aggravated and it is difficult to compensate for aberration at the rear lens group. If focal length $F_{1.2}$ is greater than $F / 0.8$, miniaturization of the lens system is not likely to be attained. Under this condition, steps must be taken to obtain greater back focus at the rear lens group, and also corresponding steps must be taken for correction of aberration.

Conditions 2, with relation to the condition 4, indicate steps for compensation of chromatic aberration, and is, naturally, for correcting aberrations caused under the condition 1. If the focal length $F_{1.2.3.4}$ is smaller than $F / 1.4$, the desired chromatic aberration can be advantageously corrected, but this is apt to cause decrease of Petzval sum or decrease of the radius of curvature of each surface, and especially variation of coma aberration. Furthermore, this will disadvantageously prevent increase in the value of back focus determined by the focal length $F_{1.2}$. On the other hand, a focal length value which is greater than $F / 0.9$ is advantageous for Petzval sum, but this will naturally cause a limitation such that for correction of chromatic aberration, a very small value of Abbe's number ν must be utilized. Thus, condition 2 is most advantageous.

Condition 3 is necessary for miniaturization and also for keeping balance between the front lens group and the rear lens group. If the value of the condition 3 ratio is smaller than the left side value, miniaturization is advantageously attained, but a far greater power combination is required at the front lens group and this will naturally cause failure of condition 1 and disadvantage in correction. In order to retain vignetting light, in relation to coma aberration, certain steps are taken such as increasing the diameter of the rear lens group, but this causes a failure in balance between the front lens group and the rear lens group. Further, difficulty is caused in correction of aberration. This requires such undesirables as increasing the number of lenses used or impossibility in retaining numerical aperture. On the other hand, if condition 3 is greater than 1.3, for the admission of the proper amount of light into the diaphragm aperture, the front lens group must be made greater in size. This is contra to the object of miniaturization and is therefore undesirable.

Condition 4 is closely related with condition 2 and determines the value of Abbe's number ν which is necessary for correction of chromatic aberration. If $(\nu_1 +$

$\nu_2) / (\nu_3 + \nu_4)$ is smaller than 1.1, correction of chromatic aberration up to the fourth lens is not sufficient and particularly too much of the transverse chromatic aberration may be produced. This requires that special steps should be taken at the rear lens group which is undesirable for correction of aberrations. On the other hand, if the last mentioned value of ratio is greater than 1.6, it is feared that correction of chromatic aberration up to the fourth lens would be too little, and this is undesirable for overall balance of chromatic aberration.

The data for the examples and the Seidel's coefficients of the examples are as follows:

In the foregoing examples, the number of the lens surfaces and the radius of curvature are taken from the left hand side of the figures.

What is claimed is:

1. An intermediate wide angle retro focus objective lens system comprising a 7 group, 8 element lens wherein the lens elements have the following characteristics:

	Radius of Curvature in m m		Lens spacing in m m	n_i / ν_i
r_1	92.500	d_1	3.95	1.51633 / 64.1
r_2	57.275	d_2	9.52	
r_3	132.250	d_3	5.32	1.69350 / 53.3
r_4	55.875	d_4	9.42	
r_5	167.500	d_5	7.50	1.83400 / 37.2
r_6	1537.500	d_6	2.50	
r_7	68.313	d_7	26.50	1.78590 / 44.2
r_8	−178.523	d_8	9.27	
r_9	−149.500	d_9	9.00	1.76182 / 26.6
r_{10}	68.250	d_{10}	9.67	
r_{11}	−159.375	d_{11}	5.00	1.74077 / 27.8
r_{12}	80.750	d_{12}	19.20	1.806610 / 40.8
r_{13}	−79.500	d_{13}	3.75	
r_{14}	−951.448	d_{14}	8.75	1.78590 / 44.2
r_{15}	−111.275			

F = 100.0
$F_{1.2}$ = 95.13
$F_{1.2.3.4}$ = 83.54.

[57] **ABSTRACT**

A retrofocus type objective lens system consists of five lenses, from the object side, a front first lens, a biconvex second lens, a biconcave third lens, a positive meniscus fourth lens having a rear convex surface, and a positive fifth lens, the system satisfying the following conditions:

a. $d_4 > d_5 + d_6 + d_7 + d_8 + d_9$
b. $0.7d_4 < d_3 < 1.3d_4$
c. $-0.5 < r3/r4 < -0.1$
d. $N_1 < N_3$
e. $d_2 > 0.2f$

wherein r_j is the radius of curvature of the jth lens surface, designated sequentially from the object side: d_j is the axial distance between the jth and the $j+1$ lens surfaces; N_i is the refractive index of the ith lens; and f is the focal length of the entire lens system.

RETROFOCUS TYPE OBJECTIVE LENS SYSTEM

BACKGROUND OF THE INVENTION

The present invention relates generally to a retrofocus type objective lens system, and more particularly to a retrofocus type objective lens system for use in a single lens reflex camera having a backfocus longer than 0.9 times the focal length of the entire lens system.

A known retrofocus type lens for use in a single reflex camera incorporates a divergent lens ahead of the entire lens system and a convergent lens in the rear half portion thereof overcoming the divergency of the aforesaid lens system, for the purpose of obtaining a long backfocus. An attempt to achieve better compensation for the aberration of the entire lens system results in a complicated construction of the lenses. The objective lenses of the retrofocus type of this kind consists of five lenses and are known as the simplest construction of lenses, i.e., consisting from the object side, a first negative lens, a second positive lens, a third negative lens, a fourth positive lens and a fifth positive lens.

According to the present invention, there is provided a small size and light weight objective lens system having an image forming capability at least equal to or better than that of the conventional retrofocus type lens system which consists of six or seven lenses, by providing an improved lens arrangement and dimensional relationship of the retrofocus type lens system consisting of five components defining five lenses.

OBJECT OF THE INVENTION

It is an object of the present invention to provide a retrofocus type objective lens system whose backfocus is longer than 0.9 times as long as the focal length (f) of the entire lens system and in which aberration is well compensated, said system consisting of five components defining five lenses.

It is another object of the invention to provide a retrofocus type objective lens system whose backfocus is longer than 0.9 times as long as the focal length of the entire lens system and which is adapted for use as an interchangeable lens in a single reflex camera having a field angle of over 64° and being light in weight, said system consisting of five components, five lenses.

These and other objects and features of the present invention will be apparent from the reading of the following description in conjunction with the accompanying drawings, which set forth embodiments of the invention.

SUMMARY OF THE INVENTION

It has been found that the above and related objects of the invention may be readily attained in a retrofocus type objective lens system of five groups, five lenses consisting, from the object side, of a negative meniscus first lens having a convex surface facing the front or object side, a second lens having convex surfaces on both sides, a third lens having concave surfaces on both sides, a positive meniscus fourth lens having a convex surface facing the rear or image side and a fifth positive lens, said system satisfying the following conditions:

a. $d_4 > d_5 + d_6 + d_7 + d_8 + d_9$

b. $0.7d_4 < d_3 < 1.3d_4$

c. $-0.5 < r3/r4 < -0.1$

d. $N_1 < N_3$

e. $d_2 > 0.2f$

wherein $r1, r2, r3, r4 \ldots r10$ are the radii of curvatures of the lens refracting surfaces arranged sequentially from the object side; $d_1, d_2 \ldots d_9$ are the axial lengths between the refracting surfaces arranged sequentially from the object side; $N_1, N_2 \ldots N_5$ are the refractive indexes of the lenses arranged sequentially from the object side; and f is focal length of the entire lens system.

Since the objective lens system according to the present invention is of a retrofocus type, it is required that a divergent lens be disposed at the forward side of the lens system. According to the present invention, a single negative first lens placed closest to the object side is used as the aforesaid divergent lens, while a biconvex second lens follows this single meniscus negative lens and possesses an axial position and configuration as defined in the conditions (a), (b), (c), thereby providing a retrofocus type objective lens system having the least number of lenses, yet possessing effective aberration compensation.

More particularly, following the condition (a) the biconvex second lens is placed at a considerably greater air distance $d4$ apart from the lenses subsequent to the third lens inclusive, while the second lens is located somewhat ahead of the center of the entire lens system and has a relatively greater thickness as defined in the condition (b), thereby functioning to effectively compensate for coma aberration, distortion aberration and lateral chromatic aberration which are created by the first lens.

In addition to the aforesaid feature, the condition (c) permits proper compensation for coma aberration by means of the second lens and the minimization of spherical aberration a highly satisfactory degree, while the condition (d) provides a small Petzval sum and good image surface characteristic, while preventing the development of a halo component for improving the image contrast. Furthermore, the condition (e) presents a backfocus longer than 0.9 times the focal length of the entire lens system.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a longitudinal medial sectional view of a retrofocus lens system embodying the present invention;

FIG. 2*a*, 2*b* and 2*c* are graphs illustrating the aberration characteristics of a specific example of the lens system of FIG. 1; and

FIGS. 3*a*, 3*b* and 3*c* are graphs similar to those of FIGS. 2*a*, 2*b* and 2*c* of another specific example of the lens system.

DESCRIPTION OF THE INVENTION

Referring now to FIG. 1, the improved retrofocus type objective lens system consists of five consecutively designated lenses; a front or object side first lens G_1 which is a negative meniscus lens with a rear concave face, a biconvex second lens G_2, a biconcave third lens G_3, a positive meniscus fourth lens G_4 with a rear convex face and a positive fifth lens G_5. The following Table 1 sets forth the specific dimensions and parameters of a lens system embodying the present invention in which r_j is the radius of curvature of the jth lens surface which surfaces are successively designated from the front to the rear; d_j is the axial distance between the jth lens surface and the $j+1$ surface, N_i is the refractive index of the ith lens; and V_i is the Abbe's number of the ith lens, the values of r_j and d_j being

based on the focal length f of the lens system being equal to 1 :

TABLE I

f = 1.0 1:2.8 radius of curvature	field angle 2ω = 64° length on axis	refractive index	backfocus s' = 1.06 Abbe's number
r1 = 2.3437	d1 = 0.0441	N1 = 1.5714	v1 = 53.0
r2 = 0.4709	d2 = 0.3538		
r3 = 0.6206	d3 = 0.28	N2 = 1.6583	v2 = 58.5
r4 = −1.8643	d4 = 0.3182		
r5 = −0.4012	d5 = 0.0379	N3 = 1.6889	v3 = 31.2
r6 = 2.3930	d6 = 0.0283		
r7 = −1.4595	d7 = 0.067	N4 = 1.7200	v4 = 50.3
r8 = −0.4496	d8 = 0.0029		
r9 = 2.4019	d9 = 0.068	N5 = 1.6204	v5 = 60.3
r10 = −1.1931			

In the aforesaid specific embodiment, $d4=0.3182$

$d_5 + d_6 + d_7 + d_8 + d_9 = 0.0379 + 0.0283 + 0.067 + 0.0029 + 0.068$ $d_5 + d_6 + d_7 + d_8 + d_9 = 0.2041$

thus satisfying the condition (a) $d_4 > d_5 + d_6 + d_7 + d_8 + d_9$. In addition, $d_3 = 0.28$, $d_4 = 0.3182$.

d3/d4 = 1.136

thus satisfying the condition (b) $0.7d_4 < d_3 < 1.3d_4$ Furthermore,

r3/r4 = 0.6206/−1.8643 ≈ −0.333

thus satisfying the condition

(c) **−0.5 < r3/r4 < −0.1**

$N_1=1.5714 < N_3 = 1.6583$

thus satisfying the conditions that $N_1<N_3$ Furthermore, $d_2=0.3538 > 0.2$ thus satisfying the condition that $d_2 > 0.2f$.

Seidel's coefficient at each refracting surface in the objective lens system of the aforesaid first embodiment as specified in Table I are set forth in the following Table II:

TABLE II

surface	spherical aberration	coma	astigmatism	Petzval sum	distortion
1	0.0179	0.0328	0.0601	0.1551	0.3940
2	−9.9235	1.5625	−0.2463	−0.7721	0.1604

7	0.0690	0.2028	0.5957	−0.2868	0.9074
8	4.9718	−0.6484	0.0845	0.9311	−0.1324
9	0.0000	0.0002	0.0007	0.1594	0.5695
10	3.1335	−0.7222	0.1664	0.3209	−0.1123
Σ	0.8972	−0.0018	−0.0205	0.1730	0.1521

The excellent optical properties and aberration compensation of the lens system set forth in Table I are illustrated in the graphs shown in FIGS. 2*a*, 2*b* and 2*c*.

A second specific embodiment of a retrofocus type objective lens system in accordance with the present invention is shown in the following Table III in which the designations are similar to those of the first specific embodiment.

TABLE III

f=1.0 1:2.8 radius of curvature	field angle 2ω=64° thickness on axis	refractive index	backfocus s'=1.06 Abbe's number
r1 = 2.5414			
r2 = 0.4915	d1 = 0.0469	N1 = 1.5725	v1 = 57.5
r3 = 0.6600	d2 = 0.3284		
r4 =−1.8698	d3 = 0.3345	N2 = 1.6968	v2 = 55.6
r5 =−0.4287	d4 = 0.2722		
r6 = 2.1911	d5 = 0.0428	N3 = 1.7006	v3 = 30.1
r7 =−1.9373	d6 = 0.0376		
r8 =−0.4795	d7 = 0.067	N4 = 1.7495	v4 = 50.1
r9 = 4.3712	d8 = 0.0029		
r10=−1.1652	d9 = 0.068	N5 = 1.6214	v5 = 61.3

In the last embodiment, as well,

$d_5 + d_6 + d_7 + d_8 + d_9 = 0.0428 + 0.0376 + 0.067 + 0.0029 + 0.068$ $d_5 + d_6 + d_7 + d_8 + d_9 = 0.2183 < 0.2722 = d_4$

thus satisfying the condition (a). Furthermore,

$$\frac{d3}{d4} = 1.232$$

thus satisfying the condition (b). Furthermore,

$$\frac{r3}{r4} = \frac{0.6600}{-1.8698} = -0.353$$

thus satisfying the condition (c). Still further, $N_1 = 1.5725 < N_3 = 1.7006$ thus satisfying the condition (d). Additionally, $d_2 = 0.3284 > 0.2$ thus satisfying the condition (e).

Seidel's coefficients at the respective refracting surfaces of the aforesaid second embodiment set forth in Table III are shown in the following Table IV :

TABLE IV

9	−0.0001	0.0040	−0.1058	0.0876	0.4808
10	3.2265	−0.7520	0.1753	0.3289	−0.1175
Σ	1.0820	−0.0026	−0.0275	0.1843	0.1604

The excellent optical properties and aberration compensation of the lens system set forth in Table III are illustrated in the graphs shown in FIGS. 3*a*, 3*b* and 3*c*.

The aforesaid condition (a) affords to the second lens G2 the function of positively compensating for coma, distortion, etc. which are created due to the first lens G1 of the single divergent system. If the air spacing d4 between the second lens G2 and the third lens G3 is added to the value exceeding the upper or lower limit value of the condition (a), there will result an abrupt decrease in the compensating function, whereby there will be imposed a limitation on the refractive index of the first lens or the selection of the thickness of the lens so as to decrease coma or distortion.

In addition, since coma and the like are compensated for by means of lenses subsequent to the third lens, the freedom in the configuration of the lenses subsequent to the third lens will be lost or the number of those lenses has to be increased.

The condition (b) defines the thickness of the second lens G2 to a desired range with respect to the aforesaid air spacing *d4*, whereby the combined or multiplicated actions of the functions of the second lens G2 according to the condition (b) and the function of the second lens G2 according to the aforesaid condition (a) may well compensate for aberrations.

If the thickness d3 of the second lens G2 is smaller than that of the lower limit of the condition (b), then there will be an abrupt increase in the lateral chromatic aberration at the corner portions of the image surface, while the balance of coma will be lost over the entire surface of the image, thereby losing the sphero achromatic characteristic. On the other hand, if the thickness *d3* exceeds the upper limit, then there will remain a negative distortion which will not allow for its compensation.

The condition (c) defines the relationship of the radii of curvatures *r3* and *r4* of the second lens having convex surfaces on both sides, thereby optimizing the compensating function for coma, of the second lens G2, while maintaining minimized spherical aberration created due to the second lens G2. In other words, if the upper limit is exceeded, the spherical aberration produced thereby may not be compensated for by the third lens G3. If the lower limit is exceeded, then external coma is produced due to the second lens G2 as well as the third lens G3. However, this coma may not be compensated for by the other three lenses.

The condition (d) defines the relationship of the refractive indexes of the first lens G1 and the third lens G3, to thereby minimize the Petzval sum of the entire lens system, with the attendant good image surface. If the aforesaid condition (d) is not followed, there will result an increase in the halo component, although the Petzval sum may be reduced, thus impairing the contrast of the image materially, such that the performance of the entire lens system will be lowered at the time of the diaphragm being released.

The condition (e) defines an air spacing between the first lens G1 and the second lens G2, thereby limiting the second lens so as not to be over-biased forwardly. This condition (e) maintains the backfocus longer than 0.9 times as long as the focal length '*f*' of the entire lens system. If this condition is not followed, then there will be created considerable internal coma in the lens system, thus failing to meet practical application standards.

It should be appreciated that the present invention is by no means limited to the aforesaid two embodiments, but presents a retrofocus type objective lens system of five components, five lenses, which consists of a first lens of a negative meniscus, a second lens having convex surfaces on its both sides, a third lens having concave surfaces on its both sides, a fourth lens of a positive meniscus and having its convex surface facing the image side, and a fifth positive lens, and which system satisfies the aforesaid conditions (a) to (e), thereby presenting a long backfocus and being well compensated for the various aberrations.

It will be understood that the above description is merely illustrative of preferred embodiments of the invention. Additional modifications and improvements utilizing the discoveries of the present invention can be readily anticipated by those skilled in the art from the present disclosure, and such modifications and improvements may fairly be presumed to be within the scope and purview of the invention as defined by the claims that follow.

I claim:

1. A retrofocus objective lens system comprising a negative meniscus front first lens having a concave rear face, a biconvex second lens, a biconcave third lens, a positive meniscus fourth lens with a convex rear face, and a positive fifth lens, said lens system satisfying the following conditions:

$$1.6\,(d_5 + d_6 + d_7 + d_8 + d_9) > d_4 > d_5 + d_6 + d_7 + d_8 + d_9 \quad 0.7d_4 < d_3 < 1.3d_4$$

$$-0.5 < \frac{r3}{r4} < -0.1$$

wherein r_j is the radius of curvature of the jth lens face successively designated from the front lens face, and d_j is the axial distance between the jth and the $j+1$ lens faces of the lens system.

2. A retrofocus type objective lens as set forth in claim **1**, wherein the arrangement and construction of the five lenses are as follows:

f=1.0 1:2.8 radius of curvature	field angle 2ω=64° length on axis	refractive index	backfocus s'=1.06 Abbe's number
r1 = 2.3437			
r2 = 0.4709	d1 = 0.0441	N1 = 1.5714	v1 = 53.0
r3 = 0.6206	d2 = 0.3538		
r4 = −1.8643	d3 = 0.28	N2 = 1.6583	v2 = 58.5
r5 = −0.4012	d4 = 0.3182		
r6 = 2.3930	d5 = 0.0379	N3 = 1.6889	v3 = 31.2
r7 = −1.4595	d6 = 0.0283		
r8 = −0.4496	d7 = 0.067	N4 = 1.7200	v4 = 50.3
r9 = 2.4019	d8 = 0.0029		
r10 = −1.1931	d9 = 0.068	N5 = 1.6204	v5 = 60.3

wherein Vi is the Abbe's number of the ith lens.

3. A retrofocus type objective lens system set forth in claim **1**, wherein the arrangement and construction of the five lenses are as follows.

f=1.0 1:2.8 radius of curvature	field angle 2ω=64° length on axis	refractive index	backfocus s'=1.06 Abbe's number
r1 = 2.5414			
r2 = 0.4915	d1 = 0.0469	N1 = 1.5725	v1 = 57.5
r3 = 0.6600	d2 = 0.3284		
r4 = −1.8698	d3 = 0.3345	N2 = 1.6968	v2 = 55.6
r5 = −0.4287	d4 = 0.2722		
r6 = 2.1911	d5 = 0.0428	N3 = 1.7006	v3 = 30.1
r7 = −1.9373	d6 = 0.0376		
r8 = −0.4795	d7 = 0.067	N4 = 1.7495	v4 = 50.1
r9 = 4.3712	d8 = 0.0029		
r10 = −1.1652	d9 = 0.068	N5 = 1.6214	v5 = 61.3

Wherein Vi is the Abbe's number of the ith lens.

UNITED STATES PATENT AND TRADEMARK OFFICE

CERTIFICATE OF CORRECTION

PATENT NO. : 3,936,153

DATED : February 3, 1976

INVENTOR(S) : Toshinobu Ogura

It is certified that error appears in the above-identified patent and that said Letters Patent are hereby corrected as shown below:

Claim 1, lines 7 and 8: Delete and substitute the following:

--1.6 $(d_5+d_6+d_7+d_8+d_9) > d_4 > d_5+d_6+d_7+d_8+d_9$

$0.7d_4 < d_3 < 1.3d_4$--

Signed and Sealed this

eighth Day of June 1976
